The supraclavicular triangle, the lower, smaller division, is bounded like the posterior triangle, except above where the omohyoid limits it. It corresponds in the living neck with the lower part of the deep, prominent hollow, the *greater supraclavicular fossa* (colloquially 'the salt cellar'). Its floor contains the first rib, scalenus medius and the first slip of serratus anterior. Its size varies with the extent of the clavicular attachments of the sternocleidomastoid and trapezius and also the level of the inferior belly of the omohyoid. The triangle is covered by the skin, superficial and deep fasciae and platysma and crossed by the supraclavicular nerves. Just above clavicular level the third part of the subclavian artery curves inferolaterally from the lateral margin of the scalenus anterior, across the first rib to the axilla. The subclavian vein is behind the clavicle and is not usually in the triangle; but it may rise as high as the artery and even accompany it behind scalenus anterior. The *brachial plexus* is partly above, partly behind the artery and closely related to it. The *trunks* of the brachial may easily be palpated here, the neck being contralaterally flexed and the examining finger drawn across the trunks at right angles to their length. With the musculature relaxed, pulsation of the subclavian artery may be felt or the arterial flow controlled by retroclavicular compression against the first rib. The suprascapular vessels pass transversely behind the clavicle; at a higher level are the transverse cervical artery and vein. The external jugular vein descends behind the posterior border of the sternocleidomastoid to end in the subclavian vein; it receives the transverse cervical and suprascapular veins, which form a plexus in front of the third part of the subclavian artery; occasionally it is joined by a small vein crossing the clavicle anteriorly from the cephalic vein. The nerve to the subclavius also crosses this triangle and some lymph nodes are contained in it.

The Internal Carotid Artery

The internal carotid artery (6.77–84) supplies most of the ipsilateral cerebral hemisphere, eye and accessory organs, forehead and, in part, the nose. From the carotid bifurcation, where it usually has a carotid sinus (p. 734), it ascends to the cranial base, enters the cranial cavity by the carotid canal and turns anteriorly through the cavernous sinus in the carotid groove on the side of the sphenoid body, ending below the anterior perforated substance by division into the anterior and middle cerebral arteries.

It may be divided conveniently into cervical, petrous, cavernous and cerebral parts. In the broadest outline its course is: (1) *vertically upwards* in the neck; (2) curving *horizontally forwards and medially* in the petrous carotid canal; (3) *upwards* in the upper foramen lacerum; (4) *horizontally forwards* in the cavernous sinus;

6.78 Internal carotid arteriogram (right): anteroposterior view of same subject as **6.77**. Parts of the internal carotid artery: 1. cervical. 2. intrapetrous. 3. cavernous. 4. branches of middle cerebral artery. 5. branches of anterior cerebral artery. Note the lack of contrast medium on the left side.

(5) *vertically upwards* medial to the anterior clinoid *process*; (6) looping a short distance *backwards and upwards* to its terminal division.

The Cervical Part

This section begins at the carotid bifurcation and ascends in front of the upper three cervical transverse processes to the inferior aperture of the carotid canal in the petrous temporal bone. It is superficial at first in the carotid triangle, then passes deeper, medial to the posterior belly of the digastric. Except near the skull, the internal jugular vein and vagus nerve are lateral; the external carotid is first anteromedial but then curves back to become superficial. The artery has many other relations. *Posteriorly* it adjoins the longus capitis, with the superior cervical sympathetic ganglion between them and the superior laryngeal nerve crossing obliquely behind it. *Medial* is the pharyngeal wall separated by fat and pharyngeal veins from the ascending pharyngeal artery and superior laryngeal nerve. *Anterolaterally* the artery is covered by the sternocleidomastoid; *below the digastric* the hypoglossal nerve and superior root of the ansa cervicalis and the lingual and facial veins are superficial. *At the level of the digastric* it is crossed by the stylohyoid muscle and the occipital and posterior auricular arteries. *Above the digastric* it is separated from the external carotid by the styloid process, styloglossus and stylopharyngeus, glossopharyngeal nerve, vagal pharyngeal branch and the deeper part of the parotid gland. At the base of the skull the glossopharyngeal, vagus, accessory and hypoglossal nerves are between the internal carotid artery and the internal jugular vein, which here has become posterior.

The Petrous Part

The artery at first ascends in the carotid canal, curves anteromedially and then superomedially above the cartilage filling the foramen lacerum, to enter the cranial cavity, passing between the lingula and petrosal process. It is at first anterior to the cochlea and tympanic cavity, separated from the latter and the pharyngotympanic tube by a thin, bony lamella, cribriform in the young, partly absorbed in old age; anterior to this it is separated from the trigeminal ganglion by the thin roof of the carotid canal, often deficient. The artery is surrounded by a venous plexus and the carotid autonomic plexus derived from the internal carotid branch of the superior cervical ganglion.

The Cavernous Part

In the cavernous sinus the artery is covered by lining endothelium. It ascends to the *posterior* clinoid process, turns anteriorly on the side of the sphenoid and again curves up medial to the *anterior* clinoid process, emerging through the dural roof of the sinus; occasionally the two clinoid processes form a ring round the artery, which is also surrounded by a sympathetic plexus; the oculomotor, trochlear, ophthalmic and abducent nerves are lateral to it.

The Cerebral Part

Having traversed the dura mater the artery turns back below the optic nerve, passing between this and the oculomotor nerve to the anterior perforated substance at the medial end of the lateral cerebral sulcus, where it divides into anterior and middle cerebral arteries.

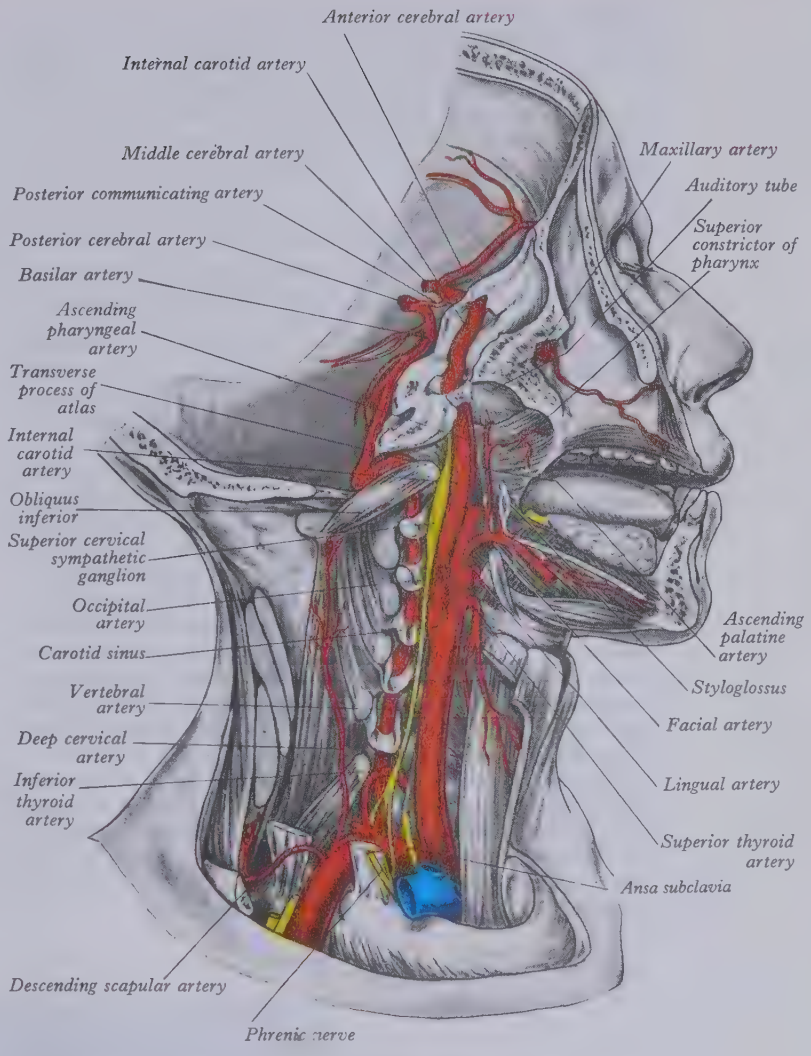
Variations. The length of the artery varies with the length of the neck and the point of carotid bifurcation. It may arise from the aortic arch and then be medial to the external carotid as far as the larynx but there crossing behind it. Its cervical part is normally straight but on occasion may be very tortuous, being nearer to the pharynx than usual and very near the tonsil. Its absence has also been recorded.

Surface Anatomy. The internal carotid corresponds in position to a broad line from the termination of the common carotid to the back of the mandibular neck (**6**.70).

Branches. The cervical part has no branches. Those from the other parts are:

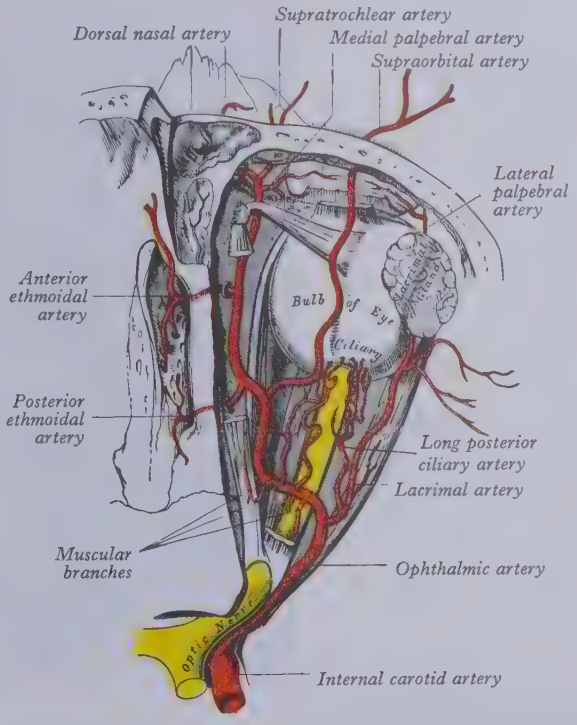
From the petrous part	1. Caroticotympanic
	2. Pterygoid
From the cavernous part	3. Cavernous
	4. Hypophysial
	5. Meningeal
From the cerebral part	6. Ophthalmic
	7. Anterior cerebral
	8. Middle cerebral
	9. Posterior communicating
	10. Anterior choroid

1. The caroticotympanic artery is small, occasionally double; it enters the tympanic cavity by a foramen in the carotid canal, anastomosing with the anterior tympanic branch of the maxillary artery and the stylomastoid artery.



2. The pterygoid artery, inconstant, enters the pterygoid canal with the nerve of the same name, anastomosing with a (recurrent) branch of the greater palatine artery.

3. The cavernous rami, numerous small vessels, supply the trigeminal ganglion, walls of the cavernous and inferior petrosal sinuses and contained nerves. Some anastomose with middle meningeal rami.



4. The hypophysial rami are small but numerous and important vessels (for details see p. 1455).

5. The meningeal branch is minute and passes over the lesser sphenoid wing to supply the dura mater and bone in the anterior cranial fossa; it anastomoses with a meningeal branch of the posterior ethmoidal artery.

6. The ophthalmic artery (**6**.80) leaves the internal carotid as it quits the cavernous sinus medial to the anterior clinoid process; it enters the orbit by the optic canal, inferolateral to the optic nerve; for a short distance it is then lateral to the nerve, medial to the oculomotor and abducent nerves, ciliary ganglion and rectus lateralis. It crosses between the optic nerve and rectus superior to

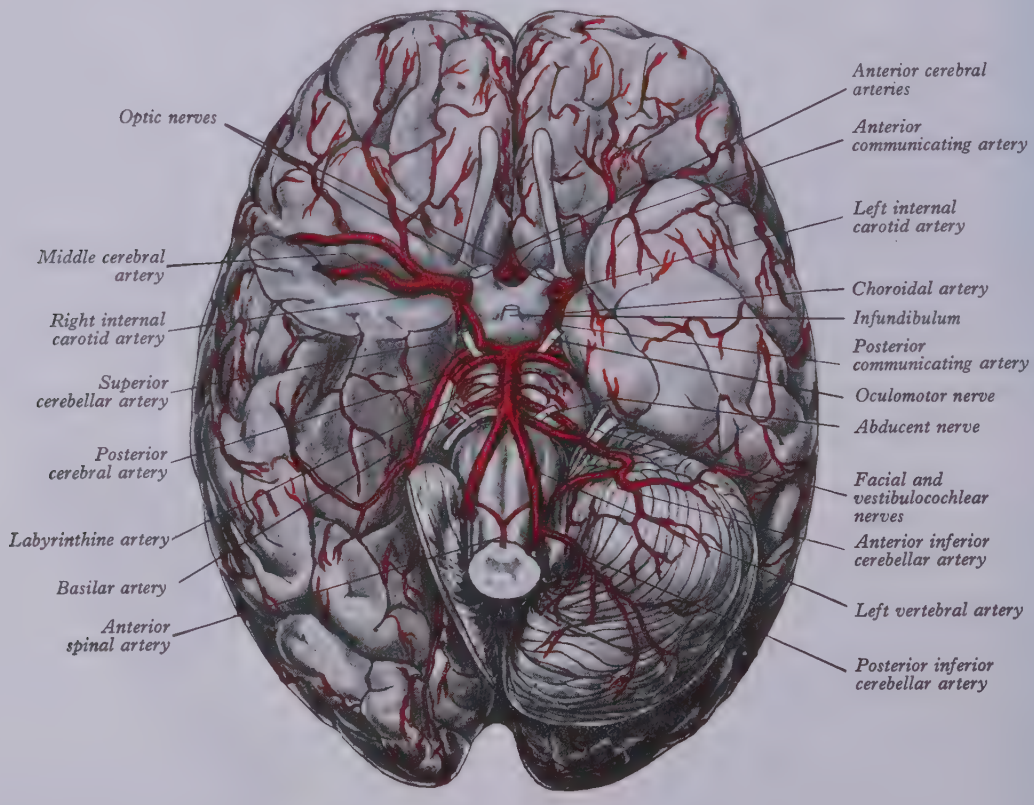
6.79 Dissection to show the course of the right vertebral and internal carotid arteries and some of their branches.

6.80 The ophthalmic artery and its branches in the right orbit, as seen from above.

the medial orbital wall, runs between the obliquus superior and the rectus medialis to the medial end of the upper eyelid, dividing into *supratrochlear* and *dorsal nasal* rami. As it crosses the optic nerve with the nasociliary nerve it is separated from the frontal nerve by the rectus superior and levator palpebrae superioris; its terminal ramus accompanies the infratrochlear nerve. In about 15% the ophthalmic artery is below the optic nerve. Its branches are as follows:

The *central artery of the retina*, a first and small branch, begins below the optic nerve. For a short distance it is in the nerve's dural sheath; about 1.25 cm behind the eye it enters the nerve's inferomedial surface and runs to the retina along its axis. Its distribution is described on p. 1204.

The *lacrimal artery* leaves the ophthalmic near its exit from the optic canal and is a large branch, sometimes arising before the ophthalmic enters the orbit; a branch of the middle meningeal artery (p. 689) may replace it. It accompanies the lacrimal nerve along the upper border of the rectus lateralis, supplying the lacrimal gland, after traversing which it ends in the eyelids and conjunctiva as *lateral palpebral arteries* running medially in the upper and lower lids to anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two *zygomatic branches*: one reaches the temporal fossa via the zygomaticotemporal foramen, anastomosing with the deep temporal arteries; another reaches the cheek by the zygomaticofacial foramen, anastomosing with transverse facial and zygomatico-orbital arteries. A *recurrent meningeal ramus* passes back via the lateral part of the superior orbital fissure to anastomose with a middle meningeal branch; enlargement of this anastomosis may provide an alternative lacrimal artery.



Muscular branches frequently spring from a common trunk but form superior and inferior groups, most accompanying branches of the oculomotor nerve. The inferior, more constant, contains most of the anterior ciliary arteries. Other muscular rami branch from the lacrimal and supraorbital or the trunk of the ophthalmic artery.

Ciliary arteries are divisible into three groups: long and short posterior and anterior. *Long posterior ciliary arteries*, usually two, pierce the sclera near the optic nerve (p. 1194). About seven *short posterior ciliary arteries* pass around the optic nerve to the eyeball; dividing into 15–20 branches, they pierce the sclera around the optic nerve to supply the choroid and the ciliary processes. At the optic disc they anastomose with twigs of the central retinal artery and at the ora serrata with the long posterior and anterior ciliary arteries. *Anterior ciliary arteries* are rami of muscular branches of the ophthalmic; reaching the eyeball on tendons of the recti to form a circumcorneal subconjunctival vascular zone, they pierce the sclera near the sclerocorneal junction and end in the greater arterial circle of the iris (p. 1194).

The *supraorbital artery* leaves the ophthalmic where it crosses the optic nerve, ascends medial to the rectus superior and levator palpebrae superioris, meets the supraorbital nerve and runs with it between the periosteum and levator palpebrae superioris to the supraorbital foramen or notch; traversing this it divides into superficial and deep branches, supplying the skin, muscles and frontal periosteum, anastomosing with the supratrochlear artery, frontal branch of the superficial temporal and its fellow. It supplies the rectus superior and levator palpebrae and sends a branch across the trochlea to the medial canthus. At the supraorbital margin it often sends a branch to the diploë of the frontal bone and may also supply the mucoperiosteum in the frontal sinus.

The *posterior ethmoidal artery* enters the posterior ethmoidal canal, supplies the posterior ethmoidal air sinuses, enters the cranium, sends a meningeal branch to the dura mater and nasal branches descending into the nasal cavity via the cribriform plate, to anastomose with the sphenopalatine branches supplying bone.

The *anterior ethmoidal artery* and nerve traverse their canal, the artery supplying anterior and middle ethmoidal, and frontal air sinuses and, entering the cranium, giving a meningeal branch to the dura mater and nasal branches descending into the nasal cavity with the anterior ethmoidal nerve; they run in a groove on the deep

6.81A The arteries at the base of the brain. The right temporal pole and most of the right hemisphere of the cerebellum have been removed. Variations in the pattern of these vessels is common.

surface of the nasal bone to supply the lateral nasal wall and septum; a terminal branch appears on the nose between the nasal bone and the upper nasal cartilage. Angiographic studies (Kuru 1967) show the meningeal branch extending to the falx; Muller (1977, 1978) has confirmed this in fetal and adult material; he also derives such '*falciate arteries*' from the recurrent meningeal branch of the lacrimal artery.

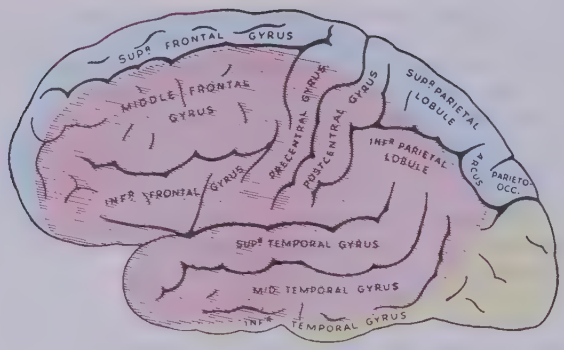
The *meningeal branch*, a small artery passing back by the superior orbital fissure to the middle cranial fossa, anastomoses with the middle and accessory meningeal arteries, supplying bone.

Medial palpebral arteries, superior and inferior, leave the ophthalmic below the trochlea, descending behind the lacrimal sac to enter the lids, where each divides into two rami coursing laterally along the tarsal edges, to form the superior and inferior arches, completed by anastomoses with rami of the supraorbital and zygomatico-orbital (superior arch) and palpebral branches of the lacrimal (both arches); the inferior arch also links with the facial artery, thus supplying the mucosa of the naso-lacrimal duct.

The *supratrochlear artery*, a terminal branch of the ophthalmic, leaves the orbit superomedially with the supratrochlear nerve, ascending on the forehead to supply the skin, muscles and pericranium, anastomosing with the supraorbital artery and with its fellow.

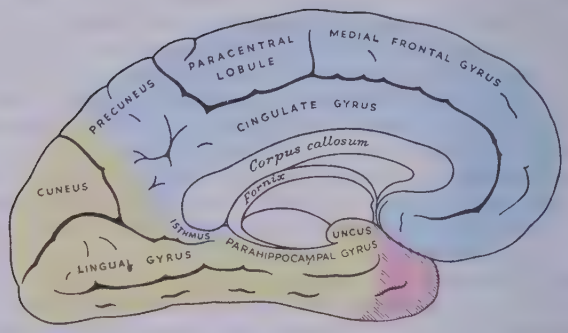
The *dorsal nasal artery*, the other terminal branch, emerges from the orbit between the trochlea and medial palpebral ligament, gives a ramus to the upper lacrimal sac and divides; one branch joins the terminal part of the facial artery, the other along the dorsum of the nose supplying its exterior and joining its fellow and lateral nasal branch of the facial.

7. The anterior cerebral artery (**6**.81A,B,82,83,84A,B), the smaller terminal branch of the internal carotid, starts at the medial end of the stem of the lateral cerebral sulcus and passes anteromedially above the optic nerve to the longitudinal fissure, where it connects with its fellow by a short transverse anterior communicating artery. The two arteries thence travel together in the fissure, curving round the genu of the corpus callosum and back along its upper surface to its posterior end, where they anastomose with posterior cerebral arteries. Occasionally they are a single vessel. There are central and cortical branches.



The *anterior communicating artery*, with an average length of 4 mm, connects anterior cerebral arteries across the anterior end of the longitudinal fissure; it may be double. It has a few anteromedial central branches. According to Crowell & Morawetz (1977) its branches, from three to 13, supply the optic chiasma, lamina terminalis, hypothalamus, parolfactory areas, fornix (anterior columns) and cingulate gyrus.

Central branches arise from the commencement of the anterior cerebral, entering the anterior perforated substance and lamina terminalis to supply the rostrum of the corpus callosum, septum pellucidum, the anterior part of the putamen of the lentiform nucleus and the head of the caudate nucleus. *Cortical branches* are named by distribution: two or three *orbital branches* ramify on the frontal lobe's orbital surface, supplying the olfactory lobe, gyrus rectus and medial orbital gyrus; *frontal branches* supply the corpus callosum, cingulate gyrus, medial frontal gyrus and paracentral lobule, sending twigs over the hemisphere's superomedial border to the superior and middle frontal gyri and upper part of the precentral gyrus (including the 'leg area' of the motor cortex, p. 1049); *parietal branches* supply the precuneus and the adjacent lateral surface.



8. The middle cerebral artery (**6**.81A,B,82,83 84A,B), the larger terminal branch of the internal carotid, runs first in the lateral cerebral sulcus, then posterosuperiorly on the insula, dividing into branches distributed to this and the adjacent lateral cerebral surface (**6**.82). Its *central branches* are small and from its commencement they enter the anterior perforated substance, arranged in two sets: *medial striate arteries* ascend through the lentiform nucleus to supply it, the caudate nucleus and the internal capsule; *lateral striate arteries* ascend over the lower lateral aspect of the lentiform nucleus (in the external capsule) and turn medially to traverse it and the internal capsule to supply the

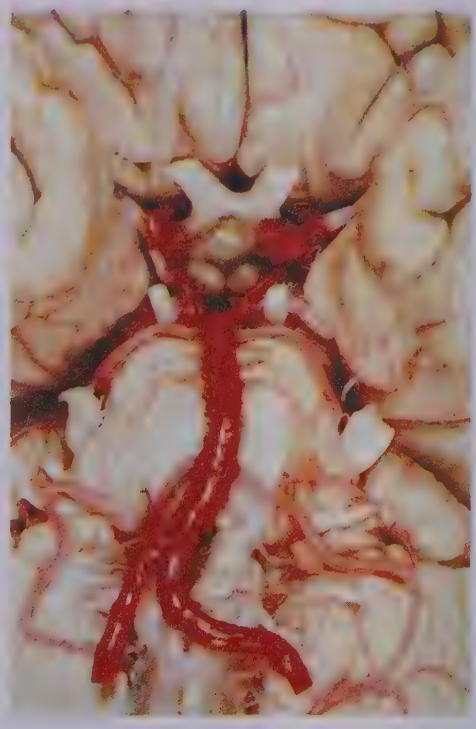
caudate nucleus. One ramus, usually the largest, was termed by Charcot the '*artery of cerebral haemorrhage*'. *Cortical branches* supply *orbital rami* to the inferior frontal gyrus and the lateral orbital surface of the frontal lobe; *frontal rami* supply the precentral, middle and inferior frontal gyri; two *parietal rami* are distributed to the postcentral gyrus, the lower part of the superior parietal lobule and the whole inferior parietal lobule. Two or three *temporal rami* supply the lateral surface of the temporal lobe. Cortical branches of the middle cerebral thus supply all the motor area (excluding the leg) (p. 1051), the corresponding somaesthetic area (p. 1056) and the auditory area (p. 1060).

9. The posterior communicating artery (6.81A,B, 84A,B) runs back from the internal carotid above the oculomotor nerve, anastomosing with the posterior cerebral, a basilar branch. It is usually small but sometimes so large that the posterior cerebral appears to come from the internal carotid rather than basilar artery. It is often larger on one side. From its posterior half several small *central branches* pierce the posterior perforated substance with others from the posterior cerebral to supply the medial thalamic surface and walls of the third ventricle (p. 1083).



10. The anterior choroidal artery, small but constant, leaves the internal carotid near its posterior communicating branch (Abbie 1933, 1934), passing back above the medial part of the uncus to cross inferior to the optic tract and reach and supply the crus cerebri. Turning laterally, it recrosses the optic tract, arrives lateral to the lateral geniculate body and supplies it with several branches. Finally it enters the inferior cornu of the lateral ventricle via the choroidal fissure to end in the choroidal plexus. It supplies: the globus pallidus, caudate nucleus and amygdaloid body, hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, the optic radiation, optic tract, hippocampus and the fimbria of the fornix.

THE CIRCULUS ARTERIOSUS (OF WILLIS)

Much of the brain is supplied by the two internal carotid arteries (p. 750) and a central anastomosis, the *circulus arteriosus*, exists

6.84A Diagram of the arteries at the base of the brain, showing the constitution of the arterial circle. A.L. = anterolateral central branches, A.M. = anteromedial central branches, P.L. = posterolateral central branches, P.M. = posteromedial central branches. The arteries constituting this so-called arterial 'circle' are commonly asymmetrical and sometimes a constituent vessel is missing.

6.84B Resin cast of the arteries at the base of the brain, showing the components of the arterial circle. Cast prepared by M C E Hutchinson and photographed by Kevin Fitzpatrick, Department of Anatomy, UMDS, Guy's Campus, London.

between these and the two vertebral arteries (p. 750) that supplies the remainder. This 'circle', more polygonal than circular, is in the cisterna interpeduncularis, surrounding the optic chiasma, the neural infundibular stem of the hypophysis cerebri and other related neural structures in the interpendicular fossa (7.81). *Anteriorly* the anterior cerebral arteries (from the carotids) are joined by the anterior communicating artery; *posteriorly* the basilar artery (p. 753) divides into two posterior cerebral arteries, each joined to the ipsilateral internal carotid by a posterior communicating artery (**6**.84A,B).

Vessels of this 'circle' vary in calibre, being often maldeveloped, sometimes even absent. About 60% of circles display 'anomalies'; the above description applies to a minority. Variations have been much studied, from Windle's account in 1888 of 200 specimens to that of Puchades-Ort et al (1976) on 62 dissections, the largest series being the 700 dissections of Fawcett & Blachford (1906) and Riggs & Rupp's (1963) 994 dissections. Fields et al (1965) have summarized such studies. Cerebral and communicating arteries, anterior and posterior, may all be absent, variably hypoplastic, double or even triple. In about 90% there is, nevertheless, a complete 'circular' channel but in most one vessel is sufficiently narrowed to impair its role as a a collateral route. The haemodynamic 'balance' is usually disturbed by variation in the calibre of communicating arteries, often with variation in the segments of anterior and posterior cerebral arteries extending from their origins to their junctions with the corresponding communicating arteries. This segment is particularly 'labile' in the posterior cerebral, being often reduced or absent; where this is coupled with an enlarged ipsilateral posterior communicating artery the posterior cerebral artery is filled from the internal carotid. Abbie (1933), Williams (1936) and Kaplan (1956) have shown that this anomaly accords with the ontogenetic and phylogenetic association of posterior cerebral and internal carotid arteries. Anterior in the arterial circle, agenesis or hypoplasia of the initial anterior cerebral segment is more frequent than anomalies in the anterior communicating, and hence a commoner cause of defective circulation. Angiographic evidence indicates such defective or absent circulation in about a third of individuals (Sedzmir 1959); existence of an effective arterial circle can never be assumed and surgical procedures involving its 'feeders' must be preceded by angiography. Radio-opaque substances may be injected into the internal carotid or vertebral arteries in the neck for radiography of the condition of their intracranial branches (**6**.77,78,88,89).

Further details of the distribution of cerebral arteries and veins appear on pp. 1083–1088 and of intracranial venous sinuses on pp. 799–805.

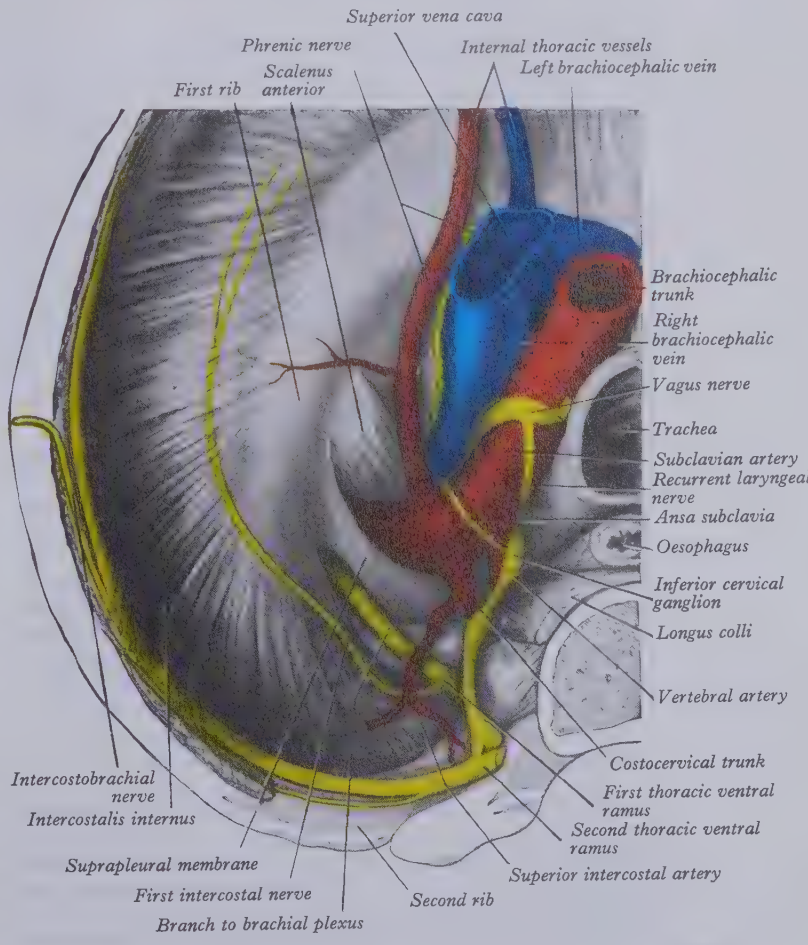
THE SUBCLAVIAN SYSTEM OF ARTERIES

The stem artery of the upper limb is single as far as the elbow, but its name changes in the regions traversed. From its origin to the outer border of the first rib it is *subclavian*; thence to the tendon of teres major it is *axillary*; and from this to its division at the elbow it is *brachial*.

The Subclavian Arteries

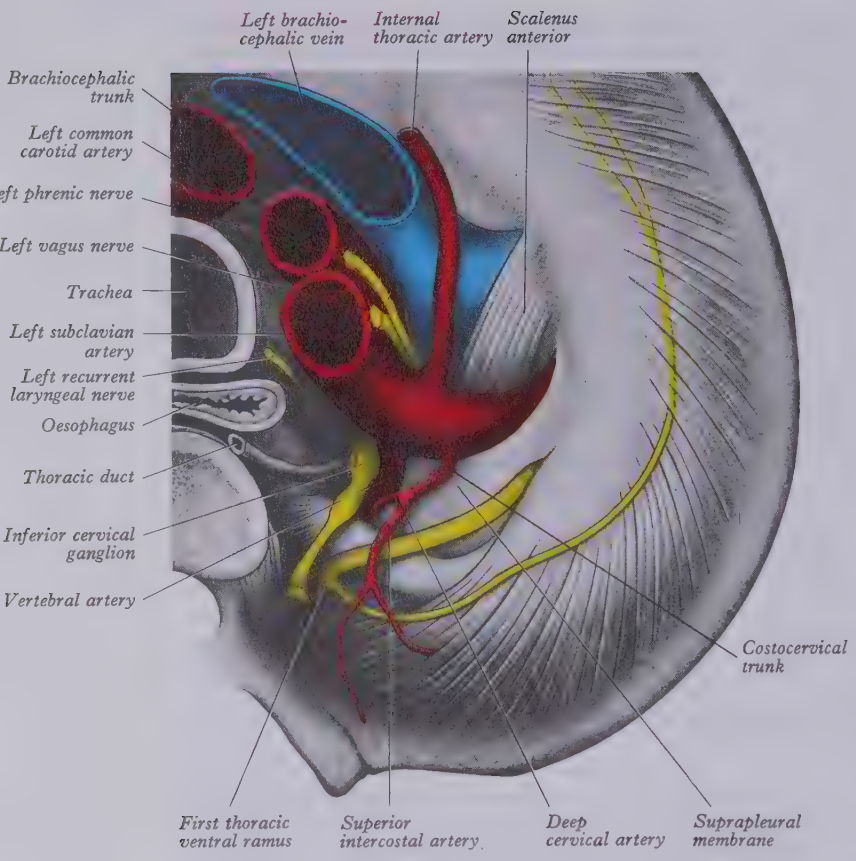
The right subclavian arises from the brachiocephalic trunk, the left from the aortic arch. For description, each is divided into a *first part*, from its origin to the medial border of the scalenus anterior, a *second part* behind this muscle and a *third part* from the muscle's lateral margin to the first rib's outer border, where the artery becomes *axillary*. Each subclavian artery arches over the cervical pleura and pulmonary apex. Their first parts differ, the second and third parts are almost identical.

First Part of the Right Subclavian Artery (**6**.60,85)



The right subclavian, branching from the brachiocephalic trunk behind the upper border of the right sternoclavicular joint, passes superolaterally to the medial margin of the scalenus anterior. It ascends about 2 cm above the clavicle but this varies.

Relations. The artery is deep to the skin, superficial fascia, platysma, anterior supraclavicular nerves, deep fascia, clavicular attachment of the sternocleidomastoid, sternohyoid and sternothyroid. It is at first *behind* the right common carotid's origin; more laterally it is crossed by the vagus nerve, the cardiac branches of the vagus and the sympathetic and by internal jugular and vertebral veins; the subclavian sympathetic loop encircles it. The anterior jugular vein diverges *laterally* in front of it, separated by the sternohyoid and sternothyroid. *Below* and *behind* the artery are the pleura and pulmonary apex but separated by the suprapleural membrane (p. 1269), the ansa subclavia, an accessory vertebral vein (p. 797) and the right recurrent laryngeal nerve (curving round inferoposterior to the vessel).



First Part of the Left Subclavian Artery (**6**.41,44,63,118)

This springs from the aortic arch, behind the left common carotid, level with the disc between the third and fourth thoracic vertebrae; it ascends into the neck, then arches laterally to the medial border of the scalenus anterior.

Relations. (Its branches are considered separately below.) In *the thorax* it is related, *anteriorly* to the left common carotid artery and left brachiocephalic vein, separated by the left vagus, cardiac (p. 1118) and phrenic nerves. Superficial to these the anterior pulmonary margin, pleura, sternothyroid and sternohyoid are between the vessel and the upper left area of the manubrium sterni. *Posterior* are the left side of the oesophagus, the thoracic

6.85 Structures related to the right cervical pleura, as seen from below.

6.86 Structures related to the left cervical pleura, as seen from below.

duct and longus colli; it is in contact posterolaterally with the left lung and pleura. *Medial* are the trachea, the left recurrent laryngeal nerve, oesophagus and thoracic duct. *Laterally* the artery grooves the mediastinal surface of the left lung and pleura which also encroach on its anterior and posterior aspects.

In the neck, near the medial border of the scalenus anterior, the artery is crossed *anteriorly* by the left phrenic nerve and the termination of the thoracic duct. Otherwise anterior relations are as previously described for the first part of the right subclavian artery. *Posteriorly* and *inferiorly*, the relations of both vessels are identical but the left recurrent laryngeal nerve, medial to the left subclavian artery in the thorax, is not directly related to its cervical part.

Second Part of the Subclavian Arteries (**6**.68,87)

This is behind the scalenus anterior; it is short and the highest part of the vessel.

Relations. *Anterior* are the skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid and scalenus anterior; the right phrenic nerve is often described as separated from the second part by the scalenus anterior, but crossing the *first* part on the left; Qvist (1977) stated that *both* nerves are anterior to the muscle. *Postero-inferior* are the suprapleural membrane, pleura and lung and the lower trunk of the brachial plexus; *superior* are the upper and middle trunks of the plexus; the subclavian vein is antero-inferior, separated by the scalenus anterior (**6**.87).

Third Part of the Subclavian Arteries

This descends laterally from the lateral margin of the scalenus anterior to the outer border of the first rib, where it becomes axillary; it is the most superficial part of the artery and lies partly in the supraclavicular triangle (p. 743), where its pulsations may be felt and it may be compressed.

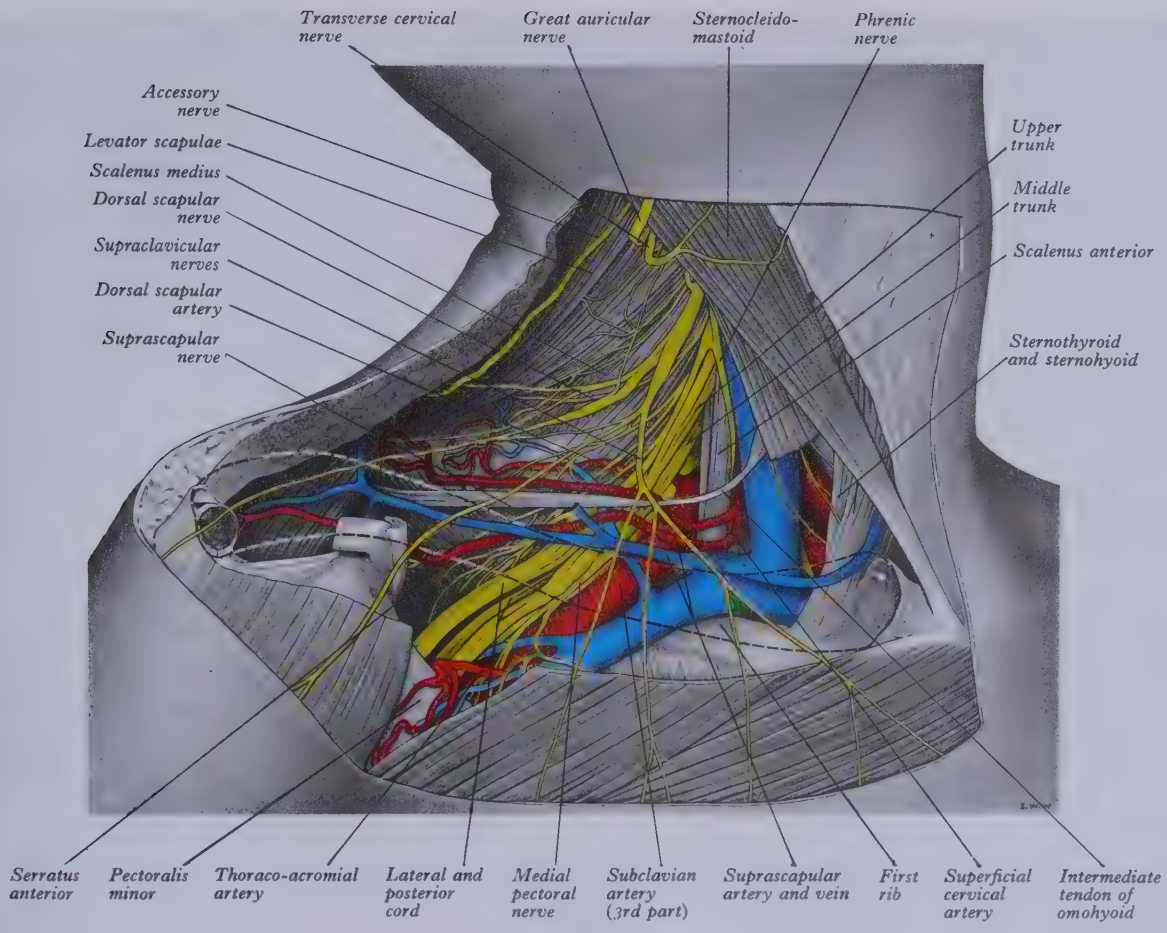
Relations. *Anterior* are the skin, superficial fascia, platysma, supraclavicular nerves and deep cervical fascia. The external jugular vein crosses its medial end and here receives the suprascapular, transverse cervical and anterior jugular veins, together often forming a venous plexus. The nerve to the subclavius descends between the veins and the artery; the latter is terminally behind the clavicle and subclavius, where it is crossed by the suprascapular vessels. The subclavian vein is antero-inferior and the lower trunk of the brachial plexus is postero-inferior, between the artery and the scalenus medius (and on the first rib). *Superolateral* are the upper and middle trunks of the brachial plexus (palpable here) and the inferior belly of the omohyoid. *Inferior* is the first rib.

Surface Anatomy. The subclavian artery corresponds to a broad line, convex superiorly, curving from the sternoclavicular joint to the midpoint of the clavicle (**6**.70).

Variations. The right subclavian may arise above or below sternoclavicular level; it may be a separate aortic branch and be the first *or* last branch of the arch; when first, it is in the position of a brachiocephalic trunk and when last it arises from the arch's left end, ascending obliquely to the right *behind* the trachea, oesophagus and right common carotid to the first rib. In this case the proximal part of the artery represents a persistent part of the right dorsal aorta, the right fourth aortic arch taking no part in its formation (p. 733); hence the right recurrent laryngeal nerve hooks round the common carotid, derived from the third arch. Sometimes, when the right subclavian is the last aortic branch, it passes *between* the trachea and oesophagus. It may perforate the scalenus anterior; very rarely it passes anterior to it. Sometimes the subclavian vein accompanies the artery behind the scalenus anterior. The artery may ascend as high as 4 cm above the clavicle or it may reach only its upper border. The left subclavian is occasionally combined at its origin with the left common carotid.

Applied Anatomy. The subclavian artery's third part is most accessible. Since the line of the posterior border of the sternocleidomastoid approximates to the (deeper) lateral border of the scalenus anterior, the artery is just lateral to the former and, as noted, can be felt in the antero-inferior angle of the posterior triangle. It can only be effectively *compressed against the first rib*; with shoulder depressed pressure is exerted *down, back* and *medially* in the angle between the sternocleidomastoid and clavicle. The palpable trunks of the brachial plexus may be infiltrated with local anaesthetic allowing major surgical procedures.

BRANCHES OF THE SUBCLAVIAN ARTERY



These are (1) vertebral, (2) internal thoracic, (3) thyrocervical, (4) costocervical and (5) dorsal scapular.

On the left all branches except the dorsal scapular arise from the first part; on the right the costocervical trunk usually springs from the second part. The origins of branches proceeding into the posterior triangle are variable but distributions are relatively constant.

1. The Vertebral Artery (**6**.79,81A,84A,85,86,88,89)

This artery arises from the superoposterior aspect of the subclavian's first part, ascending through the foramina in all cervical transverse processes except the seventh, to curve medially behind the lateral mass of the atlas and then ascending to enter the cranium via the foramen magnum. At the lower pontine border it joins its fellow to form the basilar artery. Occasionally it may enter the bone at the fifth, fourth or seventh cervical transverse foramen (p. 733).

Relations. The vertebral artery has a *first part* ascending back between the longus colli and the scalenus anterior, related anteriorly to the common carotid artery and vertebral vein, and crossed by the inferior thyroid artery, and on the left also by the thoracic duct. *Posterior* are the seventh cervical transverse process, the cervicothoracic ganglion (**6**.85,86) and ventral rami of the seventh and eighth cervical spinal nerves. The *second part* ascends through the transverse foramina, with a large branch from the cervicothoracic sympathetic (stellate) ganglion and a plexus of veins which form the vertebral vein low in the neck. It is anterior to the ventral rami of the cervical spinal nerves

6.87 The lower part of the posterior triangle showing the relations of the third part of the right subclavian artery. Note the clavicle has been removed but is shown as a dotted outline; the middle trunk of the brachial plexus gives an unusual contribution to the medial cord.

(C.2–C.6), ascending almost vertically to the transverse process of the axis, through which it turns laterally to the atlantal transverse foramen; from here the *third part* issues medial to the rectus capitis lateralis, curving back and medially behind the lateral mass, the first cervical ventral spinal ramus being medial. It is then in a groove on the upper surface of the atlantal posterior arch, entering the vertebral canal below the inferior border of the posterior atlanto-occipital membrane. This part, covered by the semispinalis capitis, is in the suboccipital triangle. The first cervical dorsal spinal ramus is between the artery and the posterior arch. The *fourth part* pierces the dura and arachnoid mater, ascends anterior to the hypoglossal roots (p. 1120) inclining anterior to the medulla oblongata where, at the lower pontine border, it unites with its fellow to form the midline basilar artery (**6**.81,84).

Winckler (1972) has described variation in elastic and muscular tissue in the vertebral artery; in its first and third parts it appears adapted by increased elasticity to the greater mobility and lack of support in these regions.

Cervical Branches of the Vertebral Artery

Spinal branches enter the vertebral canal by the intervertebral foramina, each dividing into a branch passing along the spinal roots to supply the spinal cord and membranes (p. 948); they anastomose with other spinal arteries, which fork into ascending and descending rami, to unite with those above and below, forming two lateral anastomotic chains on the posterior surfaces of the vertebral bodies near the attachment of their pedicles. From these chains branches supply the periosteum and vertebral bodies, others communicating with similar branches across the midline; from these connections small rami join similar ones above and below, forming a median anastomotic chain on the posterior surfaces of the vertebral bodies.

Muscular branches arising from the vertebral artery as it curves round the lateral mass of the atlas, supply the deep muscles of this region and anastomose with the occipital, ascending and deep cervical arteries.

Cranial Branches of the Vertebral Artery

One or two **meningeal branches** from the vertebral artery near the foramen magnum ramify between the bone and dura mater in the cerebellar fossa, supplying bone, diploë and the falx cerebelli.

The posterior spinal artery may arise from the vertebral near the medulla oblongata but most frequently from its posterior inferior cerebellar branch (vide infra). It passes posteriorly, descending as two branches, anterior and posterior to the dorsal roots of the spinal nerves; these are reinforced by spinal twigs from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, which reach the vertebral canal by the intervertebral foramina, sustaining the posterior spinal arteries to the lower spinal levels (p. 948, 7.80).

The anterior spinal artery, a small branch arising near the vertebral's end, descends anterior to the medulla oblongata and unites with its fellow at mid-medullary level. The single trunk then descends on the ventral midline of the spinal cord, reinforced by a succession of small spinal rami entering the vertebral canal through the intervertebral foramina from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries. They

6.88 Vertebral arteriogram (left): lateral view. 1. Vertebral artery, ascending part. 2. Loop between transverse foramina of axis and atlas. 3. Suboccipital part. 4. Intracranial part. 5. Basilar artery. 6. Posterior cerebral branches. 7. Inferior cerebellar branches.

unite by ascending and descending branches as a single anterior median artery, which reaches the lower spinal cord and filum terminale. This median artery is encased in the pia mater along the anterior median fissure; it supplies the spinal cord and inferiorly the cauda equina. Branches from the anterior spinal arteries and beginning of their common trunk pass into the medulla oblongata, with a central distribution sharply limited dorsally by the trigonum hypoglossi (p. 1084, 7.80).

The posterior inferior cerebellar artery (6.81), the largest branch, is sometimes absent. Arising near the lower end of the olive, it curves back around it to ascend behind glossopharyngeal and vagal roots to the inferior border of the pons, where it curves and descends along the inferolateral border of the fourth ventricle. Finally it turns laterally into the cerebellar vallecula, dividing into medial and lateral rami. The *medial branch* runs back between the cerebellar hemisphere and inferior vermis, supplying both; the *lateral branch* supplies the inferior cerebellar surface as far as its lateral border, anastomosing with the anterior inferior and superior cerebellar arteries (from the basilar artery). Its trunk supplies the medulla oblongata and choroid plexus of the fourth ventricle, sending up a branch lateral to the (cerebellar) tonsil to supply the dentate nucleus. The medullary area supplied is dorsal to the olivary nucleus and lateral to the hypoglossal nucleus and its emerging fila.

Applied Anatomy. The *posterior* inferior cerebellar artery supplies the *lateral* medulla. Thrombosis therefore causes loss of function ('*lateral medullary syndrome*') in ambigual, solitary, vestibular and cochlear nuclei, spinocerebellar tracts, the lateral spinothalamic tract, trigeminal spinal nucleus and tract. The *anterior* spinal artery supplies the *medial* medulla; thrombosis of it ('*medial medullary syndrome*') affects the hypoglossal nucleus and nerve, medial lemniscus and corticospinal tract.

The medullary arteries are minute vessels from the vertebral and its branches, distributed to the medulla oblongata.

6.89 Vertebral arteriogram (left): anteroposterior view. The circular shape of the field is due to use of a cone to improve resolution. 1. Left vertebral artery. 2. Basilar artery. 3. Right superior cerebellar artery. 4. Right posterior cerebral artery. 5. Branches of right posterior cerebral artery.

The Basilar Artery

This median vessel, the junction of the vertebral arteries, extends from the lower to the upper pontine borders in the cisterna pontis. It adjoins a shallow, median groove on the ventral pontine surface, between the abducent nerves at the lower pontine border and the oculomotor at the upper pontine border, where it divides into two posterior cerebral arteries.

The pontine branches are numerous and leave the front and sides of the basilar to supply the pons and adjacent parts.

The labyrinthine (internal auditory) artery, long and slender, may branch from the lower part of the basilar but more often from the anterior inferior cerebellar artery (vide infra); it accompanies facial and vestibulocochlear nerves into the internal acoustic meatus and is distributed to the internal ear (p. 1228). In a radiographic study of this artery Wende et al (1975) identified the origins of 238. Only 38 (16%) were from the basilar; 108 (45.4%) were from the anterior inferior cerebellar. The superior cerebellar artery accounted for 58 (24.4%), the posterior inferior cerebellar for 13 (5.4%). The remaining 21 (8.8%) were reduplicated and were branches of the basilar and one or other of the cerebellar arteries. They found a unilateral artery in 24 of 316 patients. Others have recorded different incidences. Cavatori (1908) observed a basilar origin for the labyrinthine artery in about 70% in Italians; Stopford (1916) and Adachi & Hasche (1928) recorded it as most often from a trunk common to it and one of the cerebellar arteries. Gillilan (1972) has indicated racial variation.

The anterior inferior cerebellar artery (6.81) branches from the lower part of the basilar and runs posterolaterally usually ventral to the abducent, facial and vestibulocochlear nerves, commonly forming a variable loop into the internal acoustic meatus below the nerves (Sunderland 1945), from which the laryrinthine artery often arises. Emerging from the meatus the

artery supplies the anterolateral region of the inferior cerebellar surface, anastomosing with the posterior inferior cerebellar branch of the vertebral. A few branches supply the inferolateral parts of the pons and sometimes the upper medulla oblongata.

The superior cerebellar artery (6.81), arising near the basilar's end, passes laterally below the oculomotor nerve which separates it from the posterior cerebral artery and curves round the cerebral peduncle below the trochlear nerve; arriving at the superior cerebellar surface, it divides into branches ramifying in the pia mater to supply this cerebellar aspect and anastomose with branches of inferior cerebellar arteries. It also supplies the pons, pineal body, superior medullary velum and tela choroidea of the third ventricle.

The posterior cerebral artery (6.81, 82, 83), frequently double, is larger than the superior cerebellar, from which it is separated near its origin by the oculomotor nerve and, lateral to the midbrain, by the trochlear nerve. Passing laterally, parallel with the superior cerebellar, it receives the posterior communicating artery, winds round the cerebral peduncle and reaches the tentorial cerebral surface, where it supplies the temporal and occipital lobes. Its branches are central and cortical.

Central branches. Several small *posteromedial central branches* (6.84) from the beginning of the posterior cerebral, with similar branches from the posterior communicating artery, pierce the posterior perforated substance to supply the anterior thalamus, lateral wall of the third ventricle and the globus pallidus. *Posterior choroidal rami* vary (Abbie 1933); one or more course over the lateral geniculate body and help to supply it before entering the posterior part of the inferior cornu of the lateral ventricle via the lower part of the choroidal fissure. Others curl round the posterior end of the thalamus and traverse the transverse fissure, some going to the third ventricle's tela choroidea, some to traverse the upper choroidal fissure; they supply the choroid plexuses of the third and lateral ventricles and the fornix (Percheron 1977, p. 1084). Small *posterolateral central branches* arise from the posterior cerebral artery beyond the cerebral peduncle; they supply this and the posterior thalamus, colliculi, pineal gland and medial geniculate body.

Cortical branches. The *temporal branches*, usually two, are distributed to the uncus, parahippocampal, medial and lateral occipitotemporal gyri; *occipital branches* supply the cuneus, lingual gyrus and posterolateral surface of the occipital lobe; *parietooccipital branches* supply the cuneus and precuneus. The posterior cerebral artery supplies the visual area (p. 1084) and other structures in the visual pathway.

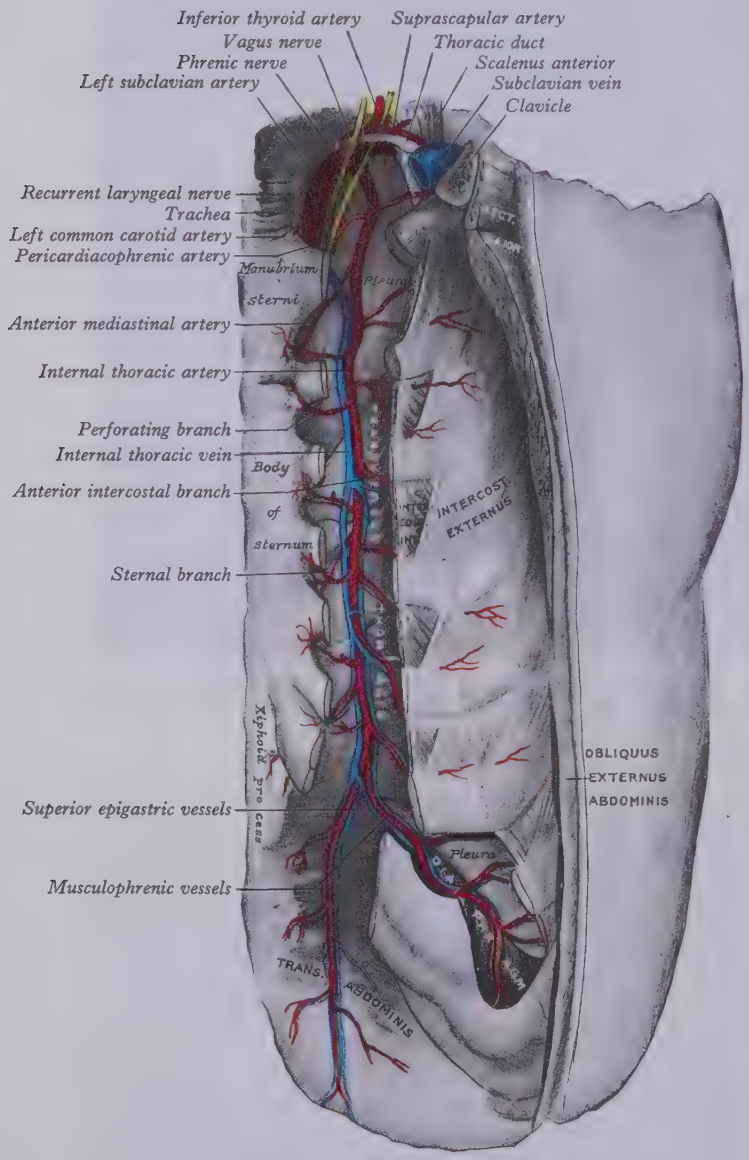
2. The Internal Thoracic Mammary Artery (6.90)

This arises inferiorly from the first part of the subclavian artery, about 2 cm above the clavicle's sternal end, opposite the root of the thyrocervical trunk. It descends behind the upper six costal cartilages about one cm from the lateral sternal border; level with the sixth intercostal space it divides into musculophrenic and superior epigastric branches.

Relations. At first it descends anteromedially behind the clavicle's sternal end, the internal jugular and brachiocephalic veins and the first costal cartilage. As it enters the thorax, the phrenic nerve crosses it obliquely from its lateral side, usually in front. The artery then descends almost vertically to its bifurcation; *anterior* to it are the pectoralis major, the upper six costal cartilages and intervening external intercostal membranes and internal intercostals and terminations of the upper six intercostal nerves. It is separated from the pleura, down to the second or third cartilage, by a strong layer of fascia and below this by the transversus thoracis. It is accompanied by a chain of lymph nodes and venae comitantes uniting at about the third costal cartilage into a single vein medial to the artery. Its intermediate branches are as follows:

The pericardiacophrenic artery is a long, slender branch accompanying the phrenic nerve to the diaphragm, descending between the pleura and pericardium, finally anastomosing with the musculophrenic and phrenic arteries.

Mediastinal arteries are distributed to the areolar tissue and lymph nodes in the anterior mediastinum and to the thymic vestiges.



Pericardial branches supply the upper anterior region of the pericardium.

Sternal branches are distributed to the transversus thoracis, the periosteum of the posterior sternal surface and the sternal red bone marrow.

The foregoing three groups, with rami of the pericardiacophrenic, anastomose with branches of the posterior intercostal and bronchial arteries to form a *subpleural mediastinal plexus*.

Anterior intercostal branches are distributed to the upper six intercostal spaces. Two in each space, they pass laterally along the borders of the space to anastomose with the posterior intercostal arteries (and their collateral branches). They lie at first between the pleura and the internal intercostals, then between the intercostales intimi and the internal intercostals. They supply the intercostal muscles and send branches through them to the pectoral muscles, breast and skin.

Perforating branches traverse the upper five or six intercostal spaces with *anterior cutaneous branches* of the corresponding intercostal nerves. They enter the pectoralis major and, curving laterally, supply the muscle and skin. In the female the second to fourth branches supply the breast; during lactation they are enlarged.

6.90 The left internal thoracic artery and vein and their main branches. The lateral end of the resected clavicle has been artificially elevated.

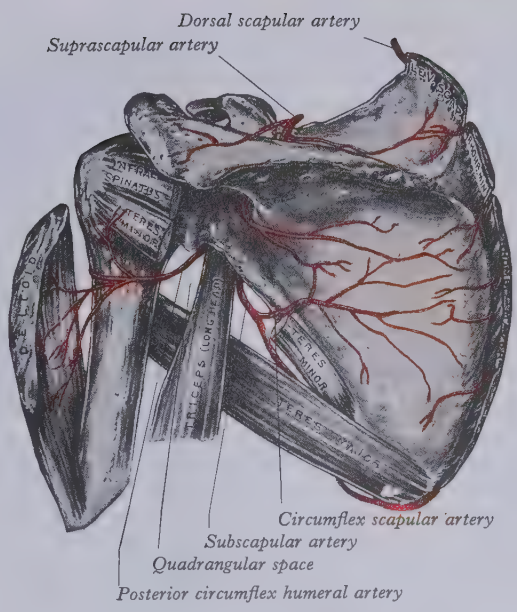
The musculophrenic artery passes inferolaterally behind the seventh to ninth costal cartilages, traverses the diaphragm near the ninth and ends near the last intercostal space. It anastomoses with the inferior phrenic and the lower two posterior intercostal and ascending branch of the deep circumflex iliac arteries. Two anterior intercostal arteries branch from it for each of the seventh to ninth intercostal spaces, distributed like those in other spaces. The musculophrenic also supplies the lower part of the pericardium and the abdominal muscles.

The superior epigastric artery descends between the costal and xiphoid slips of the diaphragm, anterior to the lower fibres of the transversus thoracis and the upper fibres of the transversus abdominis. Entering the rectus sheath, at first behind the muscle and then perforating and supplying it, it anastomoses with the inferior epigastric branch of the external iliac. Branches perforate the sheath to supply the abdominal skin; a branch anterior to the xiphoid process anastomoses with its fellow. The artery supplies the diaphragm; on the right small branches reach the falciform ligament to anastomose with the hepatic artery.

3. The Thyrocervical Trunk (6.68,146)

This short, wide artery, from the front of the subclavian's first part near the medial border of the scalenus anterior, divides almost at once into the inferior thyroid, suprascapular and superficial cervical branches.

The inferior thyroid artery is looped; first it *ascends* anterior to the medial border of the scalenus anterior, turns *medially* just below the sixth cervical transverse process, passing anterior to the vertebral vessels and posterior to the carotid sheath and its contents and usually the sympathetic trunk, whose middle cervical ganglion usually adjoins the vessel. It finally *descends* on the longus colli to the lower border of the thyroid gland. As it approaches this, its relation to the recurrent laryngeal nerve is surgically important (p. 1117). Nearing the gland the artery usually passes behind the nerve but nearer, on the right, the nerve is with equal frequency anterior or posterior to or amongst the branches of the artery; the left nerve is usually posterior. Relations between the terminal branches of artery and nerve are very variable (Bowden 1955). On the *left*, near its origin, the artery is crossed anteriorly by the thoracic duct, curving inferolaterally to its end.



Muscular branches supply the infrahyoid muscles, longus colli, scalenus anterior and the inferior pharyngeal constrictor.

The ascending cervical artery, a small branch, arises as the inferior thyroid turns medially behind the carotid sheath and ascends on the anterior tubercles of the cervical transverse processes between the scalenus anterior and the longus capitis. It supplies the adjacent muscles and has one or two *spinal branches* which enter the vertebral canal through the intervertebral foramina to supply the spinal cord and membranes and vertebral bodies, as do the spinal branches of the vertebral artery. The ascending cervical artery anastomoses with the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

The inferior laryngeal artery ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the inferior constrictor's lower border and supplies the laryngeal muscles and mucous membrane, anastomosing also with its contralateral fellow, and with the superior laryngeal branch of the superior thyroid artery.

Pharyngeal branches supply the lower pharynx, *tracheal branches* the trachea (anastomosing with the bronchial arteries), and *oesophageal branches* the oesophagus (anastomosing with the oesophageal branches of thoracic aorta). Inferior and ascending *glandular branches* supply the posterior and inferior regions of the thyroid gland, anastomosing with the opposite inferior and ipsilateral superior thyroid arteries. The ascending branch also supplies the parathyroid glands.

The suprascapular artery (6.87,88) first descends laterally across the scalenus anterior and phrenic nerve posterior to the internal jugular vein and sternocleidomastoid; it then crosses anterior to the subclavian artery and brachial plexus, posterior and parallel to the clavicle and subclavius and the inferior belly of the omohyoid, to reach the superior scapular border. Here it passes above (sometimes under) the superior transverse ligament,

6.91 Scapular anastomoses of the left side: dorsal aspect.

separating it from the suprascapular nerve, to enter the supraspinous fossa (6.91), where it lies on the bone, supplying the supraspinatus. It descends behind the scapular neck, through the great scapular notch deep to the inferior transverse ligament to the deep surface of the infraspinatus, where it anastomoses with the circumflex scapular and deep branch of the transverse cervical artery. Besides supplying the sternocleidomastoid, subclavius and infraspinatus, it has a *suprasternal branch* which crosses the sternal end of the clavicle to the skin of the upper thorax and an *acromial branch* which pierces the trapezius to supply the skin over the shoulder, anastomosing with the thoraco-acromial and posterior circumflex humeral arteries. As the suprascapular artery passes the superior transverse ligament, a branch of it enters the subscapular fossa beneath the subscapularis; this anastomoses with the subscapular artery and the deep branch of the transverse cervical. It also supplies the acromioclavicular and glenohumeral joints, the clavicle and scapula. It may arise from the third part of the subclavian artery.

The superficial cervical artery (6.87), at a higher level than the suprascapular, crosses anterior to the phrenic nerve, the scalenus anterior and brachial plexus and is covered by the internal jugular vein, sternocleidomastoid and platysma. It crosses the posterior triangle's floor to the anterior margin of the levator scapulae, ascending deep to the anterior part of the trapezius, supplying it, the adjoining muscles and the cervical lymph nodes. It anastomoses with the superficial ramus of the descending branch of the occipital artery. (See also below: variations of superficial cervical and dorsal scapular arteries.)

4. The Costocervical Trunk (6.85)

On the right, this short vessel arises posteriorly from the second part of the subclavian artery, and, on the left, from its first part. It arches back above the cervical pleura to the first rib's neck, dividing here into superior intercostal and deep cervical branches.

The superior intercostal artery descends between the pleura and necks of the first and second ribs to anastomose with the third posterior intercostal artery. Crossing the neck of the first rib it is medial to the ventral ramus of the first thoracic spinal nerve, which it crosses at a lower level (6.85), and lateral to the cervicothoracic ganglion. In the first space it provides the first posterior intercostal artery, similar in distribution to the lower posterior intercostals. It descends to become the second posterior intercostal artery, usually joining a branch from the third; it is not constant, and is more common on the right; when absent, it is replaced by a direct aortic branch.

The deep cervical artery (6.79), usually arising from the costocervical trunk, is analogous in its first segment to a posterior

ramus of a posterior intercostal artery: occasionally it is a separate branch of the subclavian. Passing back above the eighth cervical spinal nerve between the seventh cervical transverse process and the neck of the first rib (sometimes between the sixth and seventh cervical transverse processes), it then ascends between the semispinales capitis and cervicis to the second cervical level. (This ascending segment is a longitudinal post-transverse anastomosis, p. 710.) It supplies adjacent muscles and anastomoses with the deep ramus of the descending branch of the occipital artery (p. 739) and branches of the vertebral. A spinal branch enters the vertebral canal between the seventh cervical and first thoracic vertebrae.

5. The Dorsal Scapular Artery (6.87,91)

This arises from the third or less often second part of the subclavian, passing laterally through the brachial plexus in front of the scalenus medius and then deep to the levator scapulae to the superior scapular angle; here it descends with the dorsal scapular nerve under the rhomboids along the medial scapular border to the inferior angle. It supplies the rhomboids, latissimus dorsi and trapezius and anastomoses with the suprascapular, subscapular and posterior branches of some posterior intercostal arteries.

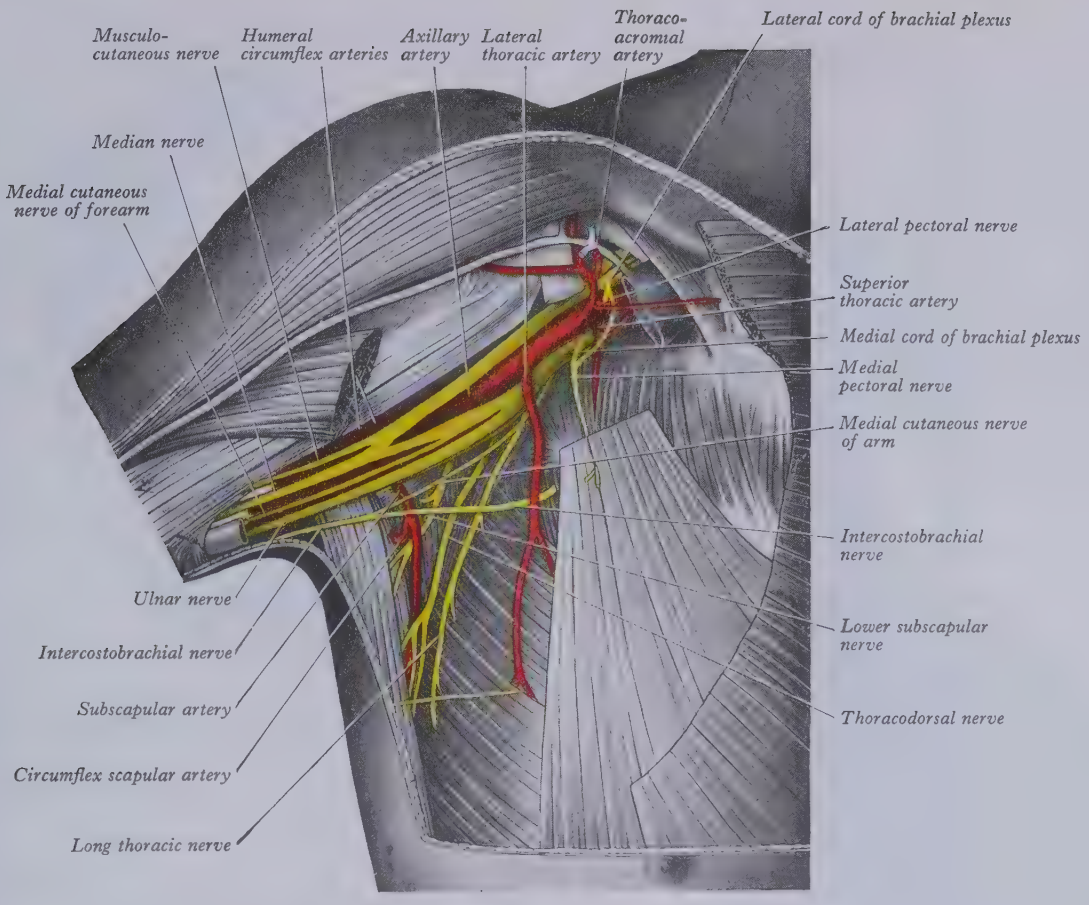
Variations. About a third of the superficial cervical and dorsal scapular arteries arise in common from the thyrocervical trunk as a *transverse cervical artery*, with a *superficial* (superficial cervical artery) and a *deep branch* (dorsal scapular artery); the latter passes laterally anterior to the brachial plexus and then posterior to the levator scapulae.

The Axilla

The axilla is a pyramidal region between the upper thoracic wall and the arm. Its blunt *apex* continues into the root of the neck (*cervico-axillary canal*) between the external border of the first rib, superior scapular border, posterior surface of the clavicle and the medial aspect of the coracoid process; through it pass the axillary vessels and nerves. Its imaginary *base*, facing down, is broad at the chest, narrow at the arm and corresponds to the skin and a thick layer of *axillary fascia*, between the inferior borders of the pectoralis major in front and the latissimus dorsi behind. It is of course convex up, conforming to the armpit's concavity. The *anterior wall* is formed by the pectorales major et minor, the former covering the whole wall, the latter its intermediate part. The interval between the upper border of the pectoralis minor and clavicle is occupied by the clavipectoral fasica. The *posterior wall* is formed by the subscapularis above, teres major and latissimus dorsi below. *Medial* are the first four ribs with their intercostal muscles and the upper part of serratus anterior; this 'wall' is convex laterally. *Laterally* anterior and posterior walls converge, the 'wall' being narrow, consisting of the humeral intertubercular sulcus; the lateral angle lodges the coracobrachialis and biceps.

The axilla contains axillary vessels, the infraclavicular part of the brachial plexus and its branches, lateral branches of some intercostal nerves, many lymph nodes and vessels, loose adipose areolar tissue and in many instances the 'axillary tail' of the breast. The axillary vessels and brachial plexus run from the apex to the base along the lateral wall and nearer to the anterior wall, the axillary vein being anteromedial to the artery. Owing to the obliquity of the upper ribs, the neurovascular bundle, emerging from behind the clavicle, crosses the first intercostal space; its relations are therefore different at upper and lower levels. Thoracic branches of the axillary artery are in contact with the pectoral muscles; along the lateral margin of the pectoralis minor the lateral thoracic artery reaches the thoracic wall. Subscapular vessels descend on the posterior wall at the lower margin of the subscapularis, and subscapular and thoracodorsal nerves cross the anterior surface of the latissimus dorsi at different inclinations; circumflex scapular vessels wind round the lateral scapular border; posterior circumflex humeral vessels and the axillary nerve curve back and laterally around the humeral surgical neck. No large vessel lies on the medial 'wall', which is crossed proximally only by small branches of the superior thoracic artery. The long thoracic nerve descends on the serratus anterior and the intercostobrachial nerve perforates the upper anterior part of this wall, crossing the axilla to its lateral 'wall'. The position and arrangement of lymph nodes are described on p. 845, nerves on p. 1130 et seq.

Applied Anatomy. When axillary suppuration occurs, fascial arrangement affects the spread of pus. As described on p. 611, the clavipectoral fascia, between the clavicle and superomedial border of the pectoralis minor, splits to enclose the muscle, blending at its lateral border with the axillary fascia in the anterior axillary fold. Suppuration may be superficial or deep to this layer, either between the pectoral muscles or behind the pectoralis minor; in the former an abscess would appear at the edge of the anterior axillary fold or the groove between the deltoid and pectoralis major; in the latter, pus would tend to surround vessels and nerves and ascend into the neck, the direction of least resistance; pus may also track along vessels into the arm. When an axillary abscess is incised a knife should enter the axillary 'base', midway between the anterior and posterior margins and near the thoracic side to avoid the lateral thoracic, subscapular and axillary vessels on the anterior, posterior and lateral walls. Relations of vessels and nerves in the axilla are important when lymph nodes are removed from the axilla in operations for mammary carcinoma; the positions of major structures in the lateral wall must be remembered.



The Axillary Artery

The axillary artery (6.92), a continuation of the subclavian, begins at the first rib's outer border, ending nominally at the inferior border of the teres major where it becomes *brachial*. Its direction varies with the limb's position: thus it is almost straight when the arm is raised at right angles, concave up when the arm is elevated above this and convex up and laterally with the arm pendent. At first deep, it becomes superficial, covered only by the skin and fasciae. The pectoralis minor crosses it and divides it into *three parts*: proximal, posterior and distal to the muscle.

Relations of the first part. Anterior are the skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of the pectoralis major and the clavipectoral fascia. This part is crossed anteriorly by the lateral pectoral nerve, the loop of communication between it and the medial pectoral nerve, and by the thoraco-acromial and cephalic veins. *Posterior* are the first intercostal space and external intercostal, the first and second digitations of the serratus anterior, the long thoracic and medial pectoral nerves and the medial cord of the brachial plexus. *Lateral* is the posterior cord of the brachial plexus. *Anteromedial* is the axillary vein. The first part is enclosed with the axillary vein and brachial plexus in a fibrous *axillary sheath*, continuous with the prevertebral layer of the deep cervical fascia.

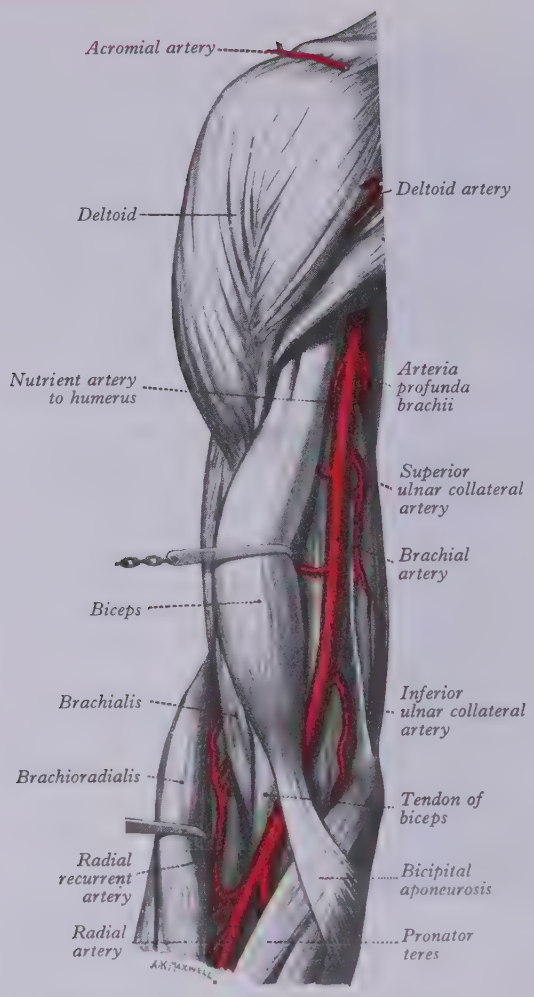
Relations of the second part. Anterior are the skin, superficial and deep fascia, pectoralis major and minor. *Posterior* are the posterior cord of the brachial plexus and the areolar tissue between it and the subscapularis. Medial is the axillary vein, separated from it by the medial cord of the brachial plexus and medial pectoral nerve. *Lateral* is the lateral cord of the brachial plexus, separating it from the coracobrachialis. The cords of the brachial plexus thus surround the second part on three sides, with the dispositions implied by their names, and separate it from the vein and adjacent muscles.

Relations of the third part. Anterior are pectoralis major, distal to this skin and fasciae. *Posterior* are the lower part of the subscapularis and tendons of the latissimus dorsi and teres major. *Lateral* is the coracobrachialis. *Medial* is the axillary vein. Branches of the brachial plexus are arranged as follows: *laterally* the lateral root and then trunk of the median nerve and, for a short distance, the musculocutaneous nerve; *medially* the medial cutaneous nerve of the forearm between the axillary artery and vein anteriorly, between them posteriorly the ulnar nerve; the medial cutaneous nerve of upper arm is medial to the vein; *anterior* is the medial root of the median nerve and *posterior* are radial and axillary nerves, the latter only to the distal border of the subscapularis.

6.92 The right axillary artery and its branches. The pectoralis major and part of the pectoralis minor have been removed. Prominent but unlabelled features are the medial and lateral roots of the median nerve.

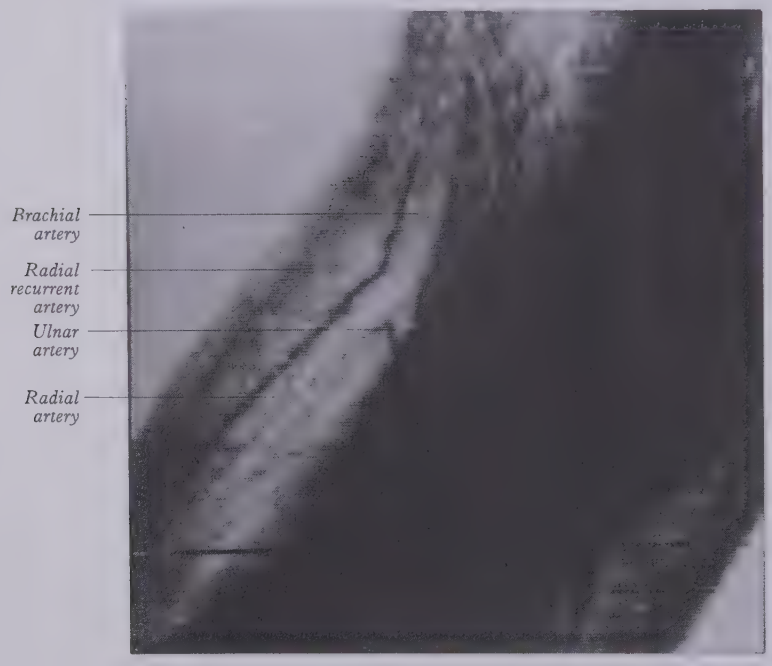
The artery's branches are superior thoracic, thoraco-acromial, lateral thoracic, subscapular, anterior and posterior circumflex humeral.

The superior thoracic artery (**6**.92), a small vessel from the first part of the axillary near the lower border of the subclavius (sometimes from the thoraco-acromial) runs anteromedially above the medial border of the pectoralis minor, then passes between it and the pectoralis major to the thoracic wall. It supplies these muscles and the thoracic wall, anastomosing with the internal thoracic and upper intercostal arteries.



The thoraco-acromial (acromiothoracic) artery (**6**.87,92), a short branch from the second part, is at first overlapped by the pectoralis minor; skirting its medial border, it pierces the clavipectoral fascia and divides into the pectoral, acromial, clavicular and deltoid branches.

The *pectoral branch* descends between the pectoral muscles, is distributed to them and the breast and anastomoses with the intercostal branches of the internal thoracic and lateral thoracic arteries. The *acromial branch* crosses the coracoid process under the deltoid, which it supplies, pierces the muscle and ends on the acromion, anastomosing with rami of the suprascapular, deltoid branch of the thoraco-acromial and posterior circumflex humeral arteries. The *clavicular branch* ascends medially between the clavicular part of the pectoralis major and clavipectoral fascia, supplying the sternoclavicular joint and subclavius. The *deltoid branch* often arises with the acromial, crossing the pectoralis minor to accompany the cephalic vein between the pectoralis major and deltoid, supplying both.



The lateral thoracic artery (**6**.92) follows the lateral border of the pectoralis minor to the thoracic wall, supplies the serratus anterior and pectoral muscles, the axillary lymph nodes and subscapularis; it anastomoses with the internal thoracic, subscapular, and intercostal arteries and the pectoral branch of the thoraco-acromial artery. In females it is large and has *lateral mammary branches* which curve round the lateral border of the pectoralis major to the mammary gland.

The subscapular artery (**6**.92), largest branch of the axillary, usually arises at the distal (inferior) border of the subscapularis which it follows to the inferior scapular angle, where it anastomoses with the lateral thoracic and intercostal arteries and the deep branch of the transverse cervical. It supplies adjacent muscles and the thoracic wall. It is accompanied distally by the nerve to the latissimus dorsi; about 4 cm from its origin it gives off the *circumflex scapular artery*, usually larger than the continuation of the subscapular. This curves round the lateral scapular border, traversing a *triangular space* between the subscapularis above and the teres major below, and the long head of triceps laterally. It enters the infraspinous fossa under the teres minor and then divides. One branch (*infrascapular*) enters the subscapular fossa deep to the subscapularis, anastomosing with the suprascapular and dorsal scapular arteries (or deep branch of the transverse cervical); the other continues along the lateral scapular border between the teres major and minor and, dorsal to the inferior angle, anastomoses with the deep branch of the transverse cervical artery. Small rami supply the posterior part of the deltoid and the long head of the triceps, anastomosing with an ascending branch of the arteria profunda brachii.

The anterior circumflex humeral artery (**6**.92), arising from the lateral side of the axillary artery at the distal border of the subscapularis, runs horizontally behind coracobrachialis and the short head of biceps, anterior to the surgical neck of the humerus. Reaching the intertubercular sulcus, it sends an ascending branch to supply the humeral head and shoulder joint. It continues laterally under the long head of biceps and deltoid, anastomosing with the posterior circumflex humeral artery.

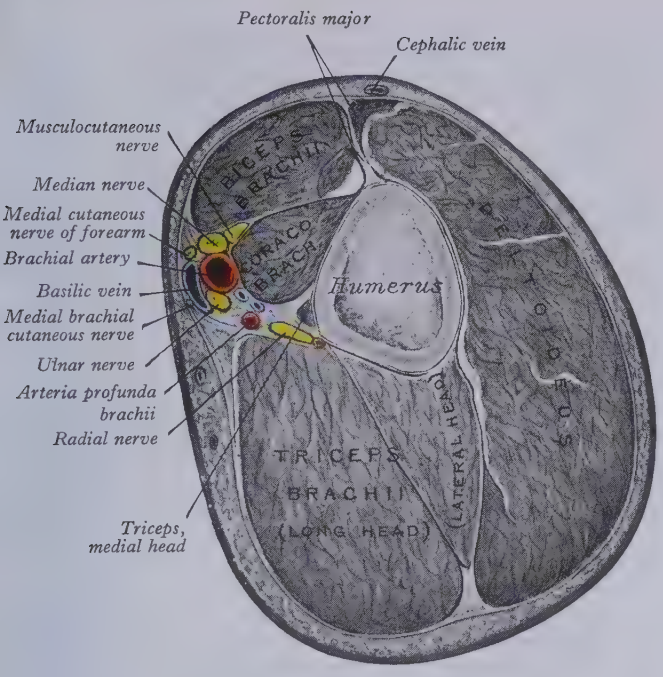
6.93A The right brachial artery and its branches.

6.93B Ultrasound transmission image of the distal part of the arm and the proximal part of the forearm, showing the radial and ulnar arteries arising from the brachial artery. The radial recurrent artery can also be seen. The image was produced using a 2 MHz ultrasound camera system with a depth of focus of 6 mm (supplied by Peter D Edmonds, SRI International, Menlo Park, California).

The posterior circumflex humeral artery (6.91), larger than the anterior, branches from the third part of the axillary at the distal border of the subscapularis and runs back with the axillary nerve through a *quadrangular space*, bounded by the subscapularis, the capsule of the shoulder joint and the teres minor above, the teres major below, the long head of triceps medially and the surgical neck of the humerus laterally. It curves round the humeral neck and supplies the shoulder joint, deltoid, teres major and minor, and long and lateral heads of triceps, giving off a descending branch to anastomose with the deltoid branch of the arteria profunda brachii and with the anterior circumflex humeral and acromial branches of the suprascapular and thoraco-acromial arteries.

Surface Anatomy. Pulsation of the axillary artery can be felt against the axillary lateral wall. Its upper segment can be mapped out, when the arm is raised, by a line from this to the midpoint of the clavicle.

Variations. Branches vary considerably; an *alar thoracic*, often from the second part, may supply fat and lymph nodes in the axilla. Occasionally the subscapular, circumflex humeral and arteria profunda arise in common and then branches of the brachial plexus surround this instead of the axillary artery. The posterior circumflex humeral artery may be from the arteria profunda brachii, passing back below the teres major instead of traversing the quadrangular space. Sometimes (anomalous 'high division') the axillary divides into radial and ulnar arteries and is occasionally the source of the anterior interosseous artery.



Applied Anatomy. Axillary compression is most effectual against the humerus. Except for the popliteal, the axillary artery is more frequently lacerated by violence than any other, being most susceptible when diseased. It has been ruptured in attempts to reduce old dislocations, especially when the artery is adherent to the articular capsule.

The Brachial Artery

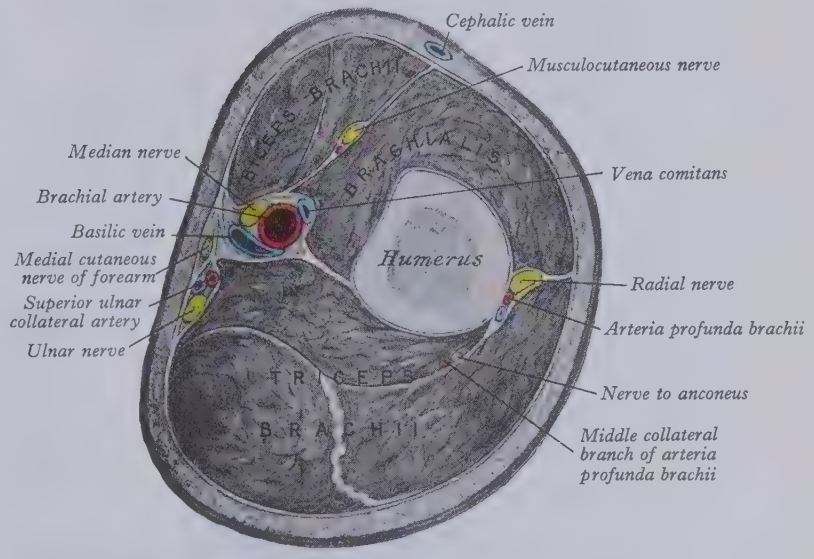
The brachial artery (6.93–96), a continuation of the axillary, begins at the distal (inferior) border of the tendon of teres major and ends about a centimetre distal to the elbow joint (at the level of the neck of the radius) by dividing into radial and ulnar arteries. At first it is medial to the humerus, but gradually spirals anterior to it until it lies midway between the humeral epicondyles. Its pulsation can be felt throughout.

Relations. The artery is wholly superficial, covered *anteriorly* only by skin and superficial and deep fasciae; the bicipital aponeurosis crosses it anteriorly at the elbow, separating it from the median cubital vein; the median nerve crosses it lateromedially near the distal attachment of coracobrachialis. *Posterior* are the long head of triceps, separated by the radial nerve and arteria profunda brachii and then successively by: the medial head of triceps, the attachment of coracobrachialis and the brachialis. *Lateral* are: proximally the median nerve and coracobrachialis and distally the biceps and the muscles overlapping the artery. *Medial* are: proximally the medial cutaneous nerve of forearm and ulnar nerve, distally the median nerve and basilic vein (separated distally by the deep fascia). With the artery are two venae comitantes, connected by transverse and oblique branches.

At the elbow the brachial artery sinks deeply into the triangular intermuscular *cubital fossa*. The fossa's base is an (arbitrary) inter-epicondylar line, the sides being the medial edge of the brachioradialis and the lateral margin of pronator teres; the 'floor' consists of brachialis and supinator. The fossa contains the tendon of the biceps, the terminal part of the brachial artery and accompanying veins, the commencement of the radial and ulnar arteries and parts of the median and radial nerves. The brachial artery is central and it divides near the neck of the radius into its terminal branches, the radial and ulnar arteries. *Anterior* to it are the skin, superficial fascia and median cubital vein, separated by the bicipital aponeurosis. *Posteriorly* the brachialis separates it from the elbow joint. The median nerve is *medial* proximally but is separated from the ulnar artery by the ulnar head of the pronator teres. *Lateral* are the tendon of biceps and the radial nerve, the latter concealed between supinator and brachioradialis.

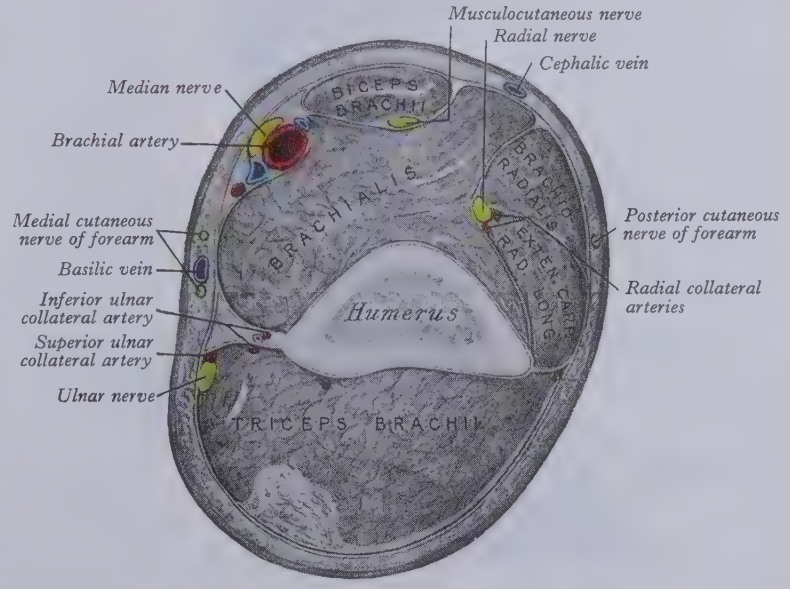
6.94 Transverse section through the right arm at the junction of the proximal and middle thirds of the humerus: proximal aspect.

Variations. The brachial artery, with the median nerve, may diverge from the medial border of the biceps, descending towards the medial humeral epicondyle, usually behind a *supracondylar process* from which a fibrous arch crosses the artery, and which then runs behind or through the pronator teres to the elbow. This resembles the normal arrangement in some carnivores (p. 410). Occasionally the artery divides proximally into two trunks which re-unite. Frequently it divides more proximally than usual into radial, ulnar and common interosseous arteries. Most often the radial branches proximally, leaving a common trunk for the ulnar and common interosseous; sometimes the ulnar arises proximally, the radial and common interosseous forming the other division; the common interosseous may also arise proximally. Sometimes slender *vasa aberrantia* connect the brachial to the axillary artery or to one of the forearm arteries, usually the radial. The brachial artery may be crossed by muscular or tendinous slips from the coracobrachialis, biceps, brachialis or pronator teres.



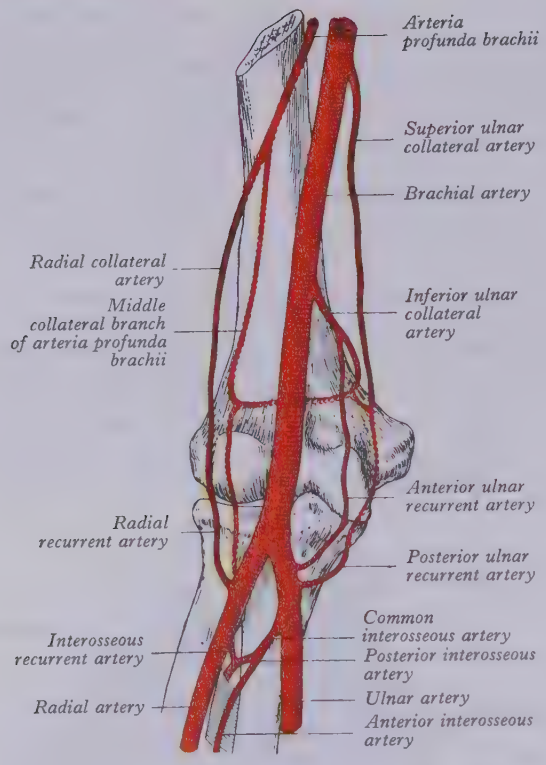
Branches are: the arteria profunda brachii, nutrient, superior and inferior ulnar collateral, muscular, radial and ulnar arteries.

The arteria profunda brachii (6.93,94,97), a large branch from the posteromedial aspect of the brachial, distal to the teres major, follows the radial nerve closely, at first back between the long and medial heads of the triceps, then in the nerve's groove covered by the lateral head of triceps; here it divides into terminal branches (6.97). Apart from the muscular rami, it supplies the following: the nutrient, deltoid, middle collateral and radial collateral arteries. A *nutrient artery* enters the humerus posterior to the deltoid tuberosity but may be absent. The *deltoid (ascending) branch* ascends between the lateral and long heads of triceps and anastomoses with a descending branch of the posterior humeral circumflex artery. The *middle collateral (posterior descending) branch*, the larger terminal ramus, arises behind the humerus and descends in the medial head of the triceps to the elbow, anastomosing with the interosseous recurrent artery behind the lateral epicondyle; it often has a small branch which accompanies the nerve to the anconeus. The *radial collateral*, the other terminal branch, is the artery's continuation. It accompanies the radial nerve through the lateral intermuscular septum, descending between the brachialis and brachioradialis anterior to the lateral epicondyle, anastomosing with the radial recurrent artery.

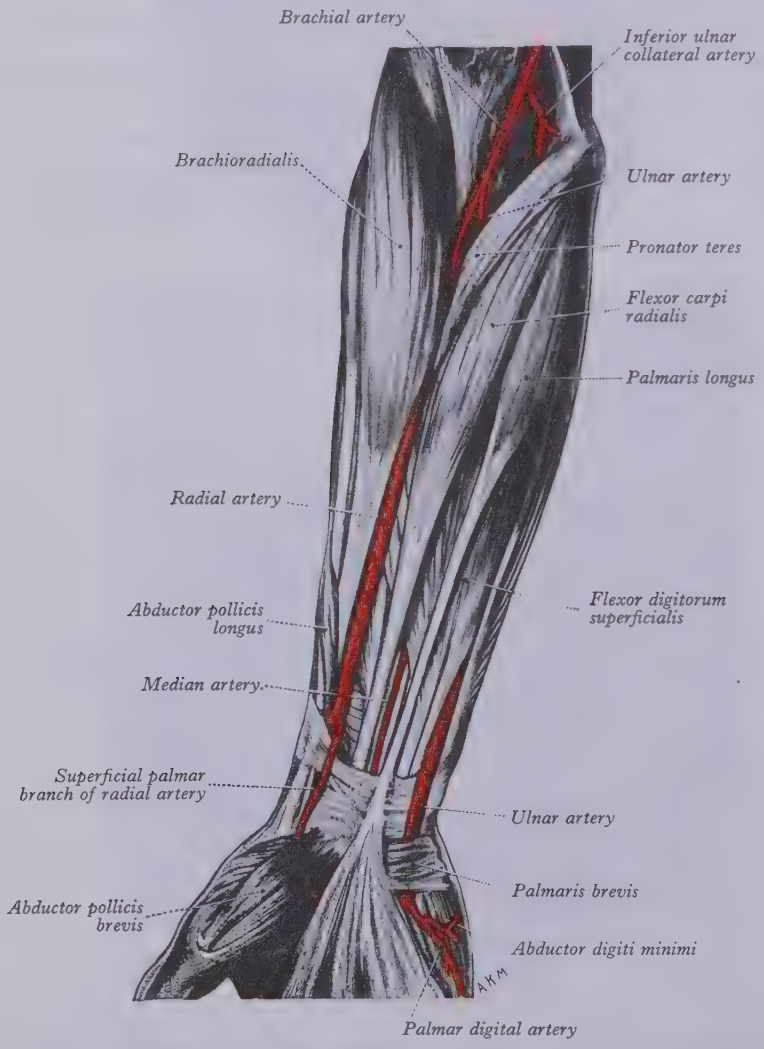


The nutrient artery of the humerus arises near the mid-level of the upper arm, entering the nutrient canal near the attachment of coracobrachialis; it is directed distally.

The superior ulnar collateral artery (6.93,95,97) arises a little distal to the upper arm's mid-level, often as a branch from the arteria profunda brachii. It accompanies the ulnar nerve, piercing the medial intermuscular septum to descend between the medial epicondyle and olecranon, ending deep to flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior collateral arteries; sometimes a branch of it passing anterior to the medial epicondyle anastomoses with the anterior ulnar recurrent artery.



The inferior ulnar collateral (supratrochlear) artery (6.93,97,98) begins about 5 cm proximal to the elbow, passes medially between the median nerve and brachialis and, piercing the medial intermuscular septum, curls round the humerus between the triceps and bone, forming, by its junction with the middle collateral branch of arteria profunda brachii, an arch proximal to the olecranon fossa. As it lies on brachialis it has branches descending anterior to the medial epicondyle to



6.95 Transverse section through the right arm, a little below the middle of the shaft of the humerus: proximal aspect.

6.96 Transverse section through the right arm, 2 cm above the medial epicondyle of the humerus: proximal aspect.

6.98 The right radial and ulnar arteries, superficial dissection.

anastomose with the anterior ulnar recurrent artery. Behind the epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

Muscular arteries from the brachial are distributed to the coracobrachialis, biceps and brachialis.

Applied Anatomy. Compression of the brachial artery may be effected at almost any level; if proximal, it should be directed laterally, if distal, backwards. The most favourable site is about midway, where the artery is on the tendon of the coracobrachialis and still medial to the humerus; pressure should be exerted slightly posterolaterally.

The Radial Artery

The radial artery (**6**.98,99,100), though smaller than the ulnar, appears a more direct continuation of the brachial. It begins about 1 cm distal to the bend of the elbow, (level of the neck of the radius, **6**.93B,100), then descends along the lateral side of the forearm to the wrist, where it is palpable between the flexor carpi radialis medially and the salient anterior border of the radius. It then curls posterolaterally round the carpus, beneath tendons of the abductor pollicis longus and extensor pollicis brevis and longus, to the proximal end of the first inter-metacarpal space, swerving medially between the heads of the first dorsal interosseous into the palm and then crossing medially to form the deep palmar arch with the deep branch of the ulnar artery. The radial artery is thus divisible into parts: in the forearm, wrist and hand.

In the forearm (**6**.98,99,100) the artery extends from the medial side of the neck of the radius to the front of its styloid process, being medial to the radial shaft proximally, but anterior to it distally. Proximally it is overlapped anteriorly by the belly of brachioradialis, whereas the rest is covered only by the skin, superficial and deep fasciae. Posterior are successively: the tendon of biceps, supinator, the distal attachment of pronator teres, radial head of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus and the lower end of the radius (where its pulsation is most accessible). Proximally pronator teres is medial, brachioradialis lateral; distally the tendon of flexor carpi radialis is medial, that of brachioradialis lateral. The superficial branch of the radial nerve is lateral in the vessel's middle third, and filaments of the lateral cutaneous nerve of the forearm run along its distal part as it curves round the carpus. The vessel is accompanied by paired venae comitantes.

At the wrist (**6**.101,103) the radial artery passes on to the dorsal aspect of the carpus between the lateral carpal ligament and tendons of abductor pollicis longus and extensor pollicis brevis. It crosses the scaphoid bone and trapezium (in the 'anatomical snuff-box'), where again its pulsation is obvious, and as it passes between heads of the first dorsal interosseous it is crossed by the tendon of extensor pollicis longus. Between the pollicial extensors it is crossed by the beginning of the cephalic vein and the (palpable) digital branches of the radial nerve supplying the thumb and index.

In the hand (**6**.104) the radial artery, having traversed the first interosseous space between the heads of the first dorsal interosseous, crosses the palm, at first deep to the oblique head of adductor pollicis and then between its oblique and transverse heads or through the transverse head. At the fifth metacarpal base it anastomoses with the deep branch of the ulnar artery, completing the *deep palmar arch* (**6**.100).

Variations. Sometimes the radial artery arises proximally, usually from the axillary or beginning of the brachial artery. In the forearm it is sometimes superficial to the deep fascia and occasionally superficial to the pollicial extensor tendons (see also under 'Variations of the Brachial Artery', above).

The radial recurrent artery (**6**.97,100) arises just distal to the elbow, passing between superficial and deep branches of the radial nerve to ascend behind the brachioradialis, anterior to the supinator and brachialis; it supplies these muscles and the elbow joint, anastomosing with the radial collateral branch of the arteria profunda brachii.

Muscular branches are distributed to muscles on the radial side of the forearm.

The palmar carpal branch (**6**.100), a small vessel, arises near the distal border of pronator quadratus and crosses the anterior surface of the distal end of the radius, near the palmar carpal surface, passing medially to anastomose behind the long flexor tendons with the palmar carpal branch of the ulnar; this transverse anastomosis is joined by longitudinal branches from the anterior interosseous and recurrent branches from the deep palmar arch, forming a cruciate *palmar carpal arch*, which, by descending branches, supplies the carpal articulations and bones. (Although so named this is usually sited near the wrist joint on the distal forearm bones.)

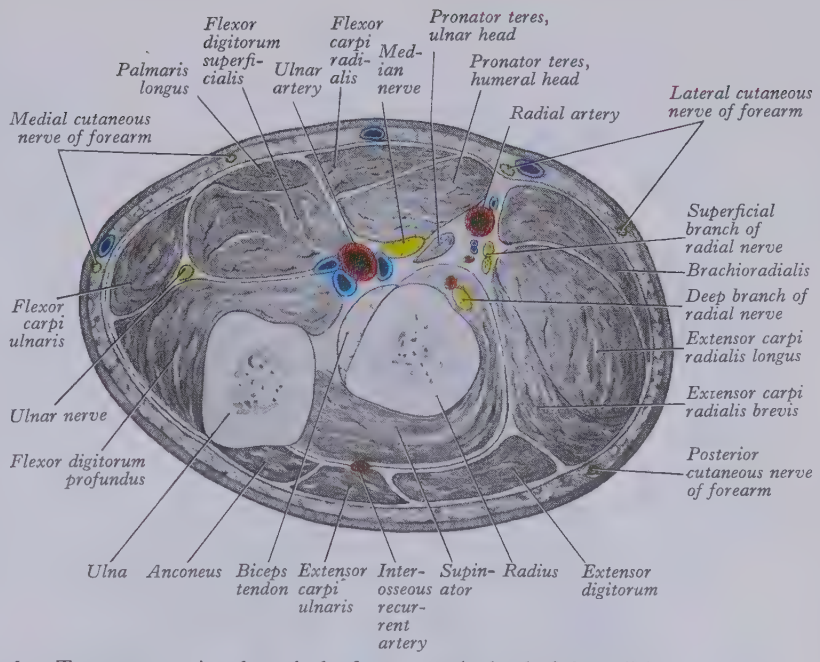
The superficial palmar branch (**6**.104) arises from the radial artery just before it curves round the carpus, passes through and occasionally over the thenar muscles, which it supplies, sometimes anastomosing with the end of the ulnar artery to complete a *superficial palmar arch*.

The dorsal carpal branch arises deep to the pollicial extensor tendons, runs medially across the dorsal carpal surface under them and anastomoses with the ulnar dorsal carpal branch and also with the anterior and posterior interosseous arteries to form a *dorsal carpal arch*. The carpal arches are both close to bone and supply the distal epiphysial parts of the radius and ulna. From the dorsal arch three *dorsal metacarpal arteries* descend on the second to fourth dorsal interosseous muscles and bifurcate into the *dorsal digital branches* for the adjacent sides of all four fingers; they anastomose with the palmar digital branches from the superficial palmar arch; near their origins they also anastomose with the deep palmar arch by the *proximal perforating arteries* and, near their bifurcation, with the palmar digital rami of the superficial palmar arch by *distal perforating arteries*.

The first dorsal metacarpal artery (**6**.103), a branch of the radial just before it passes between the heads of the first dorsal interosseous, divides almost at once into two branches supplying the adjacent sides of the pollex and index; the radial side of the pollex receives a branch direct from the radial artery itself (vide infra).

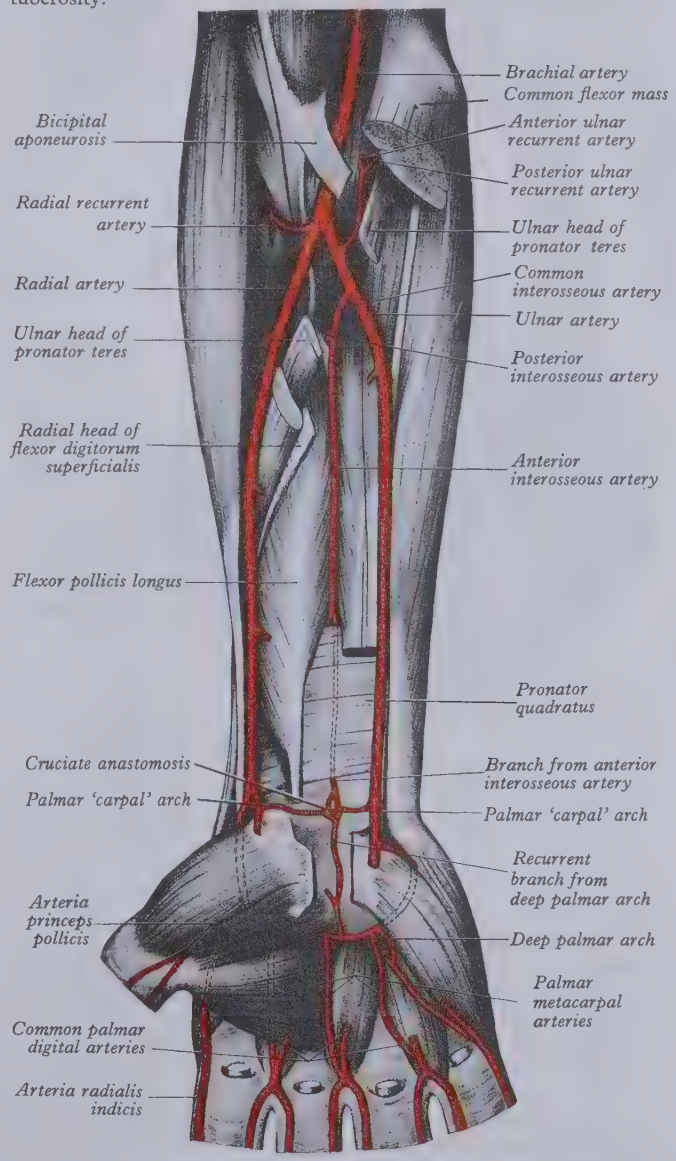
The arteria princeps pollicis (**6**.100) arises from the radial as it turns into the palm, and descends on the palmar aspect of the first metacarpal under the oblique head of adductor pollicis lateral to the first palmar interosseous. At the base of the proximal phalanx, deep to the tendon of flexor pollicis longus, it divides into two branches, appearing between the medial and lateral attachments of the oblique head of adductor pollicis to run along both sides of the pollex, forming, on the palmar surface of its distal phalanx, a pollicial arch supplying the skin and subcutaneous tissue. The arteria princeps pollicis is the usual nutrient of supply to the first metacarpal bone.

The arteria radialis indicis (**6**.100,104), often a proximal branch of the arteria princeps pollicis, descends between the first dorsal interosseous and transverse head of adductor pollicis, and along the lateral side of the index finger to its end; it anastomoses with the indicial medial digital artery. At the distal border of the transverse head of the adductor pollicis it anastomoses with the arteria princeps pollicis and links with the superficial palmar arch.



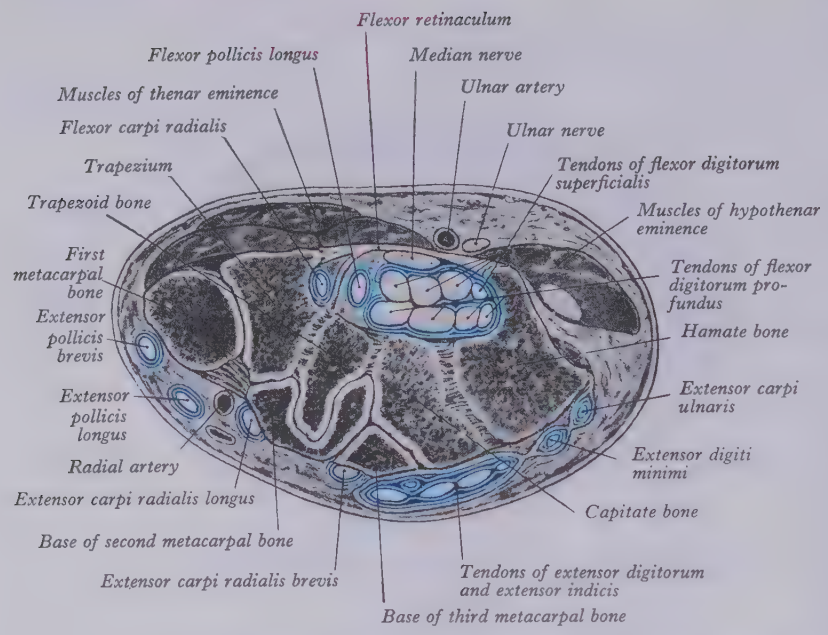
The arteriae princeps pollicis et radialis indicis may be combined as the *first palmar metacarpal artery*.

The Deep Palmar Arch (**6**.100)

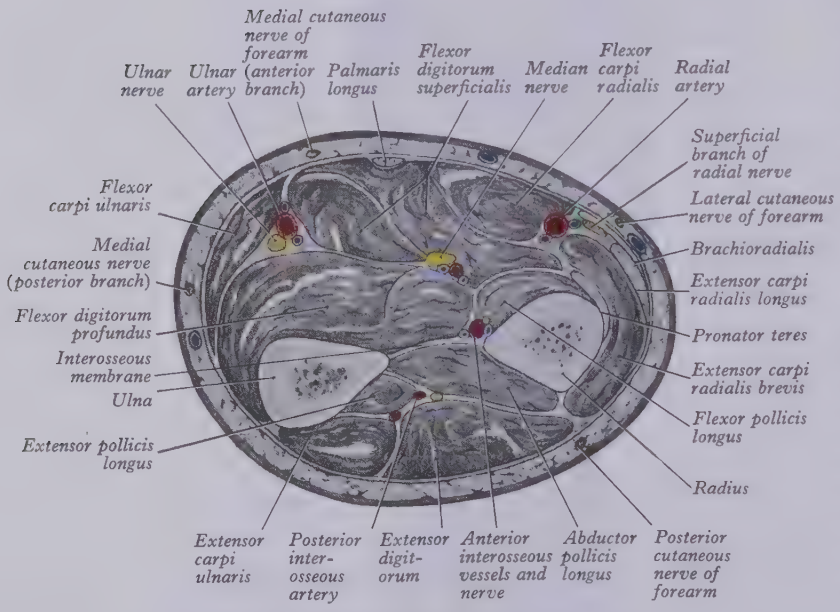


This is formed by anastomosis of the end of the radial with the deep palmar branch of the ulnar artery. It crosses the bases of the metacarpal bones and interossei, covered by the oblique head of adductor pollicis, the digital flexor tendons and lumbricals. In its concavity, running laterally, is the deep branch of the ulnar nerve. The arch was incomplete in six of 200 arches (Coleman & Anson 1961). Variation is chiefly in the size of contribution from the ulnar artery.

Surface Anatomy. The deep palmar arch is indicated by a horizontal line about 4 cm long from a point just distal to the hamate's hook (**6**.105). It is about 1 cm proximal to the superficial arch.



Branches of the deep palmar arch are the palmar metacarpal, perforating and recurrent.



6.99 Transverse section through the forearm at the level of the radial tuberosity.

6.100 The arteries of the right forearm and hand: deep dissection. The palmar 'carpal' arch lies across forearm bones.

6.101 Transverse section through the left wrist: superior aspect. The section is slightly oblique and divides the distal row of the carpus and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure represents the actual condition in the specimen. Observe that the carpometacarpal joint of the thumb is separate from the joint between the trapezium and the base of the second metacarpal bone.

6.102 Transverse section through the middle of the left forearm: proximal aspect.

The three palmar metacarpal arteries (**6.100**), run distally from the convexity of the arch on the interosseous muscles of the second to fourth spaces; at the digital clefts they join the *common digital branches* of the superficial arch. They supply nutrient branches to the medial four metacarpals.

Three perforating branches from the deep palmar arch traverse the second to fourth interosseous spaces between the heads of the corresponding dorsal interossei to anastomose with the dorsal metacarpal arteries.

Recurrent branches (**6.100**) ascend proximally from the deep palmar arch anterior to the carpus to supply the carpal bones and intercarpal articulations, ending in the palmar carpal arch (mentioned above).

The Ulnar Artery

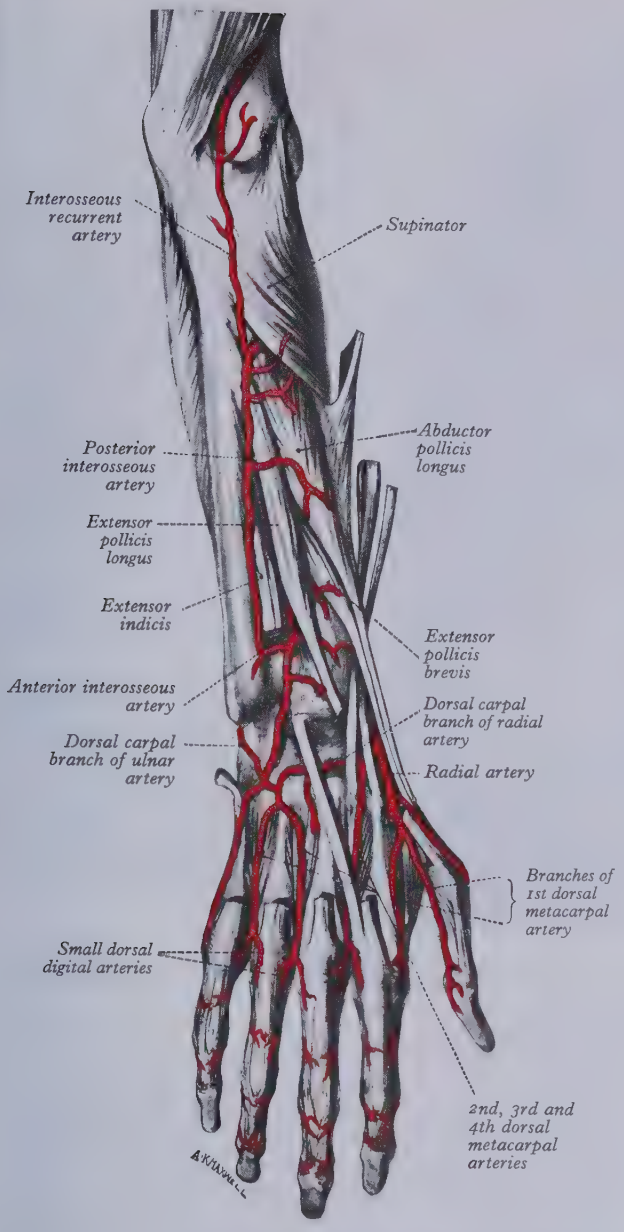
The ulnar artery (**6.98–104**), the larger terminal branch of the brachial, begins just distal to the bend of the elbow. It reaches the medial side of the forearm midway between elbow and wrist, which it passes vertically, crossing the flexor retinaculum lateral to the ulnar nerve and pisiform bone; distal to this it has a deep branch and then continues across the palm as the superficial palmar arch.

Relations. In the forearm the *proximal half* of the artery (**6.98,99,100,102**) passes posterior to the pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis; medially it is overlapped in its middle third by flexor carpi ulnaris; it lies in front of the brachialis and flexor digitorum profundus. Distal to the elbow the median nerve is medial for about 2.5 cm and then crosses it but is separated by the ulnar head of pronator teres. The artery's *distal half* (**6.98,100,104**) lies on the flexor digitorum profundus, covered by the skin, superficial and deep fasciae, between the flexor carpi ulnaris and flexor digitorum superficialis. It is accompanied by venae comitantes; the ulnar nerve lies medial to its distal two-thirds and its palmar cutaneous branch descends along it to the hand.

At the wrist (**6.100,101,104**) the artery is covered by skin, fasciae and palmaris brevis, and it lies between the superficial and main parts of the flexor retinaculum (p. 625); the ulnar nerve and pisiform bone are medial.

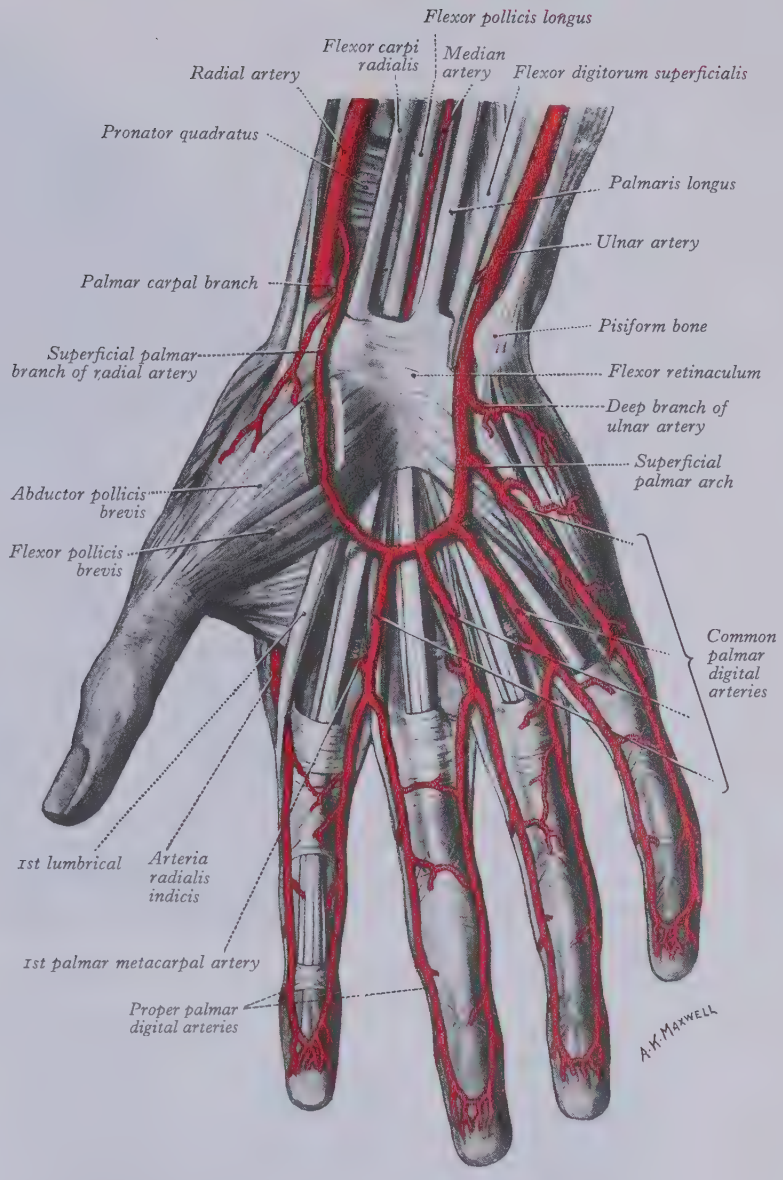
Surface Anatomy. A line from a point in the limb's midline just distal to the elbow's fold descends medially to meet a line stretching from the medial epicondyle to the pisiform bone, from the junction of its upper and middle thirds. Together these represent the artery's upper third and distal two-thirds respectively.

Variations. The ulnar artery may arise proximal to the elbow, the brachial being more often its source than the axillary artery; it is then usually superficial to the forearm flexors, commonly under the deep fascia, and is rarely subcutaneous; the brachial artery then supplies the common interosseous and this the ulnar recurrent arteries.



Branches. The artery supplies medial muscles in the forearm and hand, the common flexor synovial sheath and ulnar nerve (Blunt 1959), including the following named branches:

The anterior ulnar recurrent artery (**6.97,100**) arises just distal to the elbow, ascends between the brachialis and pronator teres, supplies them and anastomoses with the inferior ulnar collateral artery anterior to the medial epicondyle.



The posterior ulnar recurrent artery (**6.97,100**) is larger and arises distal to the anterior recurrent. It passes dorsomedially between the flexores digitorum profundus and superficialis and ascends behind the medial epicondyle; between this and the olecranon it is deep to the flexor carpi ulnaris, ascending between its heads with the ulnar nerve. Supplying adjacent muscles, nerve, bone and elbow joint, it anastomoses with the ulnar collateral and interosseous recurrent arteries (**6.97**).

The common interosseous artery (**6.100**), a short branch of the ulnar, just distal to the radial tuberosity, passes back to the proximal border of the interosseous membrane, dividing into the *anterior* and *posterior interosseous arteries*.

The anterior interosseous artery (**6.100,103**) descends on the anterior aspect of the interosseous membrane with the median nerve's anterior interosseous branch, overlapped by contiguous sides of flexor digitorum profundus and flexor pollicis longus; it has *muscular* branches and *nutrient* rami for the radius and ulna. On the membrane, branches leave to pierce it and supply deep *extensor* muscles. Proximal to pronator quadratus its continuation also traverses the membrane to the back of the forearm where it anastomoses with its own posterior interosseous branch, descending over the carpal dorsum to join the dorsal carpal arch. It is in the extensor retinacular compartment with the tendons of digital extensors. Before it pierces the interosseous membrane, a branch descends behind the pronator quadratus to the anterior 'carpal'

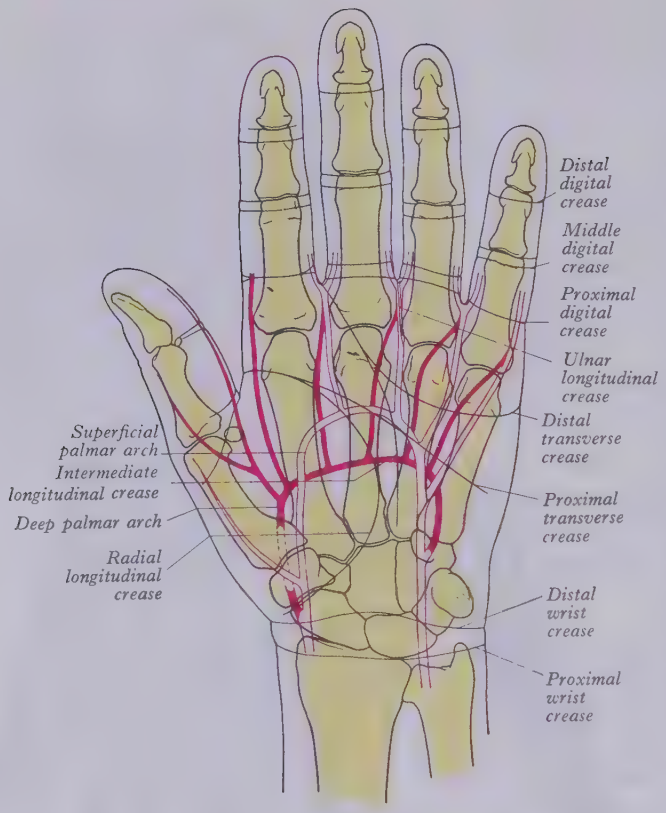
6.103 The arteries of the posterior surface of the right forearm and hand.

6.104 The superficial palmar arch and its branches. A part of the abductor pollicis brevis has been excised to expose the superficial palmar branch of the radial artery.

arch. (Strictly, as mentioned, the latter is *proximal* to the line of the wrist joint.) The slender *median artery*, from the start of the anterior interosseous, accompanies and supplies the median nerve; it often arises from the common interosseous, sometimes much enlarged, reaching the palm with the nerve (p. 218), where it may join the superficial palmar arch or end as one or two palmar digital arteries.

The posterior interosseous artery (**6**.100,103), usually smaller than the anterior, passes dorsally between the oblique cord and proximal border of the interosseous membrane and then between supinator and abductor pollicis longus, descending deep to the superficial extensors, which it supplies. On abductor pollicis longus it accompanies the deep branch of the radial nerve. Distally it anastomoses with the end of the anterior interosseous and dorsal carpal arch. Near its origin the *interosseous recurrent artery* leaves it to ascend between the lateral epicondyle and olecranon, either on or through the supinator but deep to anconeus, to anastomose with the middle collateral branch of the arteria profunda brachii, posterior ulnar recurrent and ulnar collateral arteries.

The muscular branches are direct rami of the main vessel, distributed to muscles in the ulnar region.



The palmar carpal branch (**6**.100), a small vessel, crosses the distal ulna behind the tendons of flexor digitorum profundus; it anastomoses with a palmar carpal branch of the radial to make a so-called palmar carpal arch (p. 761).

The dorsal carpal branch (**6**.103), arising just proximal to the pisiform bone, curves deep to the tendon of flexor carpi ulnaris to the carpal dorsum to pass laterally across it under the extensor tendons, anastomosing with the radial dorsal carpal branch to complete the dorsal carpal arch (p. 761). Near its origin it sends a small digital branch along the ulnar side of the fifth metacarpal to supply the medial side of the dorsal surface of the fifth finger.

The deep palmar branch (**6**.100,104), often double, passes between the abductor and flexor digiti minimi, through or deep to the opponens digiti minimi; it anastomoses with the radial, completing the deep palmar arch, accompanied by the deep branch of the ulnar nerve.

The Superficial Palmar Arch (**6**.104,105)

This anastomosis is fed mainly by the ulnar artery, entering the palm with the ulnar nerve, anterior to the flexor retinaculum and

6.105 The relation of the skin flexure lines and palmar arterial arches to the bones of the left hand (simplified).

lateral to the pisiform, passing medial to the hamate's hook, then curving laterally to form an arch, convex distally and level with a transverse line through the distal border of the fully extended pollicial base. About a third of the superficial palmar arches are formed by the ulnar alone; a further third are completed by the superficial palmar branch of the radial and a third either by the arteria radialis indicis, a branch of arteria princeps pollicis or by the median artery (Coleman & Anson 1961). It is covered by the palmaris brevis and palmar aponeurosis and it is superficial to the flexor digiti minimi, branches of the median nerve and to the long flexor tendons and lumbrical muscles.

Branches. **Three common palmar digital arteries** (**6**.104) from the convexity of the superficial palmar arch proceed distally on the second to fourth lumbricals, each joined by a corresponding palmar metacarpal artery from the deep palmar arch and dividing into two *proper palmar digital arteries*. These run along the contiguous sides of all four fingers, *dorsal* to the digital nerves, anastomosing in the subcutaneous tissue of the finger tips and near the interphalangeal joints. Each digital artery has *two dorsal branches* anastomosing with the *dorsal digital arteries* and supplying the soft parts dorsal to the middle and distal phalanges, including the matrices of the nails. The *palmar digital artery* for the medial side of *minimus* leaves the arch under the palmaris brevis. Palmar digital arteries supply metacarpophalangeal and interphalangeal joints and nutrient rami to the phalanges. They are the main digital supply, the dorsal digital arteries (p. 761) being minute.

Anastomoses between the radial and ulnar arteries occur: (1) at the wrist by the palmar and dorsal carpal arches; (2) in the hand through the superficial and deep palmar arches; (3) between their digital and metacarpal branches.

Applied Anatomy. In wounds of the palmar arches ligature of *one* forearm artery may be ineffective; simultaneous tying of both proximal to the carpus may also fail, because of interosseo-carpal anastomoses. If local pressure fails the brachial artery may be compressed (p. 758) as a temporary expedient.

THE ARTERIES OF THE TRUNK

The Thoracic Aorta

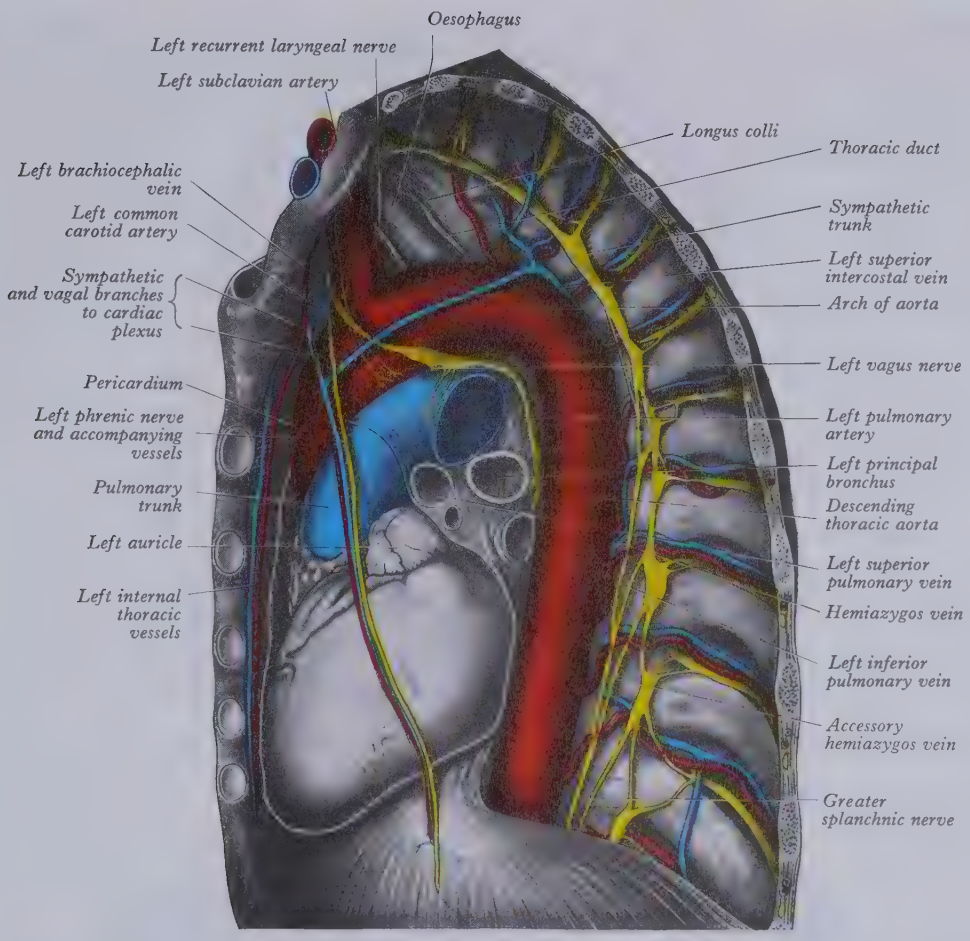
The thoracic aorta (**6**.106) is the segment of *descending aorta* confined to the posterior mediastinum. It begins level with the fourth thoracic vertebra's lower border, continuous with the aortic arch, ending anterior to the twelfth thoracic's lower border in the diaphragmatic aortic aperture. At its origin it is *left* of the vertebral column; as it descends it approaches the midline and at its termination is directly anterior to it.

Relations. Anterior, from above down, are the left pulmonary hilum, the pericardium separating it from the left atrium, oesophagus and diaphragm; *posterior* are the vertebral column and hemiazygos veins; *right lateral* are the azygos vein and thoracic duct and below, the right pleura and lung; *left lateral* are the pleura and lung. The oesophagus, with its plexus of nerves, is *right lateral* above but becomes *anterior* in the lower thorax; close to the diaphragm it is *left anterolateral*. Thus, to a limited degree, the descending aorta and oesophagus are mutually spiralized.

Surface Anatomy. The vessel is projected as a band 2.5 cm broad from the sternal end of the second left costal cartilage to a median position about 2 cm above the transpyloric plane (p. 1334).

Branches. The thoracic aorta provides *visceral branches* to the pericardium, lungs, bronchi, oesophagus and *parietal branches* to the thoracic wall.

Pericardial branches, a few small vessels, are distributed to the posterior pericardial aspect.



The bronchial arteries vary in number, size and origin. Usually one *right bronchial artery*, from the third posterior intercostal or upper left bronchial artery, runs posteriorly on the right bronchus and its branches, supplying them, the pulmonary areolar tissue and the bronchopulmonary lymph nodes, pericardium and oesophagus. The *left bronchial arteries*, usually two, arise from the thoracic aorta, the upper near the fifth thoracic vertebra, the lower below the left bronchus. They run posteriorly on the left bronchus and are distributed as on the right (p. 1248). Cauldwell et al (1948) found this arrangement in 40% of 150 cadavers; less frequent (at about 20% each) were two left and two right bronchial arteries or one on each side, all direct branches from the descending thoracic aorta, arising near the third and fourth intercostal arteries. In about 10%, *one* left and *two* right bronchial arteries existed. Complex variations consisted chiefly of more numerous aortic branches. Very rarely a bronchial artery arose from the aortic arch.

The oesophageal arteries, four or five, arise anteriorly from the aorta, descending obliquely to the oesophagus, forming a *vascular chain* on it which anastomoses above with the oesophageal branches of the inferior thyroid arteries and below with the ascending branches from the left phrenic and gastric. (Aortic oesophageal arteries are persistent supradiaphragmatic ventral splanchnic foregut arteries.)

The mediastinal branches are numerous small vessels supplying lymph nodes and areolar tissue in the posterior mediastinum. **Phrenic branches** arise from the lower thoracic aorta, distributed posteriorly to the superior diaphragmatic surface and anastomosing with the musculophrenic and pericardiacophrenic arteries.

The Posterior Intercostal Arteries

Usually nine pairs of posterior intercostal arteries are derived from the posterior aspect of the descending thoracic aorta. They are distributed to the lower nine intercostal spaces, the first and

6.106 The left aspect of the mediastinum. The left lung and pleura have been removed and an extensive opening has been made into the pericardial sac to expose the heart. Note the obliquity of the thoracic inlet, and forward inclination of the longus colli, upper oesophagus and thoracic duct.

second being supplied by the superior intercostal artery (p. 755). *Right posterior intercostal arteries* are longer, due to aortic deviation to the left; they cross the vertebral bodies behind the oesophagus, thoracic duct and azygos vein, right lung and pleura. *Left posterior intercostal arteries* turn backwards on the vertebral bodies in contact with the left lung and pleura, the upper two crossed by the left superior intercostal vein, the lower by the hemiazygos and accessory hemiazygos veins. Their further course is the same on both sides. Anterior to the heads of the ribs the sympathetic trunk descends in front of them and additionally the splanchnic nerves in front of the lower arteries.

Each artery crosses its intercostal space obliquely towards the angle of the rib above and continues forward in its costal groove (**6.**106). At first between the pleura and internal (posterior) intercostal membrane as far as the costal angle, it passes between the internal intercostal and intercostalis intimus muscles (p. 592), anastomosing with an anterior intercostal branch from an internal thoracic or musculophrenic artery. It has a vein above and a nerve below, except in the upper spaces where the nerve is at first above the artery. The third anastomoses with the superior intercostal artery and may largely supply the second space. The lower two arteries continue anteriorly into the abdominal wall to anastomose with the subcostal, superior epigastric and lumbar arteries. Each posterior intercostal artery has dorsal, collateral, muscular and cutaneous branches.

The dorsal branch runs dorsally between the necks of adjoining ribs, with a vertebral body and a superior costotransverse ligament lying medial and lateral, respectively. It has a *spinal branch* entering the vertebral canal by the intervertebral foramen to supply vertebrae, spinal cord (p. 948) and meninges; it anastomoses with the spinal arteries above and below and with its fellow. It then crosses a transverse process with the dorsal ramus of a thoracic spinal nerve to supply the dorsal muscles; a cutaneous twig accompanies the cutaneous branch of the spinal nerve's dorsal ramus.

A collateral intercostal branch leaves its posterior intercostal near the costal angle and descends to the upper border of the subjacent rib, along which it courses to anastomose with an anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches supply intercostal and pectoral muscles and the serratus anterior, anastomosing with the superior and lateral thoracic branches of the axillary artery. **Lateral cutaneous branches** accompany the same branches of the thoracic spinal nerves. **Mammary branches** from the vessels in the second to fourth spaces supply the pectoral muscles, skin and mammary tissue; they enlarge during lactation.

Un-named branches supply all other tissues constituting the thoracic wall, e.g. costal periosteum, bone and bone marrow of ribs, tissues of synovial and synarthrodial joints and parietal pleura.

The right bronchial artery may arise from the right third posterior intercostal artery (vide supra).

Applied Anatomy. A thoracic puncture needle should not be introduced posteriorly medial to the costal angles, as the intercostal artery (and vein) crosses its space medial to this. Laterally, however, it is in the upper part of its intercostal space; therefore puncture should be through the *lateral* chest wall in the *lower* half of a space.

The subcostal arteries, the last paired branches of the thoracic aorta, in series with the posterior intercostal arteries, are below the twelfth ribs. Each runs laterally anterior to the twelfth thoracic vertebral body and posterior to the splanchnic nerves, sympathetic trunk, pleura and diaphragm; the right is also posterior to the thoracic duct and azygos vein, the left to the accessory hemiazygos vein. Each then enters the abdomen posterior to the lateral arcuate ligament with the twelfth thoracic (subcostal) nerve at the lower border of the twelfth rib, anterior to quadratus

lumborum and posterior to the kidney. The right artery courses posterior to the ascending colon, the left to its descending part. Piercing the aponeurosis of the transversus abdominis each proceeds between this and the obliquus internus, anastomosing with the superior epigastric, lower posterior intercostal and lumbar arteries. Each has a dorsal branch, distributed like those of the posterior intercostal arteries.

A small *aberrant artery* sometimes leaves the thoracic aorta on its right near the right bronchial. It ascends to the right *behind* the trachea and oesophagus and may anastomose with the right superior intercostal. It is a vestige of the right dorsal aorta (p. 214); occasionally it is enlarged as the first part of a right subclavian (p. 750).

Variations. The aortic lumen is occasionally partly or completely obliterated, above (preductual or infantile type), opposite or just beyond (postductual or adult type) the entry of the ductus arteriosus. The condition, *coarctation of the aorta*, is congenital; the ductus arteriosus may remain patent, but rarely compensates, systemic blood pressure being usually much higher than pulmonary.

In the *preductual* type, the *coarctation's* length is variable and may involve the left subclavian and even the brachiocephalic artery, with little scope for the development of an effective collateral circulation to regions distal to the stenosis. Many cases are incompatible with survival for more than a few months and surgical problems are great. However, coarctation may be restricted to a short segment between the brachiocephalic and left subclavian arteries, pressures in the left arm being lower than in the right; a collateral circulation may develop through branches of the brachiocephalic.

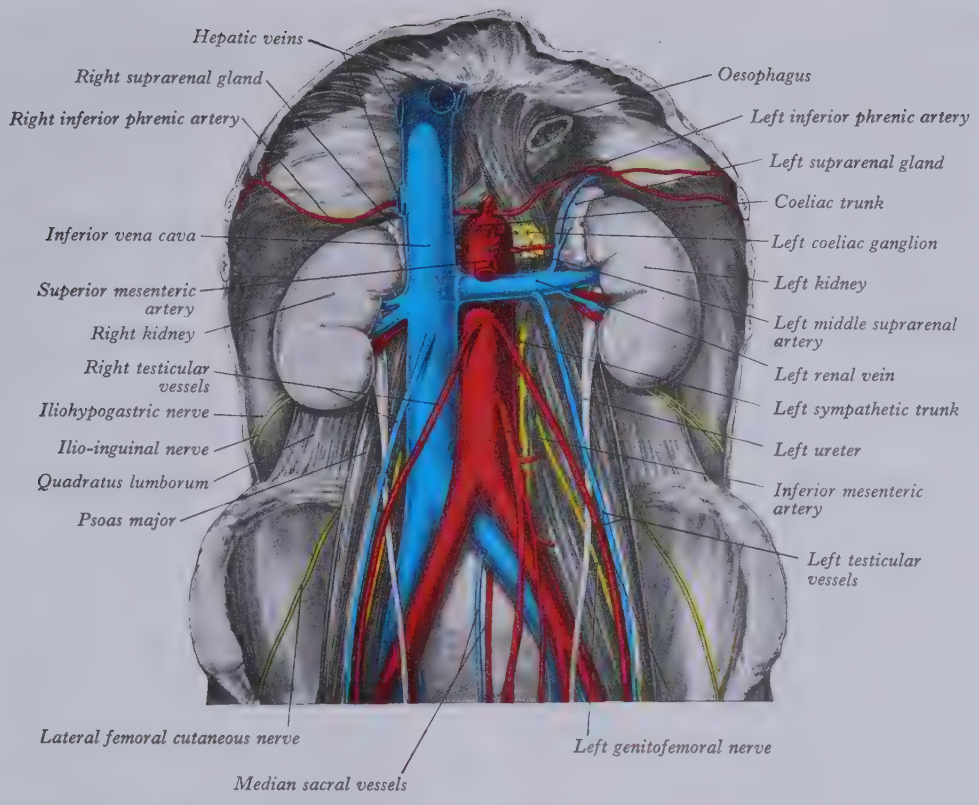
The *postductual* type of *coarctation* has been attributed to abnormal extension of the ductual tissue into the aortic wall, stenosing both vessels as the duct contracts after birth. This form can permit many years of normal life, allowing the development of an extensive collateral circulation to the aorta distal to the stenosis. High vascularity of the thoracic wall is important and clinically characteristic; many arteries arising indirectly from the aorta, *proximal* to the coarctation segment, anastomose with vessels connected with it *distal* to the block; these become greatly enlarged. In the anterior thoracic wall the thoracoacromial, lateral thoracic and subscapular arteries from the axillary, the suprascapular from the subclavian and the first and second posterior intercostal arteries from the costocervical trunk anastomose with other posterior intercostal arteries; the internal thoracic artery and its terminal branches anastomose with the lower posterior intercostal and inferior epigastric arteries. Posterior intercostal arteries are always involved, and enlargement of their dorsal branches may eventually groove ('notch') the inferior margins of the ribs. The X-ray shadow of the enlarged left subclavian artery is also increased. Enlargement of the scapular vessels and anastomoses may lead to widespread interscapular pulsation (easily appreciated with the palm of the hand, and sometimes heard on auscultation).

The Abdominal Aorta

The abdominal aorta (**6**.107A,B,119) begins at the median, aortic hiatus of the diaphragm, anterior to the twelfth thoracic vertebra's inferior border and the thoracolumbar intervertebral symphysis ('disc'), descending anterior to the vertebrae to end at the fourth lumbar, a little left of the midline, by dividing into two common iliac arteries. It diminishes rapidly in calibre, since its branches are large. Measurements of casts of the abdominal aorta in 100 individuals, from 16–70 years, showed a widening with age. In males superior and inferior ends measured 9.8–14.1 mm and 8.1–14.6 mm; in females luminal diameters were 9.7–15.7 mm and 9.1–14.6 mm (Aleksandrowicz et al 1974). These values conflict with radiological observation of 61 adults (17–41 years) by Leithner et al (1975), who recorded 26 mm and 19 mm (averages) for both ends of the abdominal aorta; they also gave a mean value of 37° for the angle of aortic bifurcation. Dimensions are of interest in attempts to estimate a suspected hydrodynamic ('haemodynamic') factor in the genesis of atherosclerosis (Newman et al 1971, Lallemand & Newman 1973). Theoretically, the pressure pulse wave in arteries is reflected at any junction, at certain values of combined arterial *luminal areas* of the branch or branches relative to that of the parent vessel; this is the *area ratio* of a junction. At an equal bifurcation, such as the aortic, with an area ratio of 1:15, reflexion of the pressure pulse wave is near to zero; the vessels are said to be 'matched'. Oscillations and possibly turbulence set up by 'mismatching' (at other ratios), perhaps also influenced by asymmetry of bifurcation, may cause intimal damage, predisposing to aortic atheroma. Luminal and other dimensions of the bifurcation may assume special significance, as may changes in these during life. Measurement of aortico-iliac junctions in humans, dogs and domestic fowls (free from vascular disease) has shown area ratios usually close to the theoretical value for 'matching' and independent of age in dog and fowl (Gosling et al 1971). However, the human aortic bifurcation appears to be 'matched' only in infancy; it is 1.11 ± 0.02 at birth, diminishing with advancing age to a value of about 0.7 in the fifth decade, at which theory predicts a 'mismatch' reflecting pulse pressure wave at about one-third of its amplitude. These studies give special interest to a study of the geometry of aortic bifurcation by Shah et al (1978), containing the most extensive data so far recorded, including diameters and angles of deviation, iliac lengths and curvatures and dorsal angulations of these vessels as they enter the pelvis. Unfortunately, diameters were external and only on a small series of cadavers at autopsy, and cannot be compared with those cited above. These interesting observations should be carried further with improved techniques and greater cohesion between different groups involved.

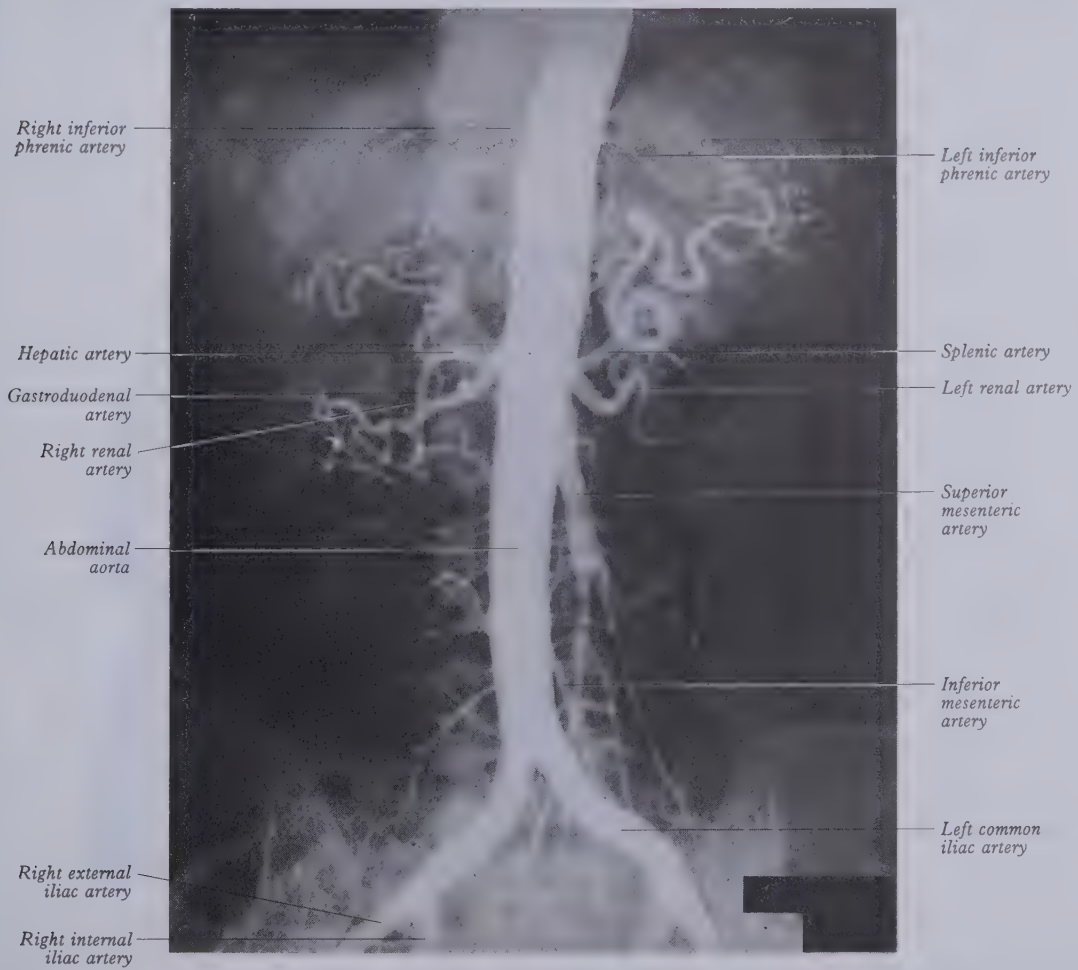
Relations. The abdominal aorta has at first *anterior* to it the coeliac trunk and its branches, with the coeliac plexus and the lesser sac (omental bursa) which intervenes between it and the hepatic papillary process and lesser omentum. Below this the superior mesenteric artery leaves the aorta, crossing anterior to the left renal vein. The body of the pancreas, with splenic vein applied posteriorly, extends obliquely up and left across the abdominal aorta, separated from it by the superior mesenteric artery and left renal vein. Below the pancreas, the proximal parts of its testicular (or ovarian) arteries, and the horizontal part of the duodenum are anterior. In its lowest part it is covered by the posterior parietal peritoneum and crossed by the oblique parietal attachment of the mesentery.

Posterior to the abdominal aorta are the thoracolumbar intervertebral 'disc' (symphysis), the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament. Lumbar arteries, arising from its dorsal aspect, and the third and fourth (sometimes second) left lumbar veins, crossing behind it to reach the inferior vena cava, separate it from the ligament. It may overlap the anterior border of the left psoas major.



On the right the aorta is related above to the cisterna chyli and thoracic duct, azygos vein and right crus of diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra it adjoins the inferior vena cava.

On the left it is related above to the left diaphragmatic crus and left coeliac ganglion. Level with the second lumbar vertebra are the duodenojejunal flexure and sympathetic trunk descending, at its left side, and the ascending duodenum and inferior mesenteric vessels.



Surface Anatomy. The vessel is indicated by a band about 2 cm wide from a median level 2.5 cm above the transpyloric plane to one about 1 cm below and left of the umbilicus. When the abdominal wall is relaxed the aorta may be felt pulsating just above its bifurcation and its pulsation may be visible.

Branches (**6**.107A,B) may be described as ventral, lateral, dorsal and terminal; ventral and lateral are distributed to the viscera, the dorsal branches supplying the body wall, vertebral column, canal and its contents:

Ventral:	Coeliac, superior and inferior mesenteric.
Dorsal:	Lumbar and median sacral.
Lateral:	Inferior phrenic, middle suprarenal, renal, ovarian or testicular.
Terminal:	Common iliac.

6.107A The abdominal aorta and its branches in the male.

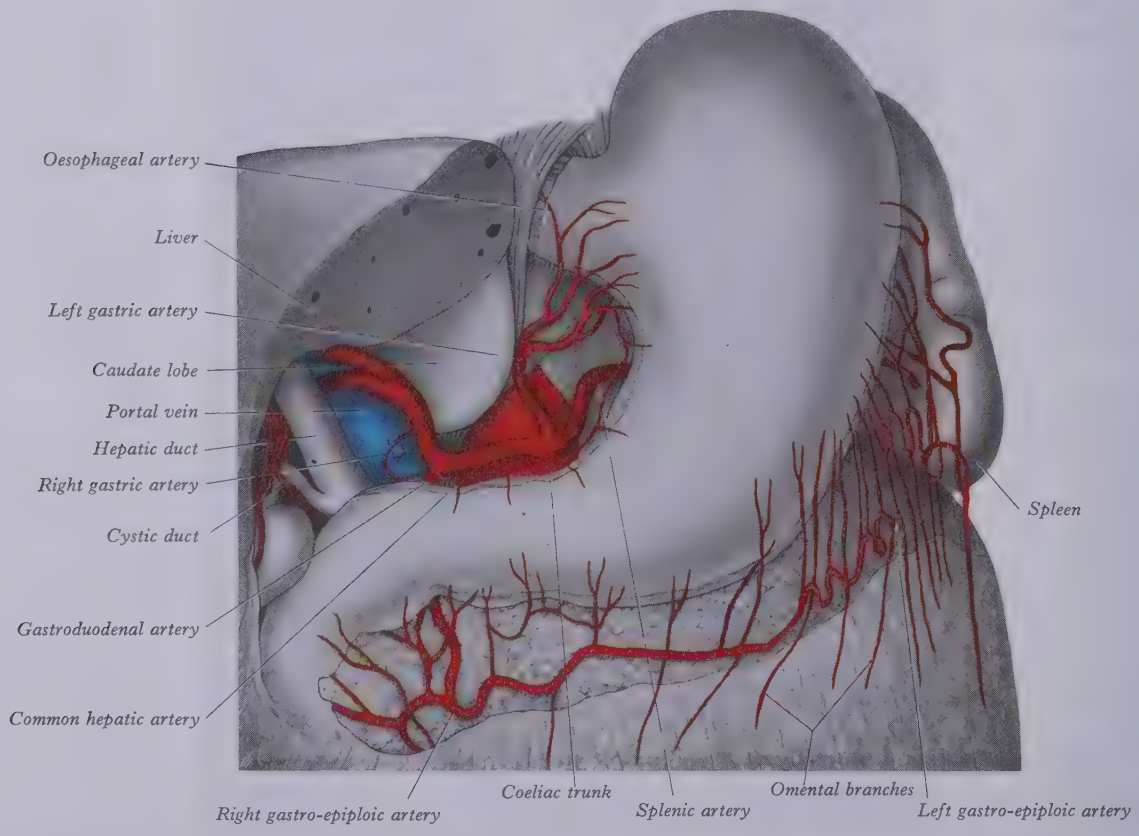
The Coeliac Trunk

The coeliac trunk (**6**.108,109,110), a wide ventral branch, about 1.25 cm long, just below the aortic hiatus, passes almost horizontally forwards and slightly right above the pancreas and splenic vein, dividing into: (1) *left gastric*, (2) *common hepatic* and (3) *splenic arteries*. It may also give off one or both inferior phrenic arteries. The superior mesenteric may arise with the coeliac trunk or the latter's usual branches may be direct independent branches of the aorta.

Relations. *Anterior* is the omental bursa (lesser sac); the coeliac plexus surrounds the trunk, sending extensions along its branches. *Right lateral* are the right coeliac ganglion, right crus and hepatic caudate process; *left lateral* are the left coeliac ganglion, left crus and cardiac end of the stomach. *Inferior* are the pancreas and splenic vein. The duodenum's suspensory muscle (p. 1357) may encircle the coeliac artery but is usually on its left.

1. The Left Gastric Artery (**6**.108)

This, the smallest coeliac branch, ascends to the left, posterior to the omental bursa, to the cardiac end of the stomach. It is near the left inferior phrenic artery and medial or anterior to the left suprarenal gland. Near the stomach two or three *oesophageal branches* ascend through the oesophageal opening to anastomose with the aortic oesophageal rami; others supply the cardiac part of the stomach and anastomose with the splenic branches. The artery then turns antero-inferiorly into the left gastropancreatic fold to run (often doubled) curving to the right near the gastric lesser curvature to the pylorus between layers of the lesser omentum; it supplies both gastric surfaces and anastomoses with the right gastric artery. An *accessory left gastric artery* may arise from the left branch of the hepatic, also reaching the lesser curvature through the lesser omentum.



2. The Hepatic Artery (**6**.108,109,110)

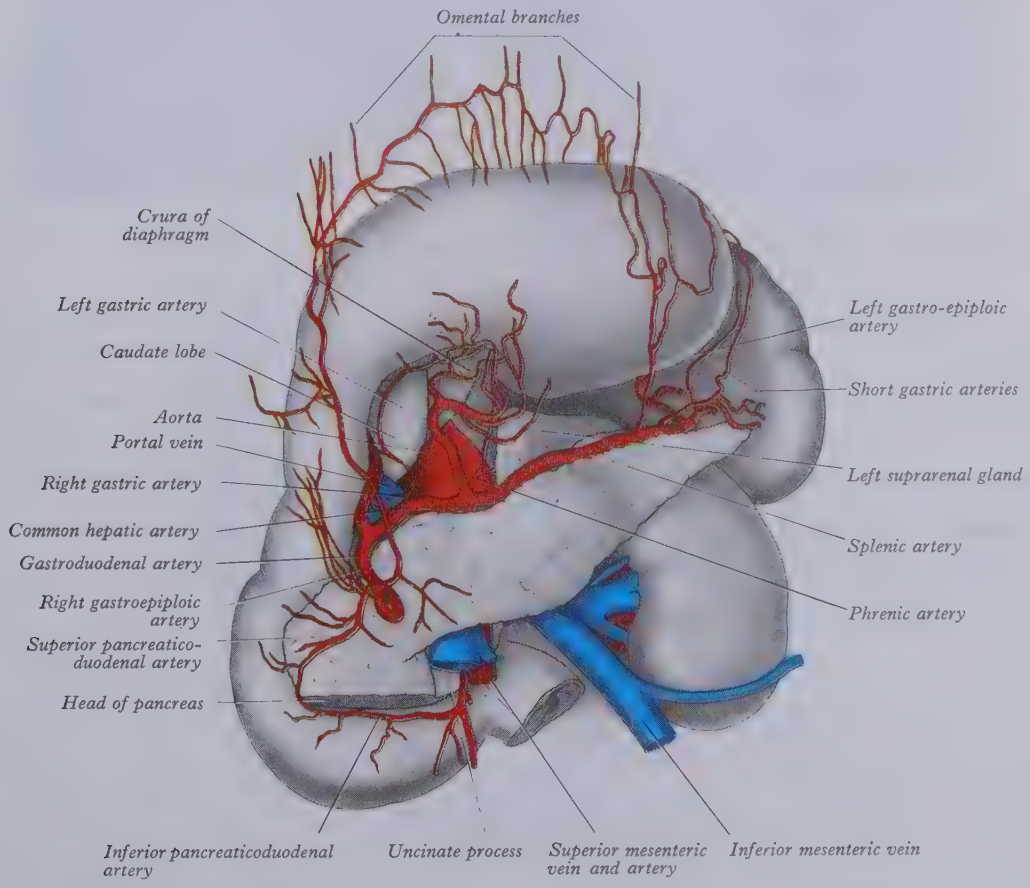
This is intermediate in size between the left gastric and splenic arteries; but in *later* fetal and early postnatal life it is the largest coeliac branch. Accompanied by the hepatic autonomic plexus it first passes forwards and right, below the epiploic foramen to the upper aspect of the superior part of the duodenum (**6**.108). Crossing the portal vein, it ascends between layers of the lesser omentum, anterior to the epiploic foramen, to the porta hepatis, where it divides into right and left branches to the hepatic lobes, accompanying the ramifications of the portal vein and hepatic ducts. In the lesser omentum it is anterior to the portal vein and left of the bile duct, its right branch crossing posterior (occasionally anterior) to the common hepatic duct (**6**.111). The artery may be subdivided into: (*a*) the *common hepatic artery*, from the coeliac trunk to the origin of the gastroduodenal artery and (*b*) the *hepatic artery proper*, from that point to its bifurcation.

In embryonic and *early* fetal life, the hepatic artery arises from the left gastric (in 67% of 56 individuals, Godlewski et al 1975). This condition rarely persists, but the hepatic may arise from the superior mesenteric, or the hepatic's right or left branches may be from other vessels; the former from the superior mesenteric, the latter from the left gastric. For other variations consult Quain (1865, 1899) and Woodburne (1962) (see also pp. 769, 1394). The hepatic artery has right gastric, gastroduodenal and cystic branches, rami to the bile duct from the right hepatic and sometimes the supraduodenal artery (vide infra).

The right gastric artery (**6**.108) arises above the duodenum's superior part, usually before, or sometimes beyond the gastroduodenal, descending in the lesser omentum to the pyloric end of the stomach; it passes left along the lesser gastric curvature, supplying the upper parts of the anterior and posterior gastric surfaces. It ends by anastomosing with the left gastric; the supraduodenal artery may be a branch (vide infra).

The gastroduodenal artery (**6**.108,109,110), arising behind, sometimes above, the superior part of duodenum, is short and wide. It descends between the duodenum and the neck of the pancreas, immediately to the right of the peritoneal reflexion from the posterior duodenal surface. It is usually left of the bile duct

6.108 The coeliac trunk and its branches. Part of the liver and all the lesser omentum have been removed, as well as the posterior wall of the omental bursa and part of the anterior layer of the greater omentum.



but sometimes anterior. At the lower border of the duodenum's superior part it divides into the *right gastro-epiploic* and *superior pancreaticoduodenal* arteries, after supplying small branches to the pyloric end of the stomach and to the pancreas, retroduodenal branches to the superior part of the duodenum, and sometimes providing the supraduodenal artery (vide infra). The first branch of the common hepatic artery is usually the gastroduodenal artery, but this may come from the superior mesenteric, coeliac trunk or an aberrant right hepatic artery (p. 770); its most invariable feature is its intermediate position between the *neck* of the pancreas and the duodenum, this being clinically important due to its frequent involvement in duodenal ulceration (Bradley 1973).

The *supraduodenal artery*, sometimes double, is variable; it may arise from the gastroduodenal, hepatic (common, proper or the latter's branches) or from the right gastric artery. It supplies the superior half circumference of the proximal half or more of the duodenum's superior part; but the duodenum is often invaded proximally by branches of the right gastric artery (p. 1358).

The right gastro-epiploic artery (6.108,109,111), the larger terminal branch of the gastroduodenal, skirts the right margin of the omental bursa and then turns left along the greater curvature, between the (anterior two) layers of the greater omentum. It ends in direct anastomosis with the left gastro-epiploic branch of the splenic. Except at the pylorus, where it adjoins the stomach, it is about 2 cm from the greater curvature. Of its many branches some ascend to both gastric surfaces, others descend into the greater omentum. It also supplies the inferior aspect of the duodenum's superior part.

The superior pancreaticoduodenal arteries are usually double: the *anterior* descends anteriorly between the duodenum and head of the pancreas. It supplies both and anastomoses with the anterior division of the inferior pancreaticoduodenal branch of the superior mesenteric. The *posterior superior pancreaticoduodenal artery*, which is usually a separate ramus of the gastroduodenal arising at the upper border of the superior part of the duodenum, descends to the right, anterior to the portal vein and bile duct and then posterior to the head of the pancreas, supplying branches to it and the duodenum; it crosses posterior to the bile duct, piercing the duodenal wall to end by anastomosing with the posterior division of the inferior pancreaticoduodenal artery. (Pancreaticoduodenal arteries form varying vascular arcades before their final distribution, see Michels 1962.) The artery supplies several branches to the lower part of the common bile duct (p. 1394).

The cystic artery (6.111), usually from the right branch of the hepatic proper, passes behind the common hepatic and over the cystic duct to the superior aspect of the gallbladder's neck, on which it descends to divide into *superficial* and *deep* branches. The former ramifies on the inferior, the latter on the superior aspect. The cystic artery may arise from the hepatic artery itself (rarely from the gastroduodenal), crossing anterior or posterior to the bile or common hepatic duct to reach the gallbladder. Variations in the artery's origin are of surgical interest. In 800 specimens Anson (1963) observed the following incidences: from the right hepatic 63.9%, the hepatic trunk 26.9%, left hepatic 5.5%, gastroduodenal 2.6%, superior pancreaticoduodenal 0.3%, right gastric 0.1%, coeliac trunk 0.3%, and superior mesenteric 0.8%. Direct origin from the hepatic artery varied from its beginning to its bifurcation. An *accessory cystic artery* may arise from the common hepatic or one of its branches. The cystic artery supplies the hepatic ducts and upper part of the common bile duct (p. 1394). A comparative study of its *distribution* in various reptilian, avian and mammalian species included 74 injected and cleared human gallbladders (Gordon 1967). Briefly, the human cystic artery reached the gallbladder at its neck; it was never in contact with the cystic duct. Coursing over the neck, one or two pairs of branches encircled it, anastomosing posteriorly. Division into two principal longitudinal branches occurred at any point along the neck; each then gave off four to eight pairs of lateral branches

6.109 The coeliac trunk and its branches exposed by turning the stomach upwards and removing the peritoneum on the posterior abdominal wall.

at right angles, anastomoses completing four to eight vascular circles. The principal vessels bifurcated to form a diamond-shaped anastomosis at the junction of the cystic body and fundus, the diamond being traversed centrally by a fine anastomotic net. The overall arterial pattern was described as *bipinnate* (bipennate).

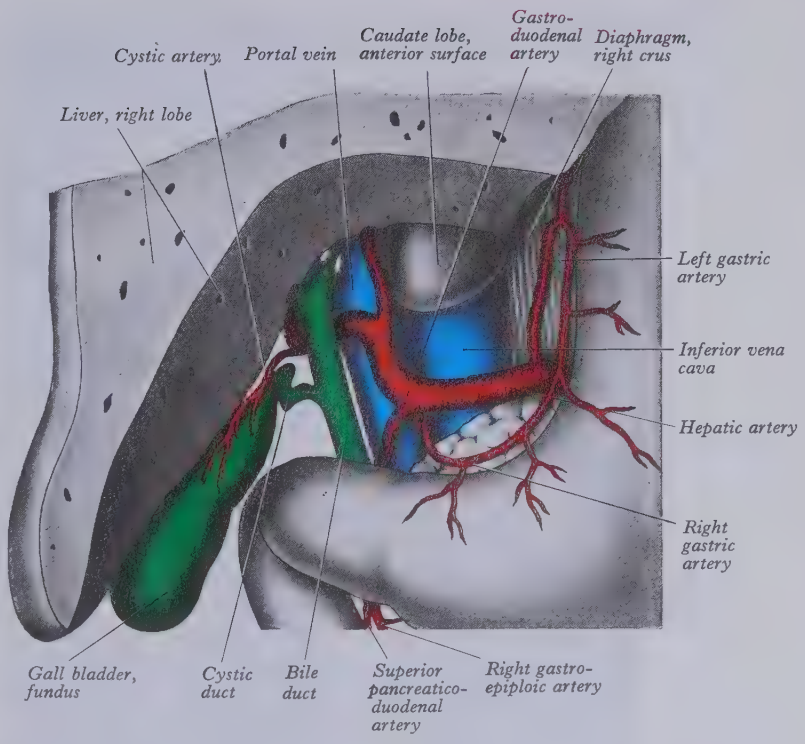
The **terminal, intrahepatic branches** display a pattern of branching relatively constant in its major details (p. 1386), which justifies a **segmental** description of the liver; it is the result, as in other organs, of growth and branching of an epithelial blastema, its pattern accompanied by vascular rami (and innervation). Arterial hepatic segmentation is described on p. 1387. Consult also Woodburne (1962).

3. The Splenic Artery (6.108,109,110)

The largest branch of the coeliac axis, the splenic is remarkably tortuous. Surrounded by a splenic nerve plexus and accompanied by the straight splenic vein, it ascends to the left, behind the stomach and omental bursa, along the superior border of the pancreas; it is anterior to the left suprarenal gland and upper part of the left kidney and enters the lienorenal ligament. Nearing the spleen it divides into five or more *segmental* branches which enter its hilum (p. 832).

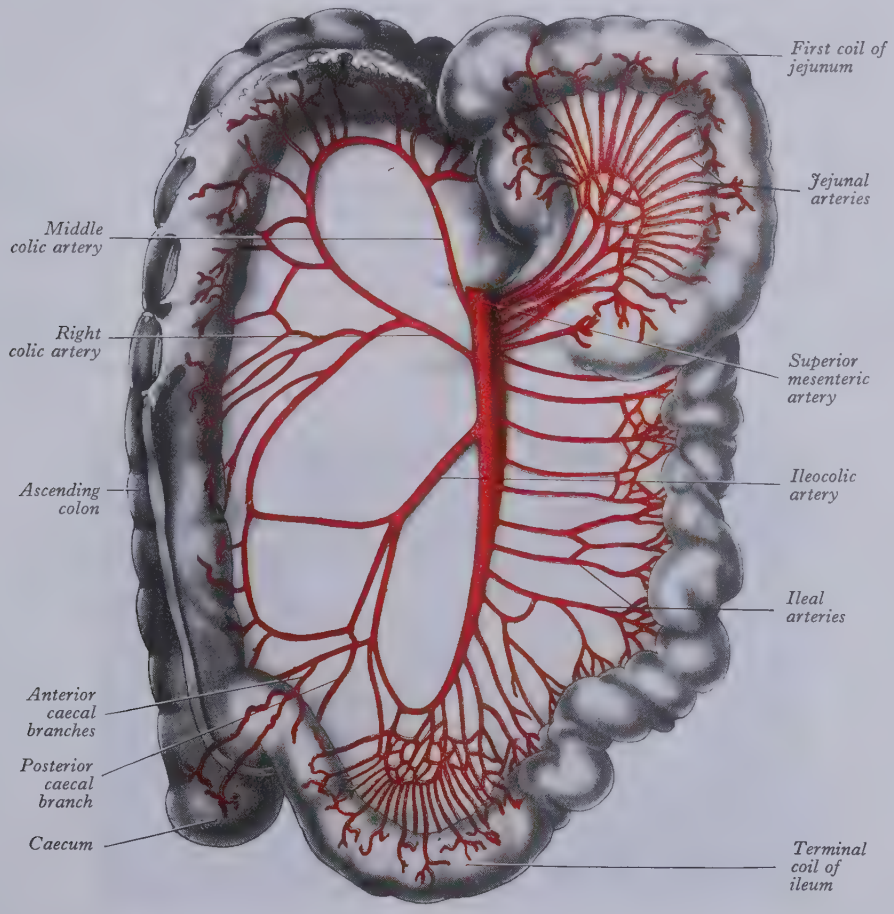
Branches of the splenic artery are as follows:

Pancreatic branches (**6**.109), numerous and small, supply the neck, body and tail of the pancreas, leaving the splenic artery as it runs along its superior border. A *dorsal branch* (sometimes from the superior mesenteric, middle colic, hepatic or, more rarely, coeliac artery) descends posterior to the pancreas, dividing into right and left rami. The former, usually double, runs between the neck and uncinate process to form a *prepancreatic arterial arch* with a branch from the anterior superior pancreaticoduodenal; the left ramus runs along the inferior border to the pancreatic tail; it anastomoses with branches (*arteria pancreatica magna* and *arteria caudae pancreatis*) from the splenic artery which supply the left part of the body and the tail.



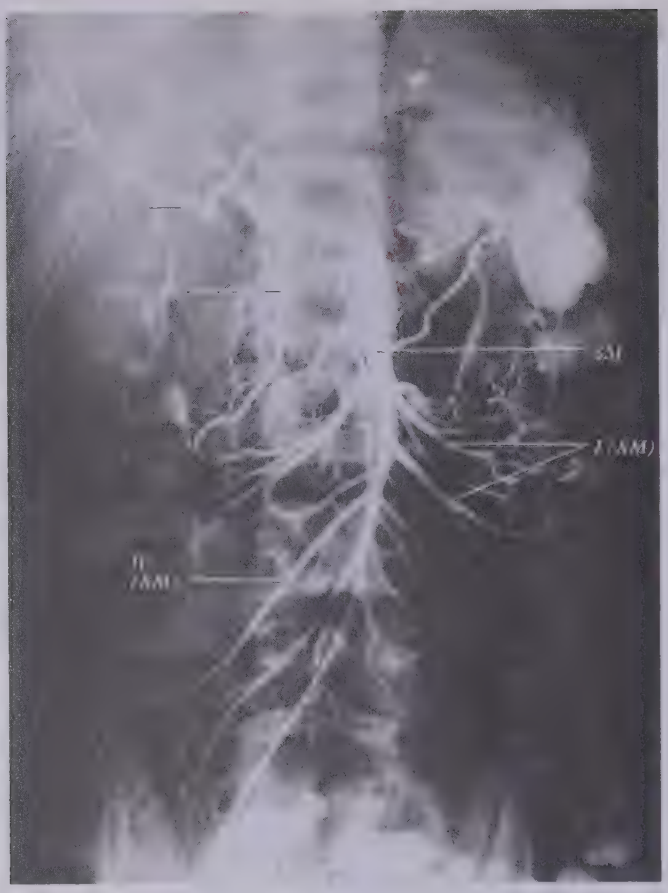
Short gastric arteries (**6**.109), five to seven, arise terminally from the splenic and its final divisions or from the left gastro-epiploic artery. They pass between layers of the gastrosplenic ligament to supply the gastric fundus, anastomosing with branches of the left gastric and gastro-epiploic arteries.

The posterior gastric artery, from any part of the splenic but most commonly its middle section, has been described by many authorities (e.g. Quain 1844) but many subsequent texts have omitted it. Susuki et al (1978), also surveying reports on it, found it present in 38 (62.3%) of 61 adult cadavers; incidences from 14 reports (1904–1968) varied from 12.7 to 77%, with an average of 58% in a total of 870 cadavers. They described the vessel as ascending behind the peritoneum of the omental bursa towards the gastric fundus to reach the posterior gastric wall in the gastrophrenic fold; it was usually about 2 mm in diameter.



The left gastro-epiploic artery (6.108,109,116), the splenic's largest branch, arises near the splenic hilum and runs anteroinferiorly and right, sending branches through the gastrosplenic ligament to supply the proximal third of the greater curvature; these are necessarily longer than the gastric branches of the right gastro-epiploic artery and may be 8–10 cm long. A large terminal omental branch descends to the right in the greater omentum. The main vessel curves forwards at a higher level to join the right gastro-epiploic. This loop leaves part of the greater curvature devoid of branches. At partial gastrectomy the greater omentum is divided below the right gastro-epiploic artery, cutting all omental branches; the greater omentum survives because its supply from this large omental branch of left gastro-epiloic usually escapes damage (Horton 1952). Vessels supplying the greater omentum are epiploic (omental) branches of the right and left gastro-epiploic arteries. The right, middle and left colic arteries do *not* supply the greater omentum; the transverse mesocolon, though usually adherent to the greater omentum, is separable from it (p. 1344).

Terminal splenic branches enter the organ's hilum in the lienorenal ligament. Their distribution is described with the spleen (p. 832).



Variations in arrangement of the hepatic artery and its branches are common and surgically important. They include: (1) the origin of the common hepatic from the superior mesenteric or, less often, from the aorta; it usually passes behind the portal vein to enter the lesser omentum; (2) an *accessory left hepatic artery* most often from the left gastric artery passing right in the lesser omentum to the porta hepatis; (3) an *accessory right hepatic artery* most often from the superior mesenteric, usually running behind the portal vein and bile duct in the lesser omentum to the porta hepatis. Accessory left or right hepatic arteries may also arise from the gastroduodenal or aorta. They may be combined with

6.111 The relations of the hepatic artery, bile duct and portal vein exposed by removal of the lesser omentum and the peritoneum on the posterior abdominal wall.

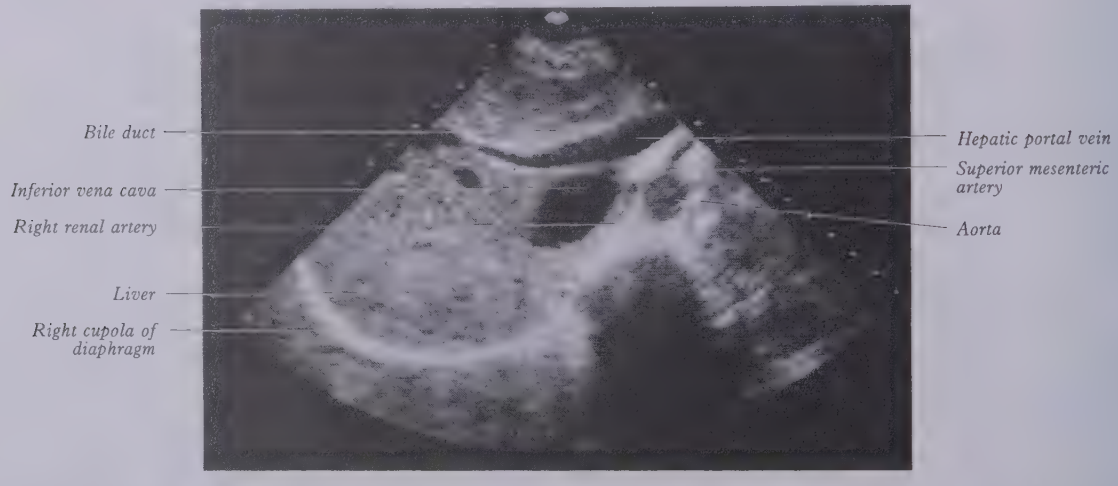
'normal' branches of the hepatic artery or *replace* them as the sole supply to parts of the liver, being called '*aberrant replacing arteries*'.



Collateral circulation after hepatic ligature or obstruction. Any blockage may lead to hepatic necrosis, the effects depending on the site of the block. Occlusion of the common hepatic artery, proximal to the origin of the right gastric, allows collateral circulation to the liver through the left and right gastric, left and right gastro-epiploic, pancreaticoduodenal and gastroduodenal arteries, and so necrosis is unlikely. If, however, an obstruction of the hepatic artery proper occurs beyond the origin of the gastroduodenal artery, any collateral circulation is limited to the small inferior phrenic arteries (p. 776).

The Superior Mesenteric Artery

This artery (**6**.112,113,114) supplies all the small intestine, except the superior part of the duodenum, the caecum, the ascending and most of the transverse colon. It leaves the front of the aorta about 1 cm below the coeliac trunk and is crossed anteriorly at its origin by the splenic vein and body of the pancreas; it is separated posteriorly from the aorta by the left renal vein. It next proceeds down and forwards, anterior to the pancreatic uncinate process and horizontal part of the duodenum, then descends obliquely in the mesentery near its root to the right iliac fossa. Here, much diminished, it joins its own ileocolic branch. As it descends it crosses anterior to the inferior vena cava, the right ureter and psoas major, forming an arch, its convexity forwards, down and to the left. Accompanied by the superior mesenteric vein on its right, it is surrounded by the superior mesenteric plexus of nerves. A fibrous strand may pass to the umbilicus from its terminal part or from a lower ileal branch, a vestige of the embryonic artery along the vitelline duct to the yolk sac.

The inferior pancreaticoduodenal artery (**6**.109) leaves the superior mesenteric, or its first jejunal branch, near the superior border of the horizontal part of the duodenum, usually dividing at once into anterior and posterior rami. The *anterior branch* passes to the right, anterior to the head of the pancreas, and ascends to anastomose with the anterior superior pancreaticoduodenal artery. The *posterior branch* ascends to the right, posterior to the head of the pancreas, which it sometimes traverses, and then anastomoses with the posterior superior pancreaticoduodenal artery. Both branches supply the pancreatic head, its uncinate process and the adjoining duodenum.

Jejunal and ileal branches (**6**.112,113) arise from the left side of the superior mesenteric; usually 12–15 are distributed to the jejunum and ileum, except in the latter's terminal part, which is supplied by the ileocolic artery. They run almost parallel in the mesentery, each dividing to unite with adjacent branches in a series of arches (**6**.112). Rami from these unite to form a second series and this may be repeated three or four times. In the short, upper part of the mesentery one set of arches exists but, as it increases in depth, a second, third, fourth and even fifth series appear. From terminal arches numerous *straight* vessels supply the intestine, distributed alternately to opposite aspects. It has been claimed, but not substantiated, that adjacent branches do not anastomose (Cokkinis 1930). Jejunal arteries are usually

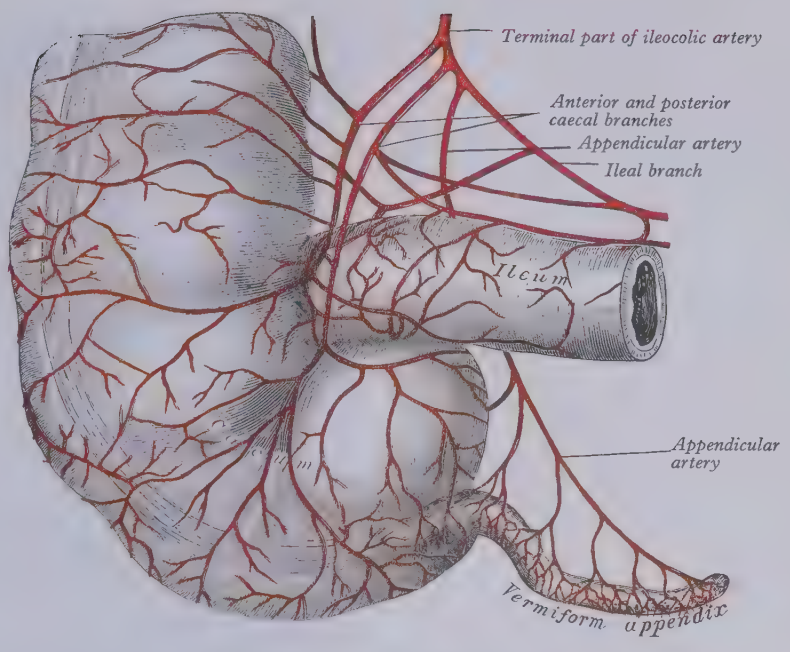
6.114 Ultrasonogram through the origin of the superior mesenteric artery. Provided by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith.

longer and less numerous. Small branches supply regional lymph nodes and other structures in the mesentery.

The ileocolic artery (**6**.112), the last branch from the *right* side of the superior mesenteric, descends to the right under the parietal peritoneum to the right iliac fossa, where it divides; its *superior branch* anastomoses with the right colic, the *inferior* with the end of the superior mesenteric. The ileocolic artery crosses anterior to the right ureter, testicular or ovarian vessels and psoas major. Its *inferior branch* approaches the superior border of the ileocolic junction and branches as follows (**6**.115): (1) *ascending (colic)* passing up on the ascending colon, (2) *anterior* and *posterior caecal*, (3) an *appendicular artery*, descending behind the terminal ileum to enter the mesoappendix; after giving off a recurrent branch anastomosing with one from the posterior caecal artery, it runs close to and then in the edge of the mesoappendix, its terminal part being in actual contact with the appendix; (4) an *ileal* branch ascending to the left on the lower ileum, supplying it and anastomosing with a terminal twig of the superior mesenteric artery.

The right colic artery (**6**.112) arises near the middle of the superior mesenteric, or in common with the ileocolic. It passes to the right behind the parietal peritoneum and anterior to the right ovarian or testicular artery and vein, right ureter and psoas major, towards the ascending colon. Sometimes it is higher and crosses the descending duodenum and right inferior renal pole. Near the colon it divides into a descending branch, which anastomoses with the ileocolic, and an ascending branch anastomosing with the middle colic. These form arches, from which vessels are distributed to the ascending colon, supplying its upper two-thirds and the right colic flexure.

The middle colic artery (**6**.112) leaves the superior mesenteric just inferior to the pancreas; descending in the transverse mesocolon it divides into a right and left branch; the former anastomoses with the right colic artery, the latter with the left, a branch of *inferior* mesenteric. Arches thus formed are 3 or 4 cm from the transverse colon, which they supply.



The superior mesenteric artery may be the source of the common hepatic, gastroduodenal, accessory right hepatic, accessory pancreatic or splenic arteries. It may arise from a common coeliaco-mesenteric trunk (Mangoushi 1975).

The Inferior Mesenteric Artery

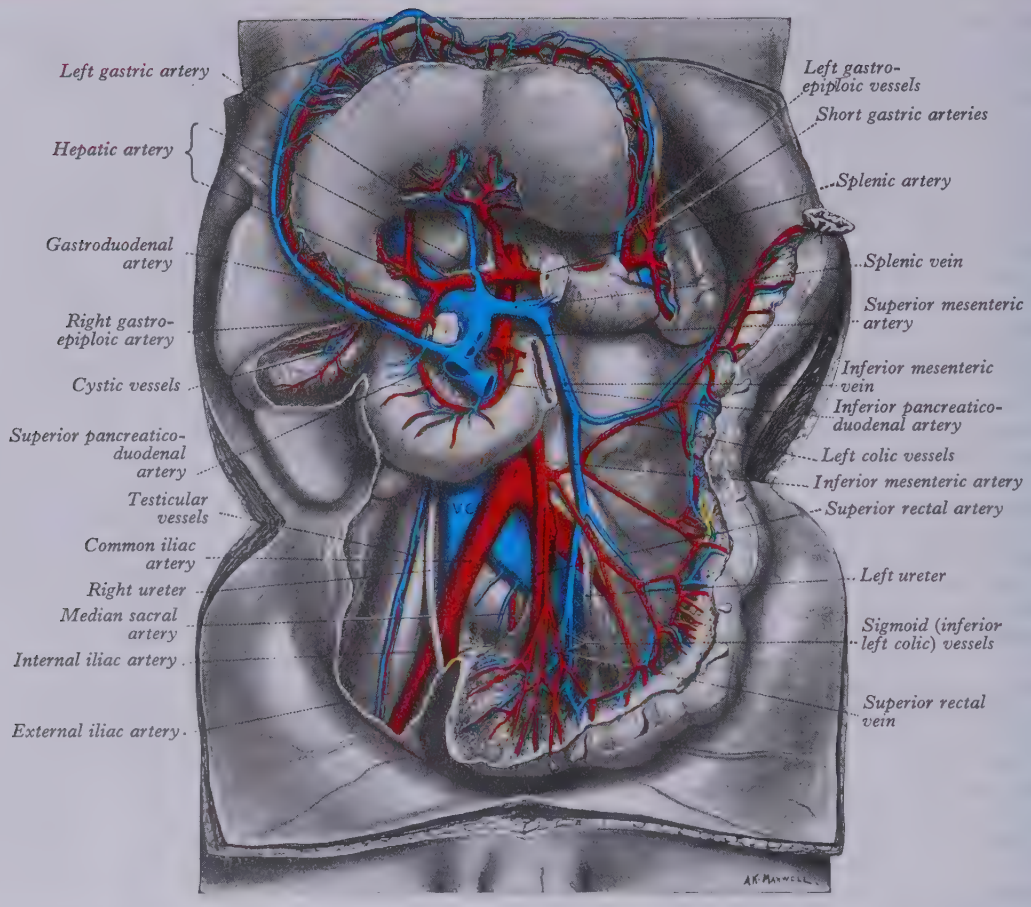
The inferior mesenteric artery (**6**.116,117,118) supplies the left third of the transverse colon, all the descending colon, sigmoid colon and most of the rectum. It is smaller than the superior mesenteric, arising 3 or 4 cm above the aortic bifurcation, posterior to the horizontal part of the duodenum. It descends behind the peritoneum, at first anterior to the aorta, then on its left, crosses the left common iliac artery medial to the left ureter and then enters and continues in the sigmoid mesocolon into the lesser pelvis as the *superior rectal artery*. Distally the inferior mesenteric vein is lateral. The artery has left colic, sigmoid and superior rectal branches.

The left colic artery (**6**.116–118) ascends subperitoneally to the left, anterior to the psoas major, and divides into ascending and descending branches. The trunk and its branches cross the left ureter and ovarian or testicular vessels. The ascending branch passes anterior to the left kidney into the transverse mesocolon, where it anastomoses with the middle colic artery; the descending branch anastomoses with the highest sigmoid artery. From arches thus formed, branches supply the left half of the transverse and the descending colon. Territories of supply by middle and left colic arteries show reciprocal variation; the left branch of the middle colic may take over the supply of the splenic flexure (in 19 of 100 cadavers, according to Sierocinski 1975).

The sigmoid (inferior left colic) arteries (**6**.116–118), two or three in number, descend obliquely to the left under the peritoneum anterior to the left psoas major, ureter and testicular or ovarian vessels. Branches supply the lower descending colon and sigmoid colon, anastomosing above with the the left colic artery, below with the superior rectal artery. Anastomoses between branches of the left colic and sigmoid arteries form a continuous 'marginal artery' near the colon (Drummond 1914). Continuity of this is *rarely* interrupted, even near the sigmoido-rectal junction, anastomosis at which is sometimes by rather tenuous vessels easily overlooked in dissection; high aortic injections, however, fill the superior rectal vessels; a series of 100 dissections by Sierocinski (1976) indicated *constant* anastomosis between the last sigmoid and superior rectal arteries. Sudeck (1907) introduced uncertainty in this anastomosis as a '*critical point*' in colico-rectal surgery; many authorities have repeated this erroneous view (see Hollinshead 1971 for a review).

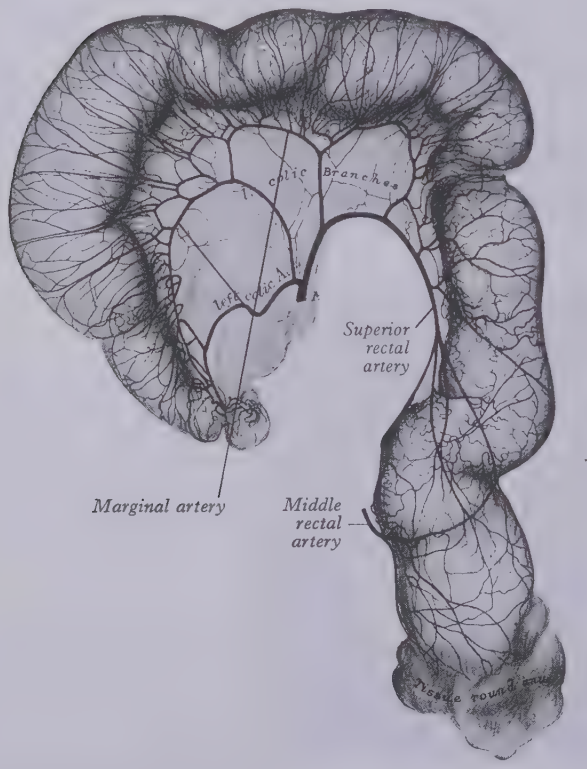
6.115 The arteries of the caecum and vermiform appendix.

The superior rectal artery (**6**.116–118), a continuation of the inferior mesenteric, descends into the pelvis in the sigmoid mesocolon, crossing the left common iliac vessels. It divides, near the third sacral vertebra, into two branches descending one on each side of the rectum; about halfway they divide into smaller branches, which pierce the muscular rectal wall to descend vertically, at submucous level, to the sphincter ani internus; here, by mutual anastomoses, they form loops around the lower rectum, communicating with the middle rectal artery, a branch of the internal iliac, and with the inferior rectal from the internal pudendal (p. 778).



Anterolateral Visceral Arteries

The Middle Suprarenal Arteries



These two small vessels arise laterally from each side of the aorta, level with the superior mesenteric, ascending slightly over the crura of the diaphragm to the suprarenal glands, where each anastomoses with the suprarenal branches of the phrenic and renal arteries. The right passes behind the inferior vena cava and near the right coeliac ganglion; the left is related to the left coeliac ganglion, splenic artery and superior border of the pancreas.

The Renal Arteries (**6**.107A,B,119)

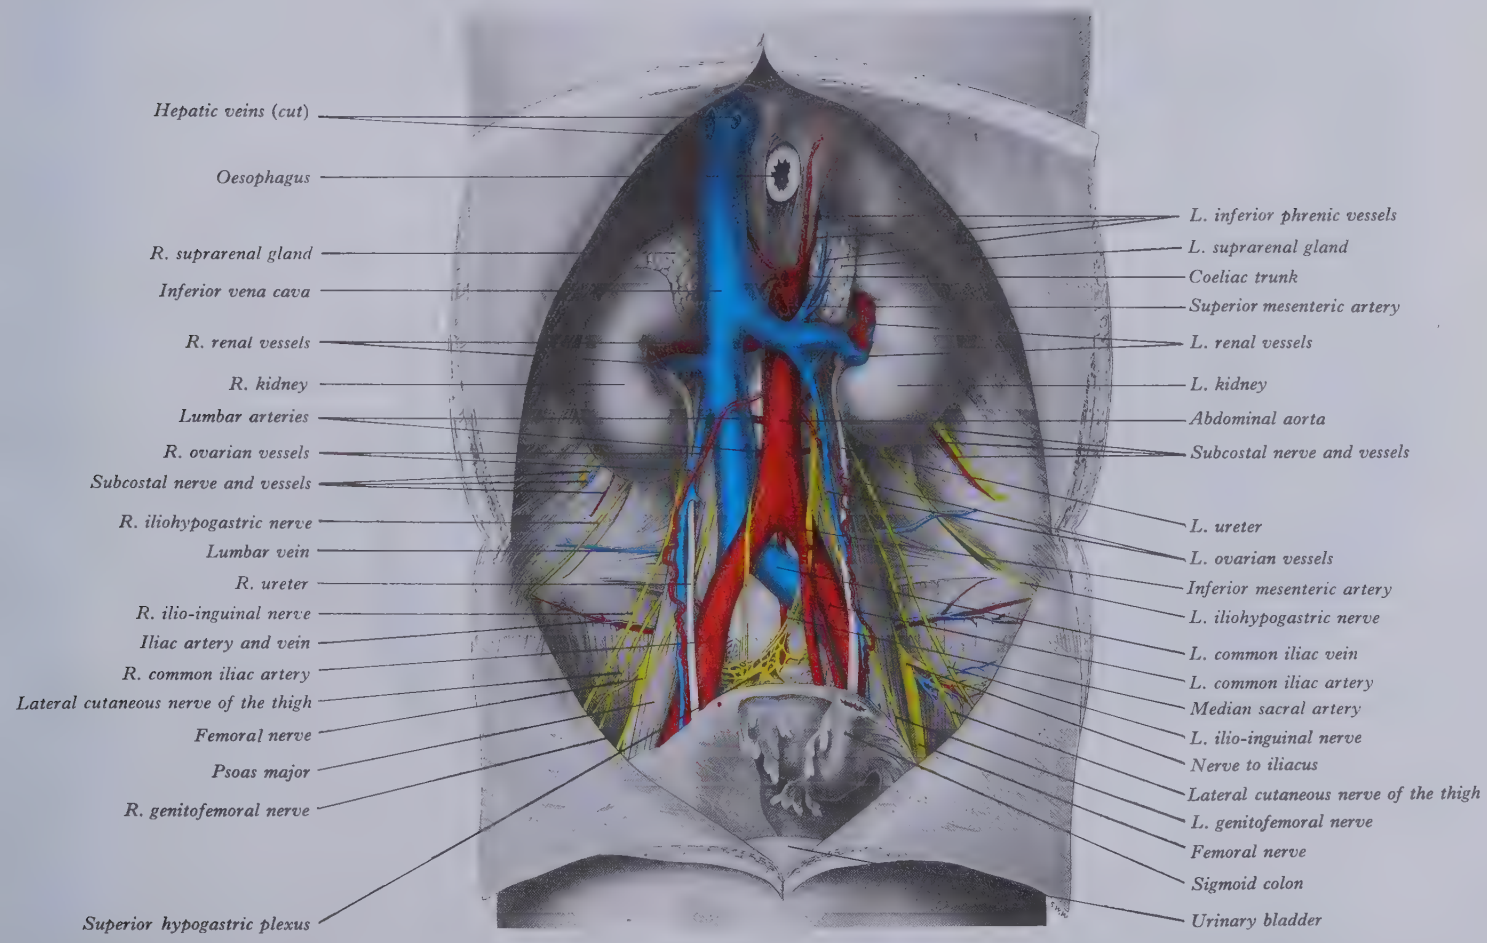
These two large vessels branch laterally from the aorta just below the inferior mesenteric; both cross the corresponding crus at right angles to the aorta. The *right* is longer and often, higher, passing posterior to the inferior vena cava, right renal vein, head of the pancreas and descending part of the duodenum. The *left* is a little lower; it passes behind the left renal vein, the body of the pancreas and splenic vein and may be crossed anteriorly by the inferior mesenteric vein. Nearing its renal hilum, each divides into four or five branches, most between the renal vein and

6.116 The inferior mesenteric vessels and their branches (male subject). Note the stomach has been turned upwards and the whole of the jejunum and ileum, the caecum, ascending colon and transverse colon have been removed, together with part of the pancreas.

6.117 The sigmoid colon and rectum, showing the distribution of the branches of the inferior mesenteric artery and their anastomoses. From a preparation by Hamilton Drummond.

ureteric pelvis, the vein being anterior, the pelvis posterior, but one or more usually behind the pelvis. Each renal artery supplies small *inferior suprarenal branches* (p. 251) and also the ureter, surrounding cellular tissue and muscles. The distribution of the renal arteries is described on p. 1407.

Surface Anatomy. The renal arteries can be projected as broad lines running laterally for 4 cm from the aorta (**6.110**) just inferior to the transpyloric plane; the left inclines across the plane.



One or two *accessory renal arteries* frequently occur, especially on the left, usually from the aorta above or below the main artery, the former slightly more often. They usually enter above or below the renal hilum; if below, the vessel crosses anterior to the ureter and, on the right, usually also anterior to the inferior vena cava.

The Testicular Arteries (6.107A,B,119)

These two long, slender vessels arise anteriorly from the aorta a little inferior to the renal arteries. Each passes inferolaterally under the parietal peritoneum on the psoas major; the right lies anterior to the inferior vena cava and posterior to the horizontal part of the duodenum, right colic and ileocolic arteries, root of the mesentery and terminal ileum; the left testicular artery lies posterior to the inferior mesenteric vein, left colic artery and lower part of the descending colon. Each crosses anterior to the genitofemoral nerve, ureter and the lower part of the external iliac artery, passing to the deep inguinal ring to enter the spermatic cord with other constituents, via which the vessel traverses the inguinal canal to the scrotum. At the posterosuperior aspect of the testis it divides into two branches on its medial and lateral surfaces, which pass through its tunica albuginea to ramify in the tunica vasculosa. Terminal branches enter the testis over its surface. Some pass into the mediastinum testis and loop back before reaching their distribution (Harrison & Barclay 1948). In the abdomen the testicular artery supplies perirenal fat, ureter and iliac lymph nodes; in the inguinal canal it supplies the cremaster.

6.118 Inferior mesenteric arteriogram. Provided by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith.

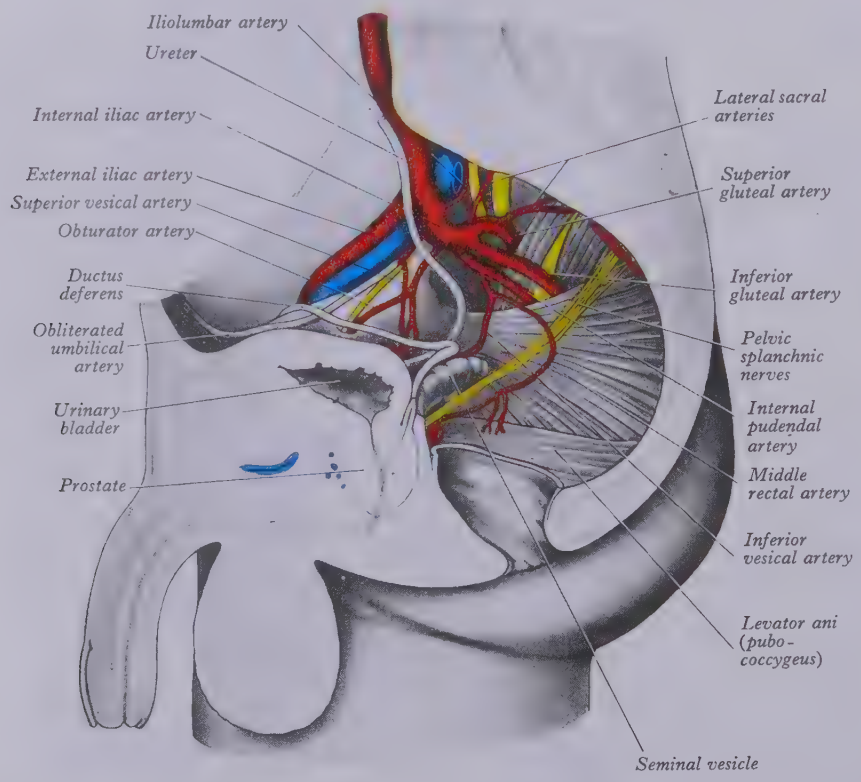
6.119 Dissection to show the relations of structures on the posterior abdominal wall (female subject).

Sometimes the right testicular artery passes *posterior* to the inferior vena cava. Both arteries represent persistent lateral splanchnic aortic branches (p. 218) which enter the mesonephros and cross ventral to the supracardinal but dorsal to the subcardinal vein. Normally the lateral splanchnic artery which persists as the *right* testicular passes *caudal* to the suprasubcardinal anastomosis forming part of the inferior vena cava (p. 218). When it passes *cranial* to this, the right testicular artery is behind the inferior vena cava.

The Ovarian Arteries

These correspond to the testicular arteries but enter the pelvis to supply the ovaries (6.122). Initially they resemble the testicular arteries but at the brim of the lesser pelvis each crosses the lower external iliac artery and vein to enter the true pelvic cavity, turning medially in the ovarian suspensory ligament to continue into the uterine broad ligament, below the uterine tube. At ovarian level it passes back in the mesovarium and divides into branches to the ovary. Small branches supply the ureter and uterine tube and one passes to the side of the uterus to unite with the uterine artery. Others accompany the round ligament through the inguinal canal to the skin of the labium majus and the inguinal region.

Early in intrauterine life, when testes or ovaries flank the vertebral column inferior to the kidneys, the testicular and ovarian arteries are relatively short; but with descent of the gonads into the pelvis and beyond, they gradually lengthen.



The (Inferior) Phrenic Arteries (6.107A,B, 119)

These two small vessels help to supply the diaphragm. They may arise separately from the aorta, just above its coeliac trunk, by a common aortic stem or from the coeliac trunk; sometimes one is from the aorta, the other from a renal artery. Each artery ascends laterally anterior to a crus of the diaphragm, near the medial border of the suprarenal gland. The left passes behind the oesophagus and forwards on the left side of its diaphragmatic opening. The right phrenic passes posterior to the inferior vena cava then along the right of its opening. Near the posterior border of the diaphragm's central tendon each divides into medial and lateral branches. The medial curves forwards to anastomose with its fellow in front of the central tendon and with the musculophrenic and pericardiacophrenic arteries; the lateral approaches the thoracic wall, anastomosing with the lower posterior intercostal and musculophrenic arteries. The lateral branch of the right artery supplies the inferior vena cava while the left sends ascending branches to the oesophagus. Each has two or three small *superior suprarenal branches*. The liver (p. 773) and spleen also receive small rami from the phrenic arteries.

The Lumbar Arteries (6.119)

These are in series with the posterior intercostal arteries. Usually four on each side, they arise posterolaterally from the aorta, opposite the lumbar vertebrae. A fifth, smaller pair occasionally arise from the median sacral artery but lumbar branches of the iliolumbar arteries usually take their place. The lumbar arteries run posterolaterally on the four upper lumbar vertebral bodies, behind the sympathetic trunks, to intervals between the lumbar transverse processes and continue into the abdominal wall. The right arteries pass posterior to the inferior vena cava; the upper two right and first left are also posterior to the corresponding crus. Arteries of both sides pass under tendinous arches (which span the lateral concavities of the vertebral bodies, p. 635) for attachment of psoas major, proceeding posterior to the muscle and the lumbar plexus. They then cross the quadratus lumborum, the upper three posterior, the last usually anterior to it. At its lateral border they pierce the posterior aponeurosis of the transversus abdominis, advancing between it and the internal oblique. They anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

Branches. Each lumbar artery has a *dorsal ramus* passing back between the adjacent transverse processes to supply the dorsal muscles, joints and skin; this also has a *spinal branch* entering the vertebral canal to supply its contents and adjacent vertebra, anastomosing with the arteries above and below it and across the midline. The spinal branch of the first lumbar supplies the terminal spinal cord itself; the remainder supply the cauda equina, meninges and vertebral canal. Branches of the lumbar arteries and their dorsal rami supply the adjacent muscles, fasciae, bones, red marrow, ligaments and joints (symphyses, syndesmoses and synovial joints).

6.120 The arteries of the male pelvis (right side). The internal iliac vein and its tributaries have been removed; the rectum has been divided just above the anal canal and its upper part has been taken away.

The Median Sacral Artery (**6**.107A,B,119)

This small posterior branch leaves the aorta a little above its bifurcation. It descends in the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx, ending in the coccygeal body. At fifth lumbar level it is crossed by the left common iliac vein and often gives off a small lumbar artery (*arteria lumbalis ima*), minute branches of which reach the rectum. Anterior to the last lumbar vertebra the median sacral anastomoses with a lumbar branch of the iliolumbar; anterior to the sacrum it anastomoses with the lateral sacral arteries and sends rami into the anterior sacral foramina.

The Common Iliac Arteries

The abdominal aorta bifurcates, anterolateral to the *left* side of the *fourth* lumbar vertebral body, into the right and left common iliac arteries (**6**.107A,B,119). These diverge as they descend to divide near the *level* of the lumbosacral intervertebral disc (between the last lumbar and first sacral vertebrae) into *external* and *internal iliac arteries*; the former supplies most of the lower limb, the latter the pelvic viscera and walls, perineum and gluteal region. The *division* of the common iliac is anterior to its *sacro-iliac joint*.

The Right Common Iliac Artery (**6**.107A,B,119)

This is about 5 cm long and passes obliquely across part of the fourth and the fifth lumbar vertebral body. *Anteriorly*, it is crossed by the sympathetic rami to the superior hypogastric plexus and, at its division, by the ureter; it is covered by the parietal peritoneum, which separates it from the coils of the small intestine. *Posteriorly*, it is separated from the fourth and fifth lumbar vertebral bodies and their intervening disc by the sympathetic trunk, the terminal parts of the common iliac veins and the commencement of the inferior vena cava; the obturator nerve, lumbosacral trunk and iliolumbar artery are also posterior, traversing fatty tissue between the fifth lumbar vertebra and the psoas major. *Lateral* to its upper part are the inferior vena cava and the right common iliac vein; lateral to its lower part is the right psoas major; *medial* to its upper part is the left common iliac vein.

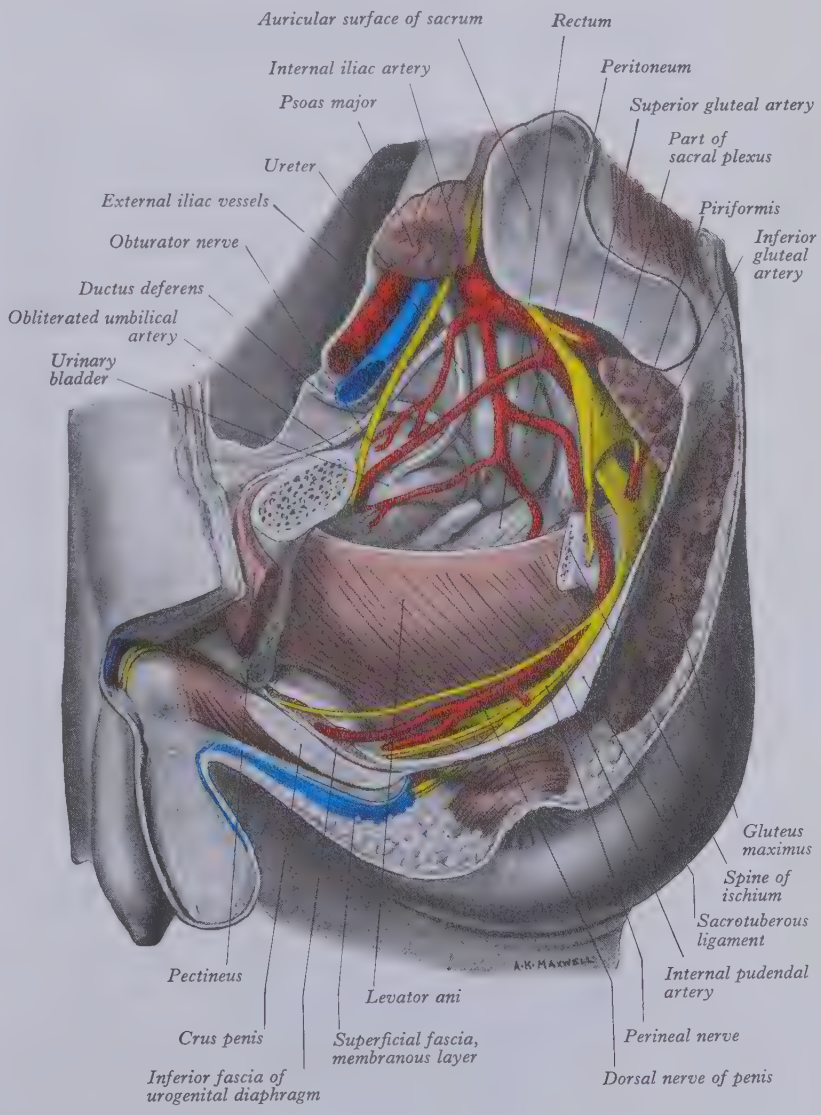
The Left Common Iliac Artery (**6**.107A,B,119)

The artery is about 4 cm long. *Anterior* are the peritoneum, ileum, the sympathetic rami to the superior hypogastric plexus, the superior rectal artery and, at its terminal bifurcation, the ureter. *Posterior* are the sympathetic trunk, fourth and fifth lumbar vertebral bodies and intervening disc; the obturator nerve, lumbosacral trunk and iliolumbar artery are more posterior (i.e. deeply situated). The left common iliac vein is partly *medial*, partly *posterior* to the artery; *lateral* and closely related is the left psoas major.

Surface Anatomy. The vessel corresponds to the superior third of a broad line from the aortic bifurcation (p. 766) to a point midway between the anterior superior iliac spine and the pubic symphysis. The *external iliac artery* corresponds to the inferior two-thirds of this line, which is laterally slightly convex.

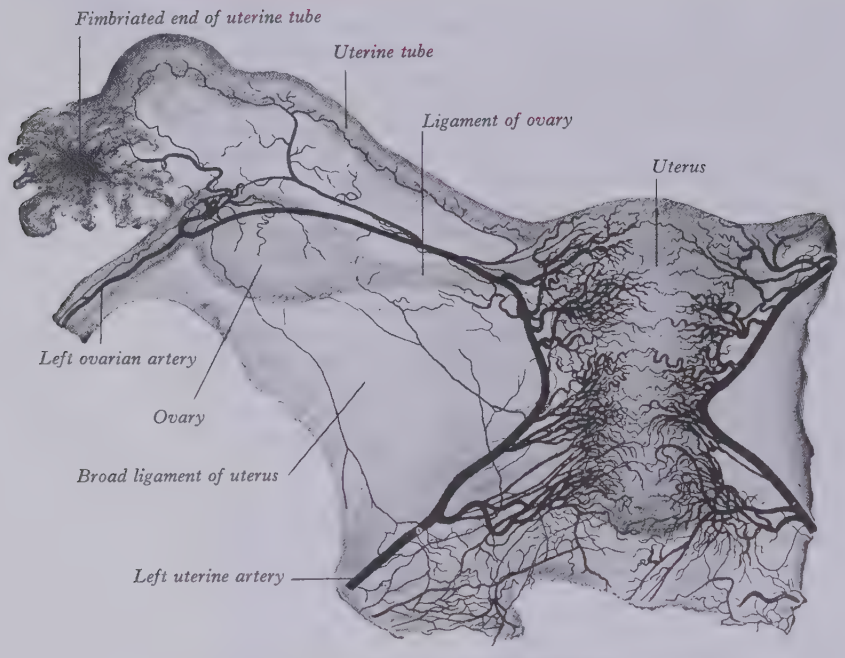
Branches. In addition to the terminal branches, each common iliac artery gives small rami to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue; occasionally it has the iliolumbar and accessory renal arteries as branches.

The Internal Iliac Arteries



Each internal iliac artery (**6**.120,121), about 4 cm long, begins at the common iliac bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacro-iliac joint; it descends posteriorly to the superior margin of the greater sciatic foramen, dividing here into: an *anterior trunk*, which continues in the same line towards the ischial spine; and a *posterior trunk*, passing back to the foramen (Braithwaite 1952).

Anterior are the ureter and, in females, the ovary and fimbriated end of the uterine tube; *posterior* are the internal iliac vein, lumbosacral trunk and sacro-iliac joint; *lateral* is the external iliac vein, between the artery and the psoas major and inferior to this the obturator nerve; *medial* is the parietal peritoneum, separating it from the terminal ileum on the right and the sigmoid colon on the left, and tributaries of the internal iliac vein.



In the fetus the internal iliac artery is twice the size of the external and is the direct continuation of the common iliac. It ascends on the anterior abdominal wall to the umbilicus, converging on its fellow. Having traversed the opening, the two arteries, now *umbilical*, enter the umbilical cord, coil round the umbilical vein and ultimately ramify in the placenta. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical, the remainder becoming a fibrous *medial umbilical ligament* raising the peritoneal *medial umbilical fold* from the pelvis to the umbilicus. In males, the patent part usually gives off an artery to the ductus deferens (vide infra).

BRANCHES FROM THE ANTERIOR TRUNK OF THE INTERNAL ILIAC ARTERY

The superior vesical artery (**6**.120,121) supplies many branches to the vesical fundus (Braithwaite 1951); from one the *artery to the ductus deferens* occasionally starts and accompanies

6.121 Structures of the male pelvic contents from the left side. Most of the left innominate bone has been removed together with the obturator internus. The sciatic nerve has been cut away close to its origin from the sacral plexus. All the vessels and nerves exposed are those of the *left* side. Note the superior vesical, obturator, inferior vesical and middle rectal arteries which are, for technical reasons, unlabelled (cf. **6**.120).

6.122 The left uterine and ovarian arteries of a nullipara of 17½ years: posterior aspect. From a preparation by Hamilton Drummond.

the ductus to the testis, anastomosing with the testicular artery. Others supply the ureter. The beginning of the superior vesical artery is the proximal, patent section of the fetal umbilical artery (vide supra).

The inferior vesical artery (**6**.120,121) often arises with the middle rectal, supplying the vesical fundus, prostate, seminal vesicles and lower ureter. Prostatic branches communicate across the midline. The inferior vesical may sometimes provide the artery to the ductus deferens.

The middle rectal artery (**6**.117,120) usually arises with the inferior vesical. It vascularizes muscular tissue in the lower rectum, anastomosing with the superior and inferior rectal arteries. It supplies the seminal vesicles and prostate by branches which join those of the inferior vesical.

The uterine artery (**6**. 122) runs medially on the levator ani to the cervix uteri; about 2 cm from this it crosses above the *ureter*, to which it supplies a small branch, and above the *lateral vaginal fornix*. It ascends tortuously lateral to the uterus in its broad ligament to the junction of the uterine tube and uterus, turning laterally towards the ovarian hilum, and ends by joining the ovarian artery. It supplies the cervix uteri and branches descend on the vagina, anastomosing with branches of the vaginal arteries to form two median longitudinal vessels, the *azygos arteries of the vagina*; one descends anterior, the other posterior to the vagina. The uterine artery supplies the body of the uterus, uterine tube and round ligament of the uterus. Terminal branches in the uterine muscle are tortuous *helicine arteries*.

The vaginal artery, often double or triple, corresponds to the inferior vesical in males; it descends on the vagina, supplying mucous membrane, and sends branches to the vestibular bulb, vesical fundus and the adjacent part of the rectum. It assists in forming the azygos arteries of the vagina (vide supra).

The obturator artery (**6**.120) inclines antero-inferiorly on the lateral pelvic wall to the upper part of the obturator foramen. Leaving the pelvic cavity by the obturator canal, it divides into anterior and posterior branches. In the pelvis it is related laterally to the obturator fascia, separating it from the obturator internus; it is crossed medially by the ureter and the ductus deferens, separating it from the parietal peritoneum. In the nullipara the ovary is medial. The obturator nerve is above, the vein below.

Branches. In the pelvis, the obturator artery provides: (1) *iliac branches* to the iliac fossa, supplying the bone and iliacus and anastomosing with the iliolumbar artery; (2) a *vesical branch* passing medially to the bladder, sometimes replacing the inferior vesical branch of the internal iliac; (3) a *pubic branch* just before it leaves the pelvis, which ascends over the pubis to anastomose with its fellow and the pubic branch of the inferior epigastric. Outside the pelvis its anterior and posterior terminal branches encircle the foramen between the obturator externus and the obturator membrane. The *anterior branch* curves forwards on the membrane and then down along its anterior margin, supplying branches to the obturator externus, pectineus, femoral adductors and gracilis and anastomosing with the posterior branch and the medial circumflex femoral artery. The *posterior branch* follows the foramen's posterior margin and turns forwards on the ischial ramus to anastomose with the anterior. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal. An *acetabular branch* enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a ramus along the ligament of the femoral head.

Variations. In 20–30% the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric (p. 781); this descends almost vertically to the obturator foramen. Such an *abnormal obturator artery* is usually near the external iliac vein, lateral to the femoral ring, and is then safe in herniotomy. Sometimes it curves along the edge of the lacunar part of the inguinal ligament, partly encircling the neck of a hernial sac, and may be inadvertently incised at operation. Rarely the artery crosses the femoral ring and may be pushed medially or laterally by a femoral hernia. According to Pick et al (1942), recording 640 dissections of obturator arteries, it is a branch of the internal iliac (24%) or its anterior (21%) or posterior (3%) divisions; incidence of epigastric origin was 27% (vide supra); apart from the superior gluteal (11%) and inferior gluteal artery (9%), abnormal origins include the external iliac, internal pudendal and iliolumbar arteries.

The Internal Pudendal Artery (**6**.120,121,123,124)

This, the smaller of two terminal branches of the anterior division of the internal iliac, supplies the external genitalia. Though similar in course, it is smaller in females and its distribution differs.

In the male the artery descends laterally to the inferior rim of the greater sciatic foramen, where it leaves the pelvis between piriformis and coccygeus and enters the *gluteal region*; then curving around the dorsum of the ischial spine to enter the *perineum* by the lesser sciatic foramen, it traverses the pudendal canal in the lateral wall of the *ischiorectal fossa*, medial to the obturator internus, about 4 cm above the ischial tuberosity's lower limit. Approaching the margin of the ischial ramus, it proceeds above or below the inferior fascia of the urogenital diaphragm along the medial margin of the inferior pubic ramus and ends behind the inferior pubic ligament, dividing into the *deep and dorsal arteries of the penis*. It may descend through the inferior fascia before its division. (The internal pudendal distal to its perineal branch has been named *artery of the penis*, appropriately in view of its distribution, vide infra.)

Relations. In the pelvis the internal pudendal artery crosses anterior to the piriformis, sacral plexus and inferior gluteal artery. Behind the ischial spine it is covered by the gluteus maximus, with the pudendal nerve medial and the nerve to obturator internus lateral. In the pudendal canal (p. 606) it travels at first with companion veins and the pudendal nerve; beyond this the dorsal nerve of the penis is above, the perineal nerve below.

Branches (**6**.123,124) **Muscular branches** leave the artery in the pelvis and gluteal region to supply the adjacent muscles and nerves.

The inferior rectal artery arises above the ischial tuberosity. Escaping from the pudendal canal (p. 606), it divides into two or three rami crossing the ischiorectal fossa medially to supply the anal skin and musculature. Small branches skirt the lower edge of the gluteus maximus to supply the gluteal skin. The inferior rectal anastomoses with its fellow, and with the superior, middle rectal and perineal arteries.

The perineal artery (**6**.123) leaves the internal pudendal near the anterior end of its canal, turns down through the inferior fascia of the urogenital diaphragm (p. 604) and approaches the scrotum in the superficial perineal region, between the bulbospongiosus and ischiocavernosus. Beyond the diaphragm, and near its base, a small *transverse branch* passes medially inferior to the superficial transverse perineal muscle to anastomose with its

fellow and the posterior scrotal and inferior rectal arteries, supplying tissues between the anus and the penile bulb. The *posterior scrotal arteries*, distributed to the scrotal skin and dartos muscle, are usually terminals of the perineal but may also arise from its transverse branch; they also supply the perineal muscles.

The artery of the bulb of the penis, short but wide, runs medially through the deep transverse perineal muscle and inferior urogenital fascia to the penile bulb. Penetrating this, it supplies the posterior part of the corpus spongiosum and the bulbo-urethral gland.

The urethral artery traverses the urogenital diaphragm's inferior fascia and enters the corpus spongiosum, reaching the glans penis. It supplies the urethra and erectile tissue around it.

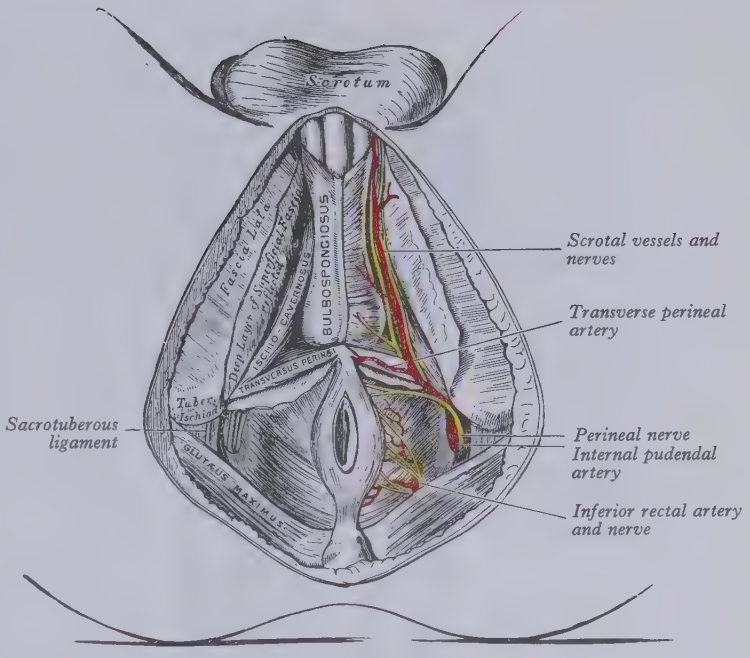
The deep artery of the penis, a terminal branch of the internal pudendal, passes through the inferior fascia of the urogenital diaphragm to enter the crus penis. It traverses the corpus cavernosum and supplies its erectile tissue.

The dorsal artery of the penis, the other terminal branch of the internal pudendal, leaves the inferior aspect of the urogenital diaphragm, *ascends* between the crus penis and pubic symphysis, and traverses the suspensory ligament of the penis to run along its dorsum to the glans, where it forks into branches to the glans and prepuce. In the penis it lies between its dorsal nerve and deep dorsal vein, the latter being most medial. It supplies penile skin and the fibrous sheath of the corpus cavernosum, anastomosing through the sheath with the deep penile artery.

In the female the internal pudendal is naturally smaller but its origin, course and branches are similar, including the *posterior labial branches*, the *artery of the bulb* (distributed to the erectile tissue of the vestibular bulb and vagina), *deep artery of the clitoris*, supplying the corpus cavernosum, and a *dorsal artery* to the glans and prepuce of the clitoris.

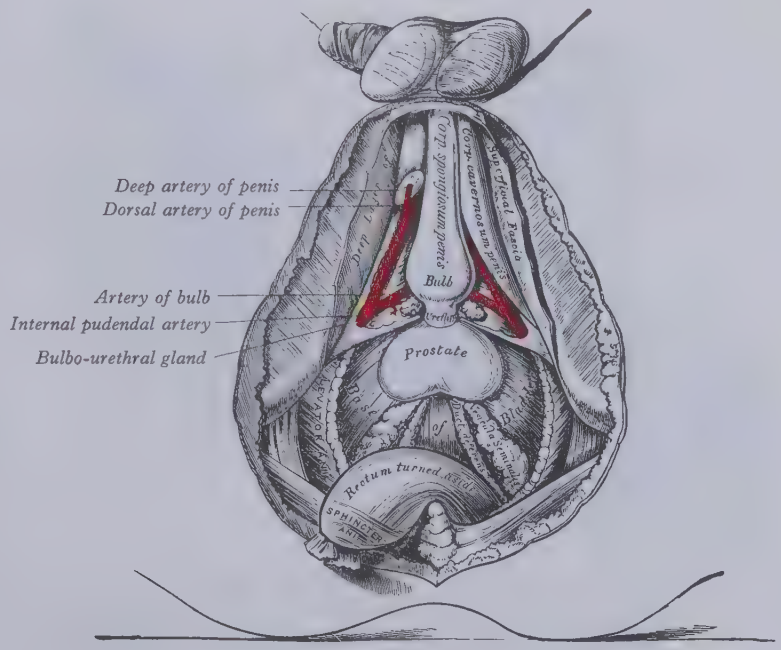
Variations. Branches of the internal pudendal are sometimes derived from an *accessory pudendal*, usually a branch of the pudendal before its exit from the pelvis.

The inferior gluteal artery (**6**.121,125), the larger terminal branch of the anterior internal iliac trunk, chiefly supplies the buttock and thigh. It descends anterior to the sacral plexus and piriformis, posterior to the internal pudendal artery. Passing between the first and second or second and third sacral anterior spinal nerve rami, then between the piriformis and coccygeus, it traverses the lower part of the greater sciatic foramen to reach the gluteal region. Descending between the greater trochanter and ischial tuberosity with the sciatic and posterior femoral cutaneous nerves, deep to the gluteus maximus, it continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries are often a common stem from the internal iliac, sometimes including the superior gluteal artery.



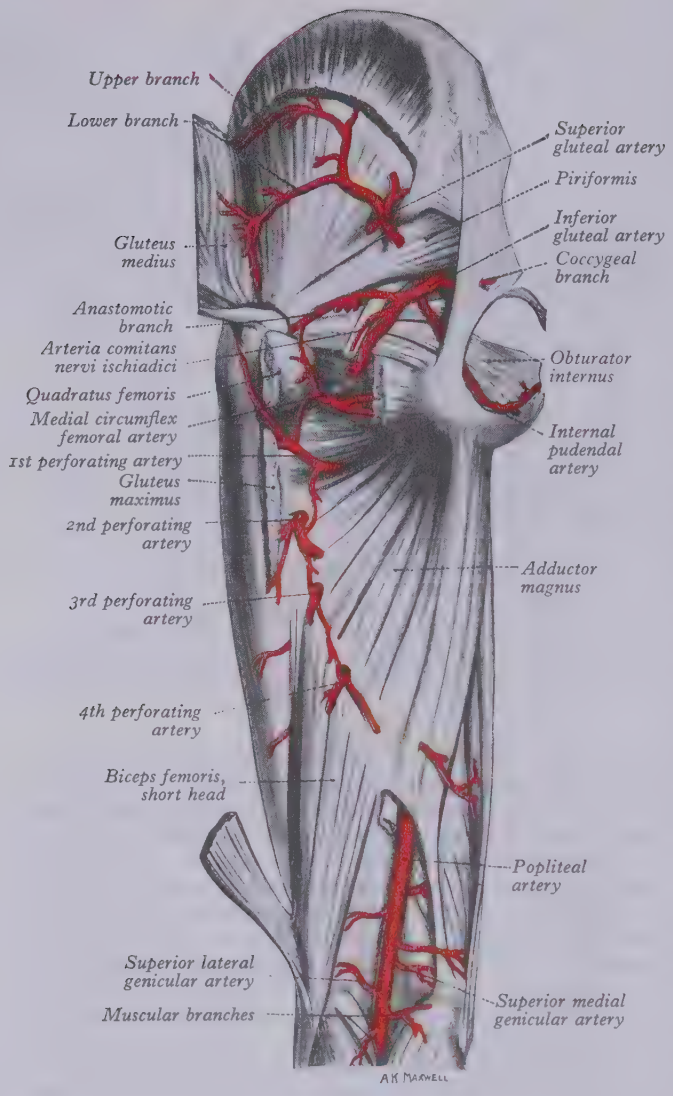
Surface Anatomy. The inferior gluteal artery leaves the pelvis near the midpoint of a line joining the posterior superior iliac spine and the ischial tuberosity.

Branches are: (*inside the pelvis*) (1) to the piriformis, coccygeus and levator ani; (2) to the perirectal fat, occasionally replacing the middle rectal artery; (3) to the vesical fundus, seminal vesicles and prostate; (*outside the pelvis*) *muscular branches* supply the gluteus maximus, obturator internus, gemelli, quadratus femoris and the proximal parts of the hamstring muscles, anastomosing with the superior gluteal, internal pudendal, obturator and medial circumflex femoral arteries. *Coccygeal branches* run medially through the sacrotuberous ligament to supply the gluteus maximus and the structures attached to the coccyx. The *artery to the sciatic nerve* runs on the nerve for a short distance, then descends in it to the lower thigh. An *anastomotic branch* descends obliquely across obturator internus, gemelli and quadratus femoris, to join the *cruciate anastomosis* (p. 783) linking with the first perforating and medial and lateral circumflex femoral arteries. An *articular branch*, usually from the anastomotic, is distributed to the hip joint. *Cutaneous branches* supply the buttock and back of the thigh.

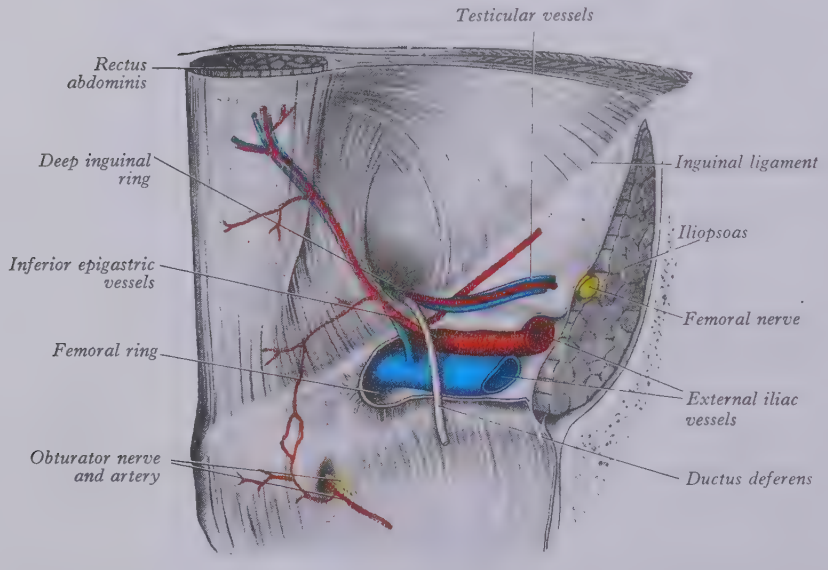


BRANCHES FROM THE POSTERIOR TRUNK OF THE INTERNAL ILIAC ARTERY

The iliolumbar artery (**6**.120) ascends laterally *anterior* to the sacro-iliac joint and lumbosacral trunk, *posterior* to the obturator nerve and external iliac vessels, to reach the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The *lumbar branch* supplies the psoas major and quadratus lumborum, anastomoses with the fourth lumbar artery and sends a small *spinal branch* through the intervertebral foramen between the fifth lumbar and first sacral vertebrae, which supplies the cauda equina. The *iliac branch* supplies the iliacus; between the muscle and bone it anastomoses with the iliac branches of the obturator. A large nutrient branch enters an oblique canal in the ilium; others skirt the iliac crest, supplying the gluteal and abdominal muscles and anastomosing with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.



The lateral sacral arteries (**6**.120) are from the posterior trunk of the internal iliac, usually as a superior and an inferior branch. The *superior* and larger passes medially into the first or second anterior sacral foramen, supplies the sacral vertebrae and



6.123 The superficial branches of the internal pudendal artery, in the male.

6.124 The deeper branches of the internal pudendal artery, in the male.

6.125 The arteries of the left gluteal and posterior femoral regions.

6.126 Dissection of the deep aspect of the lower part of the abdominal wall of the right side with the thinner posterior wall of the rectus sheath. The femoral and deep inguinal rings are displayed together with the vessels and other structures in relation to them and also the opening into the obturator canal.

contents of the sacral canal and escapes via the corresponding dorsal foramen to supply the skin and muscles dorsal to the sacrum. The *inferior lateral sacral artery* crosses obliquely anterior to the piriformis and the sacral anterior spinal rami, then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina, distributed like those of the superior artery.

The superior gluteal artery (**6.**120,125), the largest branch of the internal iliac and the continuation of its posterior trunk, runs back between the lumbosacral spinal trunk and the first sacral ramus or between the first and second rami, leaving the pelvis by the greater sciatic foramen above the piriformis and dividing into *superficial* and *deep branches*. In the pelvis it supplies the piriformis, obturator internus and an innominate nutrient artery. The *superficial branch* enters the deep surface of the gluteus maximus; its numerous rami supply the muscle and anastomose with the inferior gluteal, others perforating its tendinous medial attachment to supply the skin over the sacrum, anastomosing with the posterior branches of the lateral sacral arteries. The *deep branch* is between the gluteus medius and the bone, soon dividing into superior and inferior rami. The *superior* skirts the superior border of the gluteus minimus to the anterior superior iliac spine, anastomosing with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral. The *inferior ramus* traverses the gluteus minimus obliquely and supplies it and also the gluteus medius, anastomosing with the lateral circumflex femoral; a branch enters the trochanteric fossa to join the inferior gluteal and ascending branch of the medial circumflex femoral; other branches pierce the gluteus minimus to supply the hip joint.

The superior gluteal artery may arise from the internal iliac with the inferior gluteal and sometimes the internal pudendal.

Surface Anatomy. The artery's pelvic exit corresponds to the junction of the upper and middle thirds of a line joining the posterior superior iliac spine to the apex of the greater trochanter.

The External Iliac Arteries

The external iliac arteries (**6.**120,121,126) are larger than the internal. Each descends laterally along the medial border of the psoas major from the common iliac bifurcation (anterior to the sacro-iliac joint at lumbosacral disc level) to a point midway between the anterior superior iliac spine and the symphysis pubis, entering the thigh posterior to the inguinal ligament to become the femoral artery.

Anteromedially the artery is related to the parietal peritoneum and extraperitoneal tissue, separating the right from the terminal ileum and often the appendix, the left from the sigmoid colon and coils of the small intestine. At its origin the artery may be crossed by the ureter, in females by ovarian vessels. Testicular vessels are anterior for some distance near its distal end, and it is crossed here by the genital branch of the genitofemoral nerve, the deep circumflex iliac vein and the ductus deferens or round ligament. *Posteriorly* the iliac fascia separates it from the medial border of the psoas major. The external iliac vein is partly posterior to its upper part, medial to it below. *Laterally* it is related to the psoas major, the iliac fascia lying between them. Numerous lymph vessels and nodes lie on its front and sides.

Branches. Besides supplying the psoas major and neighbouring lymph nodes, the artery has inferior epigastric and deep circumflex iliac branches.

The inferior epigastric artery (**5.**52, **6.**126) leaves the external iliac just proximal to the inguinal ligament, curves forwards in extraperitoneal tissue, ascends obliquely along the medial margin of the deep inguinal ring, continues up to pierce the transversalis fascia and the attenuated part of the rectus sheath (p. 600) and ascends between the rectus abdominis and the posterior lamina of its sheath. It divides into numerous branches, which anastomose with those of the superior epigastric and lower posterior intercostal arteries. The artery thus skirts the deep inguinal ring inferomedially, passing posterior to the spermatic cord but separated from it by the transversalis fascia. It raises the parietal peritoneum of the anterior abdominal wall as the *lateral umbilical fold* (p. 1339). The ductus deferens, or round ligament, winds laterally round it. It supplies the following branches:

The *cremasteric artery* accompanies the spermatic cord, supplies the cremaster and other coverings of the cord and anastomoses with the testicular artery. In females it is small and accompanies the round ligament.

A *pubic branch*, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator. In 20–30% of subjects, the inferior epigastric's pubic branches are large and replace the obturator's pubic ramus (p. 778).

Muscular branches supply the abdominal muscles and peritoneum, anastomosing with the circumflex iliac and lumbar arteries.

Cutaneous branches perforate the aponeurosis of the external oblique, supply the skin and anastomose with branches of the superficial epigastric artery.

Variations. The artery may arise from the femoral and then ascend, anterior to the femoral vein, to the abdomen. It often arises from the external iliac artery in common with an abnormal obturator and, rarely, directly from the obturator artery.

Applied Anatomy. The inferior epigastric artery is a main route, through anastomosis with the internal thoracic, for collateral circulation after ligature of either the common or the external iliac arteries. It is *medial* to the neck of an oblique inguinal hernia but *lateral* to that of a direct inguinal hernia (p. 1377).

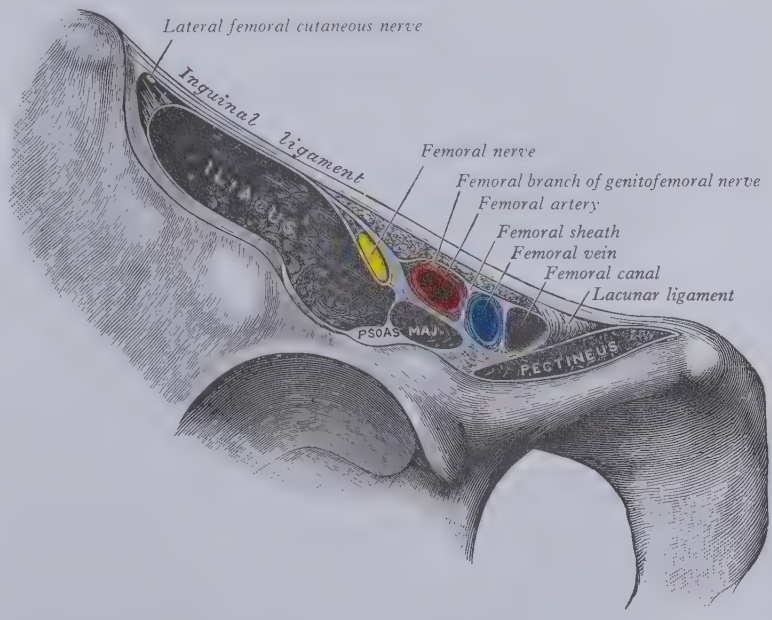
The deep circumflex iliac artery branches laterally from the external iliac almost opposite the inferior epigastric. It ascends laterally to the anterior superior iliac spine posterior to the inguinal ligament in a sheath formed by the junction of the transversalis and iliac fasciae. There it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the internal lip of the iliac crest; about halfway it perforates the transversus abdominis and runs between this and the internal oblique to anastomose with the iliolumbar and superior gluteal arteries. At the anterior superior iliac spine it has a large *ascending branch*, which runs between the internal oblique and the transversus, supplying them and anastomosing with the lumbar and inferior epigastric arteries.

Collateral Circulation. A collateral circulation may be established, in young adults, after ligature of the common iliac artery; when arterial walls degenerate in older patients it is unlikely to supply the leg adequately.

THE ARTERIES OF THE LOWER LIMBS

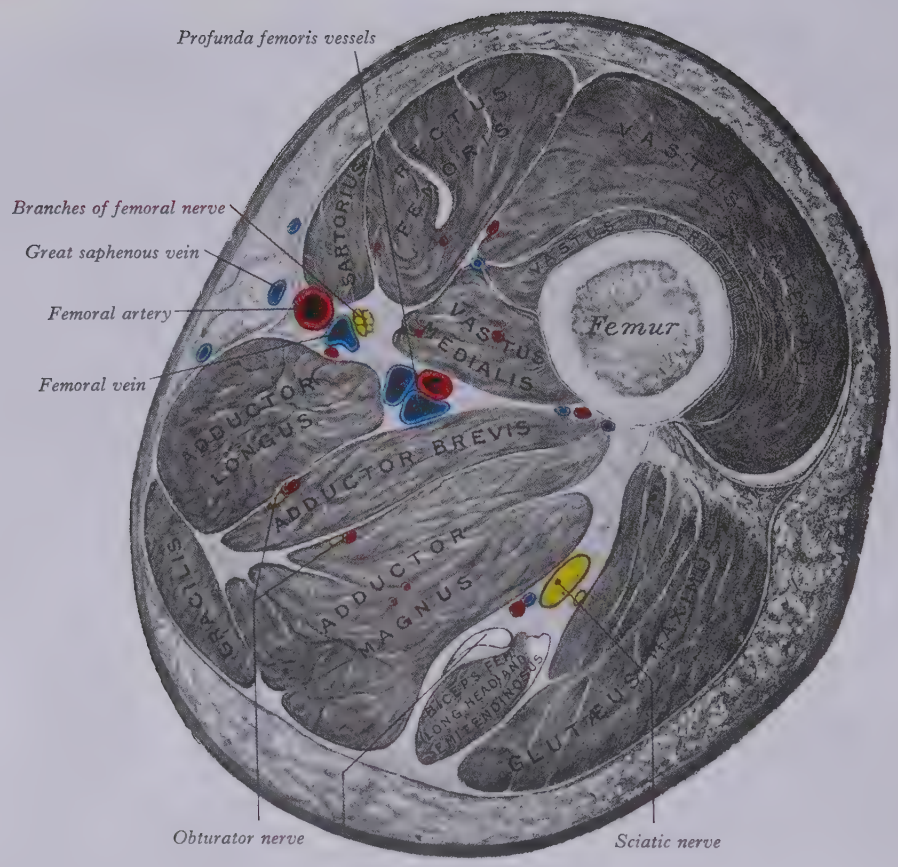
The chief artery of the thigh is the continuation of the external iliac, extending from the inguinal ligament to the distal border of the popliteus, where it divides into anterior and posterior tibial arteries. Its proximal section, the femoral artery lies among the genual extensor muscles; its distal continuation, the popliteal artery, is among the genual flexors.

The Femoral Artery



The femoral artery (**6**.128–132), a continuation of the external iliac, begins behind the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis, descends the thigh anteromedially and becomes the popliteal as it passes through an opening in the adductor magnus near the junction of the middle and distal thirds of the thigh. Proximally it is in the *femoral triangle*, distally in the *adductor (subsartorial)* canal. Its first 3 or 4 cm are enclosed, with its vein, in the *femoral sheath.*

The Femoral Sheath (6.127)



Distal prolongations, behind the inguinal ligament, of the transversalis fascia *anterior* to the femoral vessels and of the iliac fascia, *posterior*, together form a short funnel, wider proximally, its distal end fusing with the vascular fascia about 3 or 4 cm distal to the ligament. At birth the sheath is shorter, elongating when extension at the hips becomes habitual. Its (longitudinally) vertical lateral wall is perforated by the femoral branch of the genitofemoral nerve; the medial wall slopes laterally and is pierced by the great (long) saphenous vein and lymphatic vessels. Like the carotid sheath the femoral is a mass of connective tissue in which the vessels are embedded. Three compartments are described: a lateral containing the femoral artery; an intermediate for the femoral vein; medial and smallest is the *femoral canal*, containing the lymph vessels and a lymph node embedded in areolar tissue, probably to allow the vein to distend. This canal is conical, about 1.25 cm in length; its proximal end is the *femoral ring*, bounded in front by the inguinal ligament, behind by the pectineus and its fascia, medially by the crescentic edge of the lacunar ligament and laterally by the femoral vein (p. 1379). The spermatic cord, or round ligament, is just above its anterior margin; the inferior epigastric vessels are near its anterolateral rim. It is larger in women than men due partly to the greater breadth of the female pelvis, partly to the smaller size of the femoral vessels. The ring is filled by condensed extraperitoneal tissue, the *femoral septum*, covered by the parietal peritoneum (p. 1377). The femoral septum is traversed by numerous lymph vessels connecting the deep inguinal to the external iliac lymph nodes.

The femoral triangle (p. 638) underlies a depression distal to the inguinal fold. Its apex is distal, its limits being *laterally* the medial margin of sartorius, *medially* the medial margin of the adductor longus; proximally (the base) is the inguinal ligament. It is like a gutter, floored laterally by the iliacus and psoas major, medially by the pectineus and adductor longus. The femoral vessels, passing from midbase to apex, are in its deepest part. Lateral to the artery the femoral nerve divides. The triangle also contains fat and regional lymph nodes.

The adductor (subsartorial) canal (**6**.129) is an aponeurotic tunnel in the thigh's middle third from the apex of the femoral triangle to the opening in adductor mangus, through which femoral vessels reach the popliteal fossa. Triangular in section, it is bounded *anterolaterally* by the vastus medialis, *posteriorly* by the adductor longus, distally the adductor magnus and *anteromedially* by a strong aponeurosis extending between the adductors across the vessels to the vastus medialis. The sartorius is

6.127 The structures passing posterior to the right lacunar ligament: inferior (distal) aspect. Note the lacuna musculorum and the lacuna vasculorum.

6.128 Transverse section through the right thigh at the level of the apex of the femoral triangle: superior (proximal) aspect. About three-fifths of the natural size. The cutaneous nerves are omitted.

anterior. The canal contains the femoral artery and vein, the saphenous nerve, and the nerve to the vastus medialis until it enters its muscle.

Femoral artery relations:

Relations in the femoral triangle (**6.130**): *anterior* are the skin, superficial fascia, superficial inguinal lymph nodes, fascia lata, femoral sheath, superficial circumflex iliac vein (crossing in the superficial fascia) and the femoral branch of the genitofemoral nerve (at first lateral then anterior). Near the apex the medial femoral cutaneous nerve crosses the artery from the lateral to the medial side. *Posterior* are the femoral sheath, tendon of psoas, pectineus and adductor longus. The artery is separated from the hip joint by the tendon of the psoas major, from the pectineus by the femoral vein and profunda vessels, from the adductor longus by the femoral vein. Proximally, the nerve to the pectineus passes medially behind the artery; *lateral* to it is the femoral nerve. The femoral vein is *medial* in the proximal part of the triangle, becoming *posterior* near its apex, distally.

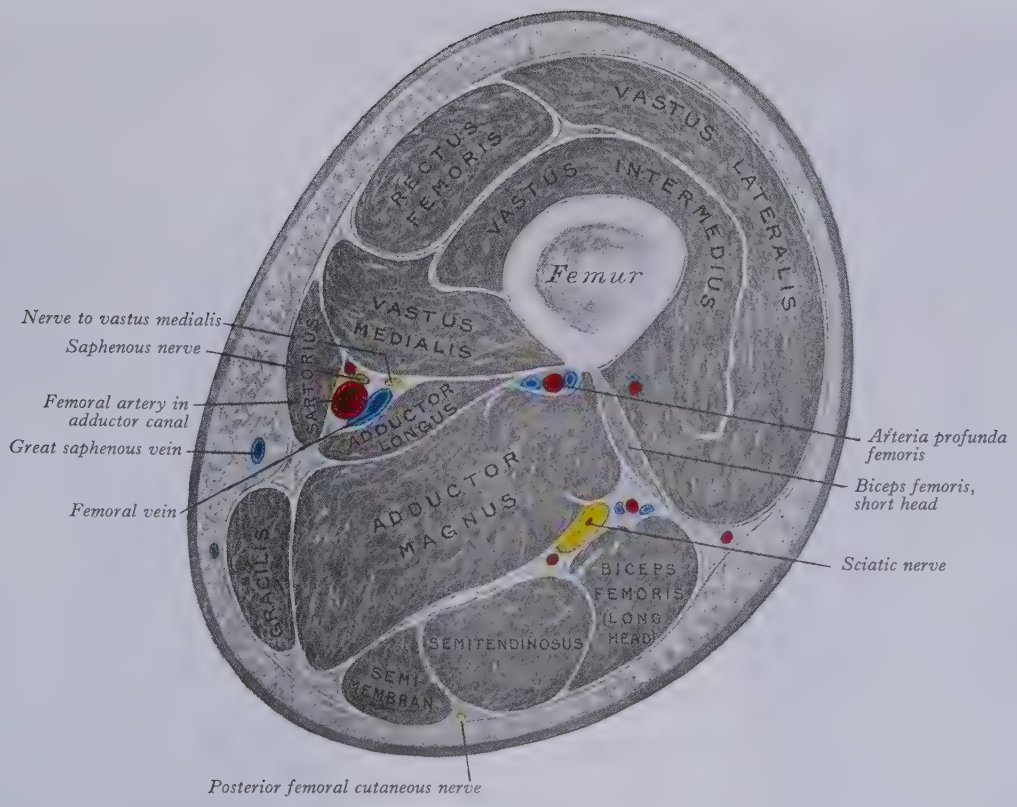
Relations in the adductor canal (**6.129,130,131**): *anterior* are the skin, superficial and deep fasciae, the sartorius and fibrous roof of the canal. The saphenous nerve is first lateral, then anterior and finally medial. *Posterior* are the adductor longus and adductor magnus; the femoral vein is also posterior proximally, but becoming lateral distally. Anterolateral are the vastus medialis and its nerve.

Surface Anatomy. The artery corresponds to the proximal two-thirds of a line drawn from the midpoint between the anterior superior iliac spine and the pubic symphysis to the adductor tubercle, with the thigh semiflexed, abducted and laterally rotated. Its pulsation is easily palpable in its proximal course.

Variations. Rarely the femoral artery divides, distal to the origin of the arteria profunda femoris, into two trunks reuniting near the adductor opening. It may be replaced by the inferior gluteal artery, accompanying the sciatic nerve to the popliteal fossa and representing a proximal persistence of the original axial artery (p. 218); the external iliac is then small, ending as the arteria profunda femoris.

Applied Anatomy. Compression of the femoral artery is most effective just distal to the inguinal ligament, where it is superficial and separated from the *bone* (iliopubic eminence) only by the psoas tendon.

Branches. **The superficial epigastric artery** (**6.130**) arises anteriorly from the femoral about 1 cm distal to the inguinal ligament, traverses the cribriform fascia to ascend anterior to the ligament and runs in the abdominal superficial fascia almost to the umbilicus. It supplies the superficial inguinal lymph nodes and superficial fascia and skin, anastomosing with branches of the inferior epigastric and its fellow.



The superficial circumflex iliac artery (**6.130**), the smallest superficial branch of the femoral, arises near or with the superficial epigastric. Usually emerging through the fascia lata lateral to the saphenous opening, it turns laterally distal to the inguinal ligament towards the anterior superior iliac spine; it supplies the skin, superficial fascia and superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial external pudendal artery (**6.130**) arises medially from the femoral, close to the preceding branches. Emerging from the cribriform fascia, it passes medially, usually deep to the great saphenous vein, across the spermatic cord (or round ligament) to supply the lower abdominal, penile, scrotal or labial skin, anastomosing with branches of the internal pudendal.

Veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries *join* the *great saphenous vein* before it enters the saphenous opening.

The deep external pudendal artery (**6.130**) passes medially across the pectineus and anterior or posterior to the adductor longus, covered by fascia lata, piercing it to supply the skin of the perineum and scrotum or labium majus; its branches anastomose with the posterior scrotal or labial branches of the internal pudendal.

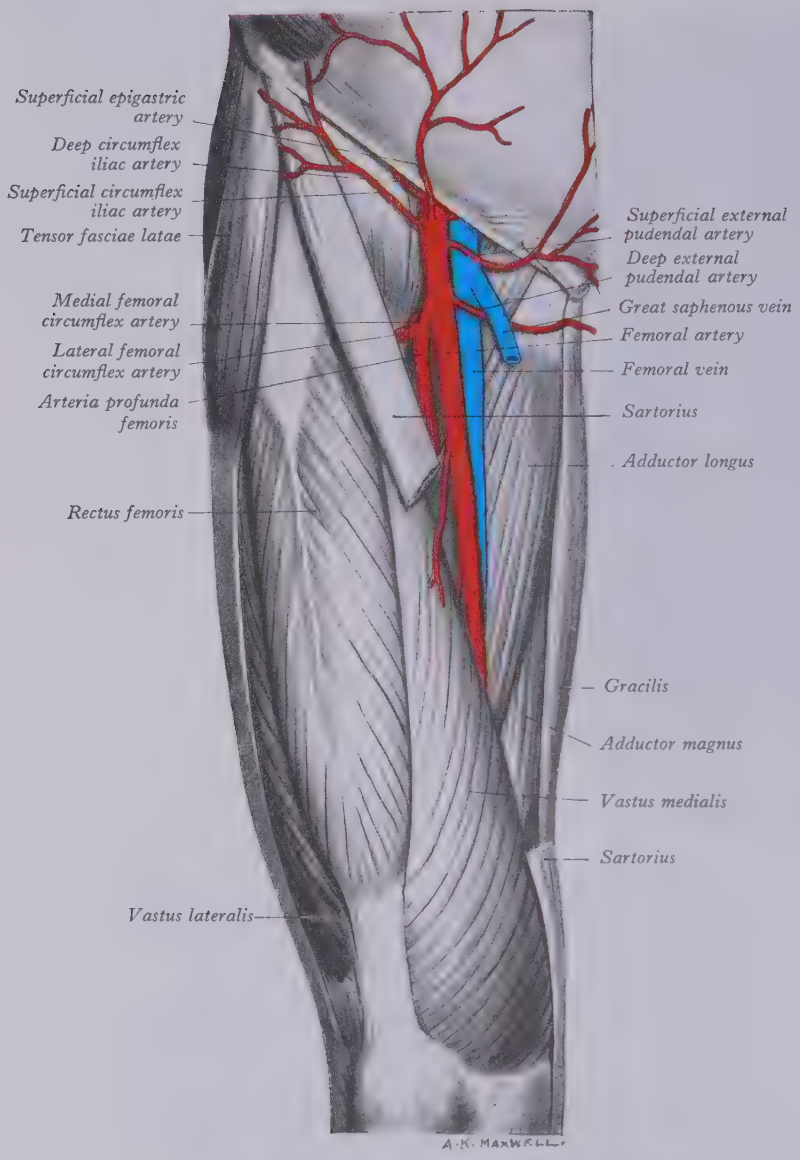
Muscular branches supply the sartorius, the vastus medialis and the adductors.

6.129 Transverse section through the middle of the right thigh: superior (proximal) aspect. About three-fifths of the natural size.

The Arteria Profunda Femoris (6.129,130,131,132)

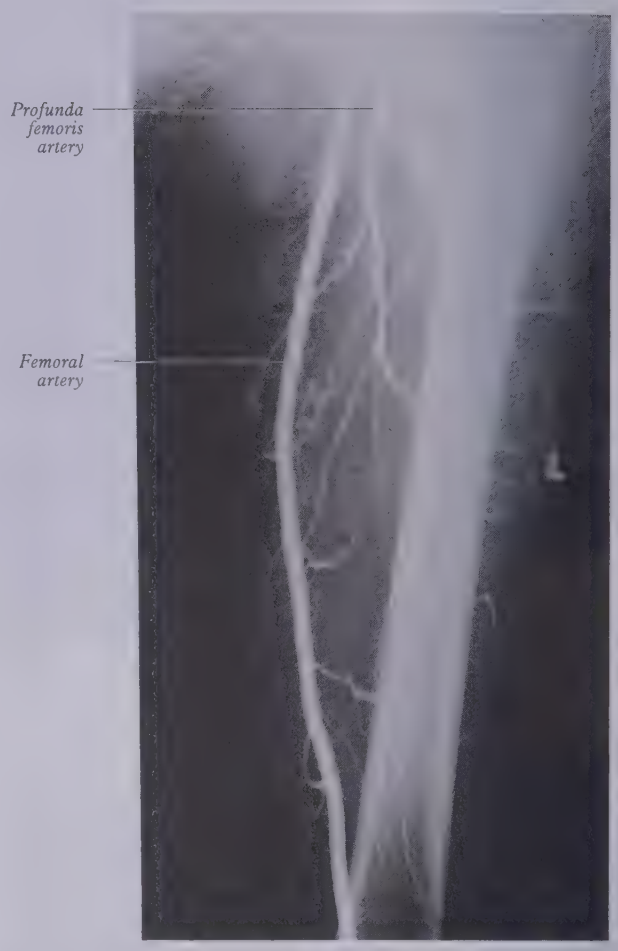
This large branch arises laterally from the femoral about 3.5 cm distal to the inguinal ligament. At first lateral to the femoral artery it spirals posterior to this and the femoral vein to the medial side of the femur; it passes between the pectineus and adductor longus, then between the latter and the adductor brevis and then descends between the adductor longus and adductor magnus to finally pierce the latter and anastomose with the upper muscular branches of the popliteal. This terminal part is sometimes named the *fourth perforating artery*.

Relations. *Posterior*, in proximodistal order, are: the iliacus, pectineus, adductor brevis and adductor magnus. *Anterior* are the femoral and profunda veins and distally the adductor longus, separating it from the femoral artery. *Laterally* the vastus medialis separates its proximal part from the femur.



Variations. Its origin is sometimes medial, or rarely posterior on the femoral artery; if the former, it may cross anterior to the femoral vein and then pass backwards around its medial side.

The deep femoral artery is the main supply to the adductor, extensor and flexor muscles; it also anastomoses with the internal and external iliac arteries above and the popliteal artery below. Its *branches* are as follows:



The lateral circumflex femoral artery, a lateral branch near the root of the profunda, inclines laterally between divisions of the femoral nerve, posterior to the sartorius and rectus femoris, dividing into ascending, transverse and descending branches. It may arise from the femoral. The *ascending branch* ascends along the inter-trochanteric line, under the tensor fasciae latae, lateral to the hip joint; it anastomoses with the superior gluteal and deep circumflex iliac arteries, supplying the greater trochanter, and forms an anastomotic ring round the femoral neck with branches of the medial circumflex femoral; from this ring the femoral neck and head are supplied. The *descending branch*, sometimes direct from the profunda or the femoral, descends posterior to the rectus femoris, along the anterior border of the vastus lateralis, which it supplies: a long ramus descends *in* vastus lateralis to the knee, anastomosing with the lateral superior genicular branch of the popliteal, accompanied by the nerve to the vastus lateralis. The *transverse branch*, the smallest, passes laterally anterior to the vastus intermedius, pierces the vastus lateralis to wind round the femur, just distal to the greater trochanter, anastomosing with the medial circumflex, inferior gluteal and first perforating arteries (*cruciate anastomosis*).

The medial circumflex femoral artery, usually from the posteromedial aspect of the profunda but often the femoral artery, supplies the adductor muscles and curves medially round the femur between the pectineus and psoas major and then the obturator externus and adductor brevis, finally appearing between the quadratus femoris and upper border of the adductor magnus, dividing into transverse and ascending branches. The *transverse branch* takes part in the cruciate anastomosis. The *ascending branch* ascends on the tendon of the obturator externus, anterior to the quadratus femoris, to the trochanteric fossa, where it anastomoses with branches of the gluteal and lateral circumflex femoral arteries. An *acetabular branch* at the proximal edge of the adductor brevis enters the hip joint under the transverse acetabular ligament with one from the obturator artery; it supplies the fat in the fossa, and reaches the femoral head along its ligament. For blood supply of the proximal end of the femur consult Crock (1965).

The perforating arteries (6.125), usually three, perforate the attachment of the adductor magnus to reach the thigh's flexor aspect. They pass close to the linea aspera under small tendinous arches in the muscle, supplying the muscular, cutaneous and anastomotic branches. Diminished, they pass deep to the short head of biceps femoris (the first usually through the attachment of gluteus maximus), traverse the lateral intermuscular septum and enter the vastus lateralis. The first arises proximal to the adductor brevis, the second anterior and the third distal. The *first perforating artery* passes back between the pectineus and adductor brevis (sometimes through the latter), piercing the adductor magnus near the linea aspera to supply the adductor brevis, adductor magnus, biceps femoris and gluteus maximus, anastomosing with the inferior gluteal, medial and lateral circumflex femoral and second perforating arteries. The larger *second perforating artery*, often arising with the first, pierces the attachments of adductor brevis

6.130 The right femoral vessels and some of their branches.

6.131 Femoral arteriogram. Supplied by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith.

and magnus, divides into the ascending and descending branches supplying the posterior femoral muscles and anastomoses with the first and third perforating arteries. The femoral *nutrient artery* usually arises from it; when two nutrient arteries exist, they usually come from the first and third. The *third perforating artery* starts distal to adductor brevis, pierces the attachment of adductor magnus and divides into branches to the posterior femoral muscles; it anastomoses proximally with the perforating arteries, distally with the end of the profunda and muscular rami of the popliteal. The femoral nutrient artery may arise from it. Rami of the diaphysial nutrient and other branches of the profunda also provide subsidiary cortical arteries (Crock 1967).

The end of arteria profunda femoris is the *fourth perforating artery*. The perforating arteries form a *double chain of anastomoses*: (1) in adductor muscles and (2) near the linea aspera.

Numerous muscular branches arise from the arteria profunda femoris; some end in adductors, others pierce the adductor magnus, supply the flexors and anastomose with the medial circumflex femoral artery and superior muscular branches of the popliteal. The profunda is thus the *main* supply to the femoral muscles.

Anastomosis on the back of the thigh. This important chain of anastomoses stretches from the gluteal region to the popliteal fossa, formed in proximodistal order by anastomoses between: (1) gluteal arteries and terminals of the medial circumflex femoral; (2) circumflex femoral arteries and the first perforating artery; (3) perforating arteries and each other; (4) the fourth perforating artery and the superior muscular branches of the popliteal.

The descending genicular artery (6.136) arises from the femoral just proximal to the adductor opening, at once supplying a *saphenous branch* and then descending in the vastus medialis anterior to the tendon of adductor magnus, to the medial side of the knee, anastomosing with the medial superior genicular artery. *Muscular branches* supply the vastus medialis and adductor magnus and have *articular branches*, which anastomose round the knee joint. One articular branch crosses above the femoral patellar surface, forming an arch with the lateral superior genicular artery and supplying the knee joint. The *saphenous branch* emerges distally through the roof of the adductor canal to accompany the saphenous nerve to the medial side of the knee. Passing between the sartorius and gracilis it supplies the skin of the proximomedial area of the leg, anastomosing with the medial inferior genicular artery.

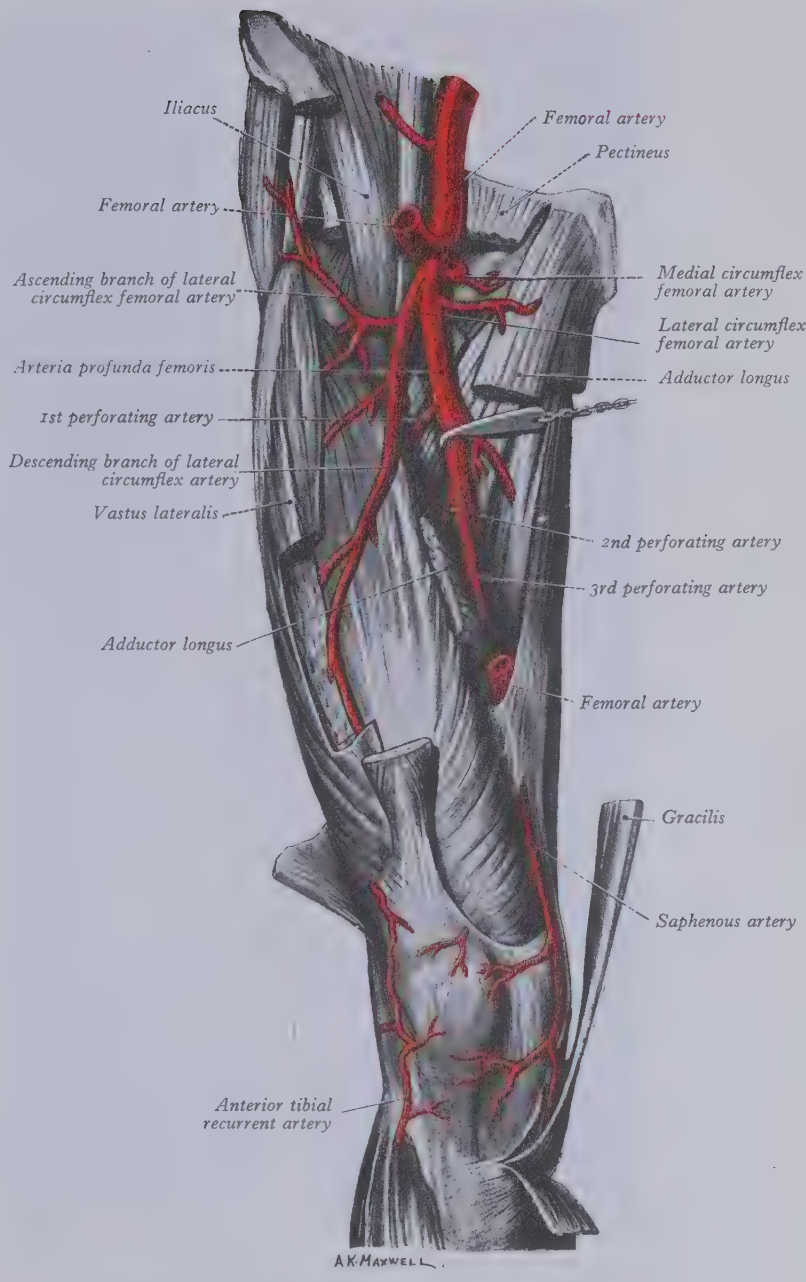
Collateral Circulation. After ligation of the femoral artery proximal to the origin of the arteria profunda femoris, the main anastomotic channels available are: (1) superior and inferior gluteal branches of the internal iliac with the medial and lateral circumflex femoral and the first perforating branch of the arteria profunda femoris; (2) the obturator branch of the internal iliac with the medial circumflex femoral of the arteria profunda femoris; (3) the internal pudendal branch of the internal iliac with superficial and deep external pudendal branches of the femoral; (4) a deep circumflex iliac branch of the external iliac with the

lateral circumflex femoral branch of the arteria profunda femoris and the superficial circumflex iliac branch of the femoral; (5) the inferior gluteal branch of the internal iliac with perforating branches of the arteria profunda femoris.

The Popliteal Fossa (5.100, 6.134, 7.259, 7.260)

This is a rhomboidal region posterior to the knee joint, more apparent when disturbed by dissection. *Lateral* are proximally the biceps femoris and distally the plantaris and lateral head of the gastrocnemius; *medial* and proximally are the semitendinosus and semimembranosus, and distally the medial head of the gastrocnemius; *anterior* are the femoral popliteal surface, oblique popliteal ligament, back of the proximal end of the tibia and the fascia covering the popliteus, collectively forming a so-called floor. The fossa is covered *posteriorly* by the popliteal fascia. (Note that 'popliteal fascia' refers to part of the general investing layer of deep fascia that forms a 'roof' for the fossa; to be carefully distinguished from the 'fascia of popliteus' which forms part of the floor.)

Contents (6.134, 7.260). Until disturbed, the popliteal fossa is about 2.5 cm wide and its contents are largely hidden, especially in its distal part, where the heads of gastrocnemius are in contact. When its boundaries are separated its contents are seen to be the popliteal vessels, the tibial and common peroneal nerves, the small saphenous vein, posterior femoral cutaneous nerve, an obturator articular branch, lymph nodes and fat. The tibial nerve descends centrally immediately anterior to the popliteal fascia, crossing the vessels *posteriorly* from lateral to medial. The common peroneal nerve descends laterally near the tendon of biceps femoris. Popliteal vessels are deep on the floor, the vein superficial to the artery, and united by dense areolar tissue. The vein is thick-walled, proximally lateral to the artery, and crossing to its medial side distally; sometimes it is double with the artery between the veins, the latter usually being interconnected. An articular branch from the obturator nerve descends on the artery to the knee. Six or seven popliteal lymph nodes are embedded in the fat, one under the popliteal fascia near the end of the small saphenous vein, one between the popliteal artery and knee joint, others around the popliteal vessels.



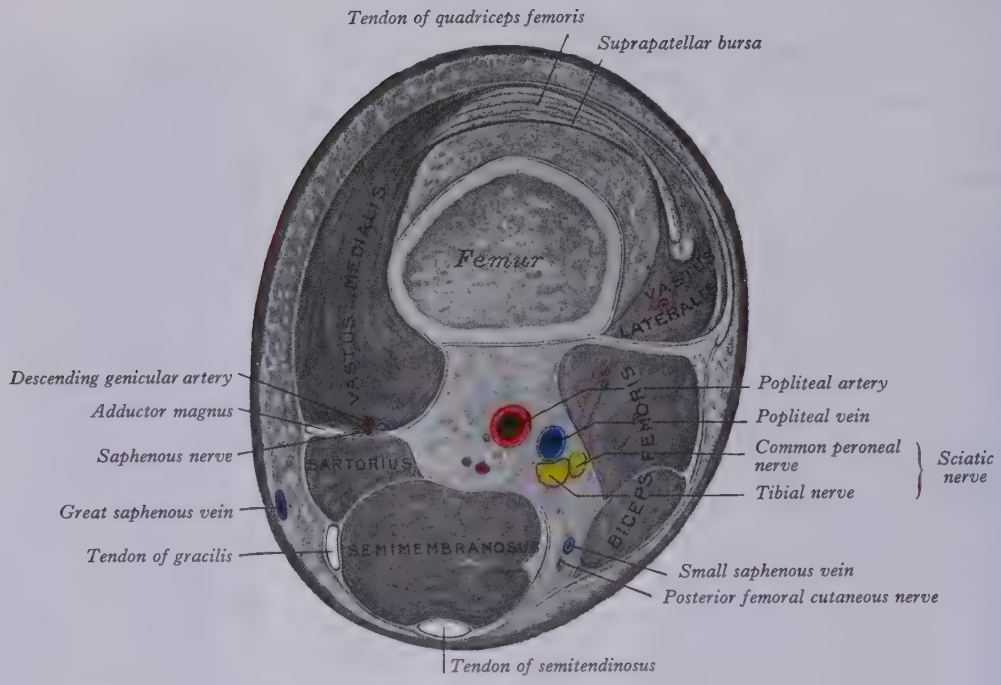
The Popliteal Artery

The popliteal artery (6.133,134,135), continuing the femoral, traverses the popliteal fossa; from the opening in adductor magnus it descends laterally to the intercondylar fossa, inclining *obliquely* to the distal border of the popliteus, where it divides into the *anterior* and *posterior tibial arteries* (6.107). This division is at the proximal end of the crural interosseous space (which is asymmetrical) between the wide tibial metaphysis and the slender fibular metaphysis. Thus the popliteal artery extends from the *medial* border of the femur to the laterally placed interosseous space, accounting for its oblique descent (6.135).

Relations. Anterior, proximodistally, are fat covering the femoral popliteal surface, the capsule of the knee joint, and the fascia of popliteus. *Posterior* are, proximally, the semimembranosus and, distally, the gastrocnemius and plantaris. At intermediate level the artery is separated from the skin and fasciae by fat and crossed from lateral to medial by the tibial nerve and popliteal vein, the vein being between the nerve and artery and adherent to the latter. *Lateral* are proximally the biceps femoris, tibial nerve, popliteal vein and lateral femoral condyle and distally the plantaris and lateral head of gastrocnemius. *Medial* are the semimembranosus and medial femoral condyle and distally the tibial nerve, popliteal vein and medial head of gastrocnemius. Relations of the popliteal lymph nodes are described on p. 848.

Variations. The artery may divide into terminal branches *proximal* to the popliteus, the anterior tibial artery then descending *anterior* to the muscle. It sometimes divides into the anterior tibial and peroneal arteries, the posterior tibial being absent or rudimentary; it may divide into the anterior and posterior tibial and peroneal.

Surface Anatomy. The popliteal artery is approximately represented as extending from the junction of the middle and lower thirds of the thigh, 2.5 cm medial to its posterior midline, to the midpoint between the femoral condyles, continuing inferolaterally to the level of the tibial tuberosity, medial to the fibular neck.



6.132 The right profunda femoris artery and its branches.

Branches are the cutaneous, muscular and genicular branches which reach the tibiofibular interosseous gap.

Cutaneous branches leave the popliteal or its rami, descend between the heads of gastrocnemius and perforate the deep fascia to supply the skin on the *flexor* aspect of the leg; one usually accompanies the small saphenous vein.

Superior muscular branches (two or three) arise proximally and pass to the adductor magnus and femoral flexors, anastomosing with the termination of the arteria profunda femoris. **Sural arteries** (two in number, and large) arise behind the knee joint to supply gastrocnemius, soleus and plantaris.

The superior genicular arteries (6.134,136) diverge from the popliteal, curving round proximal to both femoral condyles, to the anterior aspect of the knee joint. The *medial superior genicular artery* lies under semimembranosus and semitendinosus, proximal to the medial head of gastrocnemius and deep to the tendon of adductor magnus. It divides into a branch to the vastus medi-alis which anastomoses with the descending genicular and

6.133 Transverse section through the right thigh, 4 cm above the adductor tubercle of the femur: superior (proximal) aspect. About three-fifths of the natural size.

medial inferior genicular arteries, and one ramifying on the femur and anastomosing with the lateral superior genicular artery. Its size varies inversely with that of the descending genicular. The *lateral superior genicular artery* passes under the tendon of biceps femoris, dividing into superficial and deep branches; the superficial supplies the vastus lateralis, anastomosing with the descending branch of the lateral circumflex femoral and lateral inferior genicular; the deep branch anastomoses with the medial superior genicular, forming an anterior arch across the femur with the descending genicular.

The middle genicular artery is small and arises from the popliteal near the posterior centre of the knee joint; it pierces the oblique popliteal ligament to supply the cruciate ligaments and synovial membrane.

The inferior genicular arteries (**6**.134,136) arise from the popliteal deep to the gastrocnemius. The *medial* is deep to its medial head, descending along the proximal margin of the popliteus, which it supplies, and passing inferior to the medial tibial condyle and under the tibial collateral ligament, at the anterior border of which it ascends anteromedial to the joint; it supplies this and the tibia, anastomosing with the lateral inferior and medial superior genicular arteries and also with the anterior tibial recurrent artery and saphenous branch of the descending genicular. The *lateral inferior genicular artery* runs laterally across the popliteus and forwards over the fibula's head to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament and tendon of biceps femoris. Its branches anastomose with the medial inferior and lateral superior genicular, anterior and posterior tibial recurrent, and circumflex fibular arteries.

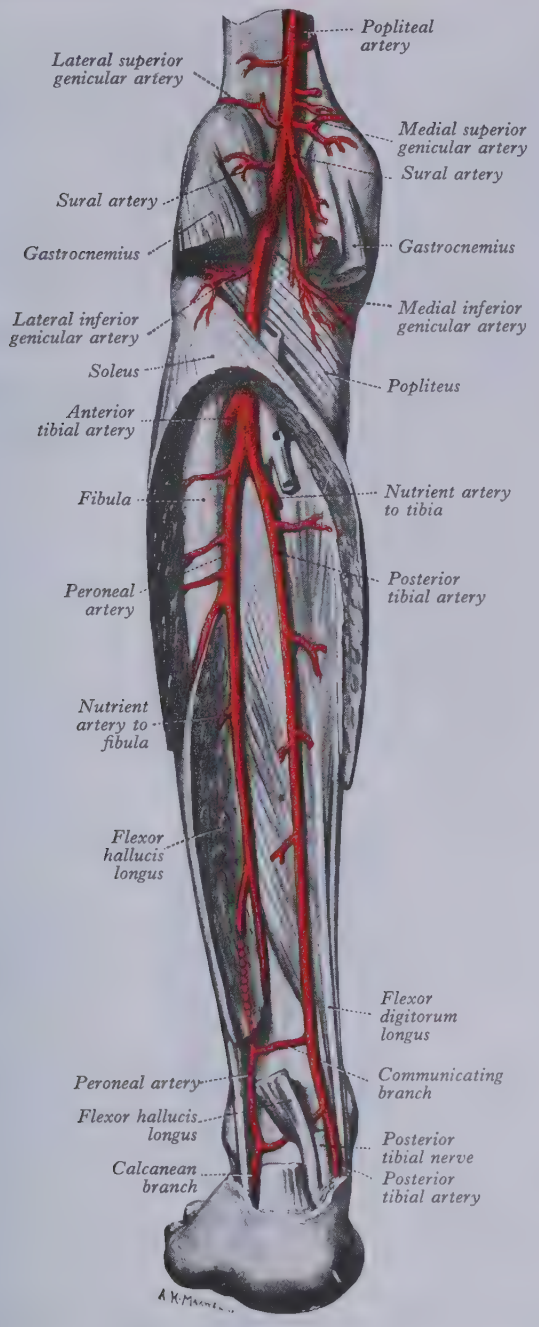
The Genicular Anastomosis

Around the patella and femoral and tibial condyles an intricate anastomosis exists. A *superficial network* spreads between the fascia and skin around the patella and in the fat deep to the ligamentum patellae. A *deep network* lies on the femur and tibia near the adjoining articular surfaces, supplying the bone and marrow, the articular capsule and synovial membrane. The vessels involved are the medial and lateral genicular, descending genicular, the descending branch of the lateral circumflex femoral, circumflex fibular and the anterior and posterior tibial recurrent arteries.

The Anterior Tibial Artery (**6**.134,135,137,138)

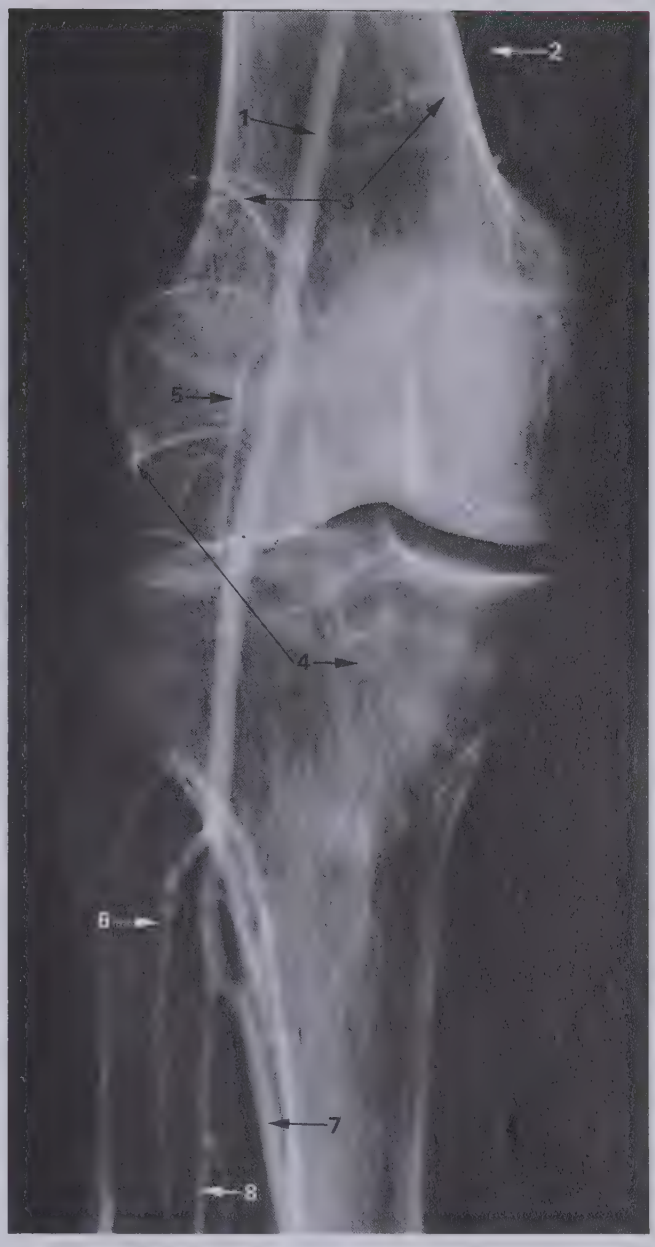
This terminal branch of the popliteal arises at the distal border of the popliteus. At first in the flexor compartment, it passes between the heads of tibialis posterior and through the oval aperture in the proximal part of the interosseous membrane (p. 534) to the extensor region, passing medial to the fibular neck. Descending anteriorly on the membrane it approaches the tibia and, distally, lies anterior to it (**6**.139). At the ankle it is midway between the malleoli, continuing on the dorsum of the foot as the *arteria dorsalis pedis*.

Relations. In its proximal two-thirds the artery descends on the interosseous membrane, in its distal third anterior to the tibia and ankle joint. Proximally it is between the tibialis anterior and extensor digitorum longus, then between the tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral side by the tendon of extensor hallucis longus and is then between this and the first tendon of the extensor digitorum longus. Its proximal two-thirds is covered by adjoining muscles and deep fascia, its distal third by the skin, fasciae and extensor retinacula. Venae comitantes accompany it. The deep peroneal nerve, curling laterally round the fibular neck, reaches the lateral side of the artery where it enters the extensor region but in the middle third of the leg becomes anterior to it and distally again becomes lateral.



Surface Anatomy. Surface projection of the anterior tibial artery begins 2.5 cm distal to the medial side of the fibular head and ends midway between the malleoli. It can be felt pulsating lateral to the tendon of extensor hallucis longus.

Variations. This vessel may be small or even absent, replaced by perforating branches from the posterior tibial or the perforating branch of the peroneal. It occasionally deviates laterally, regaining its usual position at the ankle.



Branches are the anterior and posterior tibial recurrent, anterior medial and lateral malleolar and muscular.

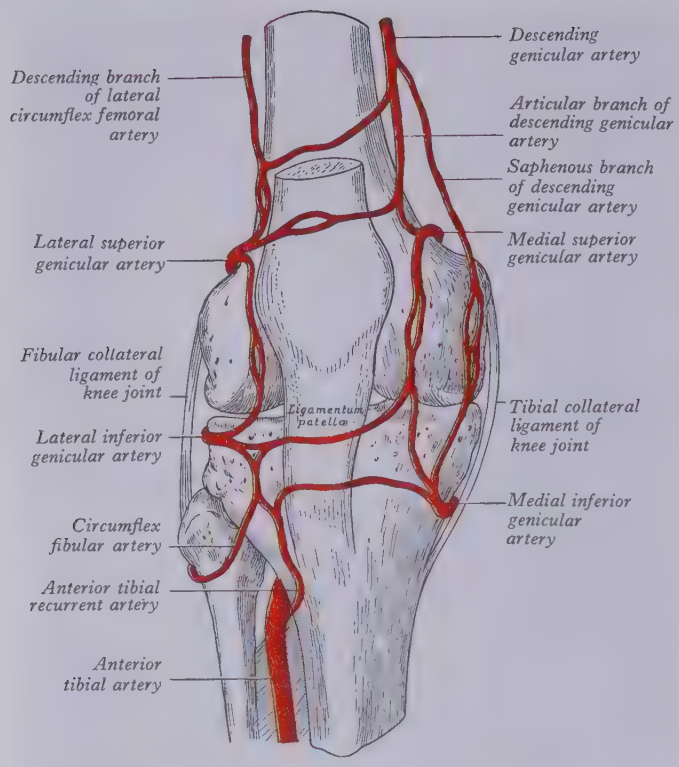
The posterior tibial recurrent artery, an inconstant branch, arises before the anterior tibial reaches the extensor compartment, ascending anterior to the popliteus with the muscle's recurrent nerve, anastomosing with the inferior genicular branches of the popliteal. It supplies the superior tibiofibular joint.

The anterior tibial recurrent artery (**6**.137) arises near the preceding vessel, ascends in tibialis anterior, ramifies on the front and sides of the knee joint and joins the patellar network, anastomosing with the genicular branches of the popliteal and circumflex fibular arteries.

6.134 The left popliteal, posterior tibial and peroneal arteries: dorsal aspect.

6.135 Popliteal arteriogram: anteroposterior view of adult male of 63 years. The following arteries can be identified: 1. popliteal. 2. descending genicular. 3. superior medial and lateral genicular. 4. inferior medial and lateral genicular. 5. middle genicular. 6. anterior tibial. 7. posterior tibial. 8. peroneal. Note the (normal) obliquity of the popliteal artery.

Numerous muscular branches supply the adjacent muscles; some pierce the deep fascia to supply the skin, others traverse the interosseous membrane to anastomose with branches of the posterior tibial and peroneal arteries.



The anterior medial malleolar artery (**6**.137,140) arises about 5 cm proximal to the ankle, passing posterior to the tendons of extensor hallucis longus and tibialis anterior medial to the joint, where it joins branches of the posterior tibial and medial plantar arteries.

The anterior lateral malleolar artery (**6**.137,140) proceeds posterior to the tendons of extensor digitorum longus and peroneus tertius to the lateral side of the ankle, anastomosing with the perforating branch of the peroneal and ascending rami of the lateral tarsal artery.

Anastomosis at the ankle joint (**6**.140) consists of networks around the malleoli. The *medial malleolar network* is formed by the anterior medial malleolar branch of the anterior tibial, medial tarsal branches of the arteria dorsalis pedis, the malleolar and calcanean branches of the posterior tibial and branches of the medial plantar artery. The *lateral malleolar network* is formed by the anterior lateral malleolar branch of the anterior tibial, lateral tarsal branch of arteria dorsalis pedis, the perforating and calcanean branches of the peroneal and rami of the lateral plantar artery.

The **arteria dorsalis pedis** (*dorsal artery of the foot*) (**6**.137), the continuation of the anterior tibial distal to the ankle, passes medially along the dorsum to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous muscle to complete the plantar arch, where it provides the *first plantar metatarsal artery*.

Relations. The dorsal artery successively crosses the talocrural articular capsule, talus, navicular and intermediate cuneiform, and their ligaments; superficial are the skin, fasciae, inferior extensor retinaculum and, near its termination, extensor hallucis brevis. *Medial* is the tendon of extensor hallucis longus, *lateral* the medial tendon of the extensor digitorum longus and medial terminal branch of the deep peroneal nerve.

6.136 The arterial anastomosis around the knee joint (schematic).

Surface Anatomy. The vessel's pulsation is palpable from the midpoint between the malleoli to the proximal end of the first intermetatarsal space.

Variations. The artery may be larger to compensate for a small lateral plantar artery or replaced by a large perforating branch of the peroneal. It often diverges laterally from its usual route.

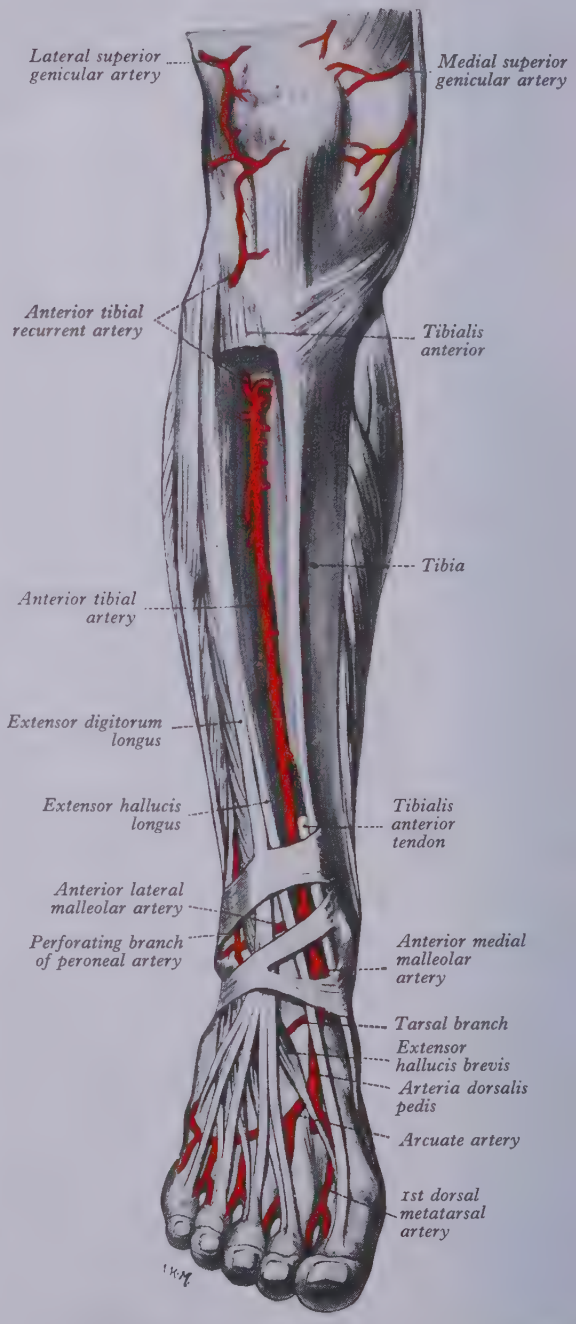
Branches: tarsal, arcuate, and first dorsal metatarsal arteries.

The tarsal arteries, lateral and medial (**6**.137), arise as the arteria dorsalis pedis crosses the navicular; the former runs laterally under the extensor digitorum brevis; it supplies this and the tarsal articulations, anastomosing with branches of the arcuate, anterior lateral malleolar, lateral plantar and the perforating branch of the peroneal. Two or three medial tarsal arteries ramify on the foot's medial border and join the medial malleolar network.

The arcuate artery (**6**.137) arises near the medial cuneiform, passing laterally over the metatarsal bases, deep to the tendons of the digital extensors, and anastomosing with the lateral tarsal and plantar arteries. It supplies the *second* to *fourth dorsal metatarsal arteries*, running distally superficial to the corresponding dorsal interosseous muscles; in the interdigital clefts each divides into two *dorsal digital branches* for the adjoining toes. Proximally, in the interosseous spaces, they receive *proximal perforating branches* from the plantar arch and distally are joined by the *distal perforating branches* from the plantar metatarsal arteries. The fourth dorsal metatarsal sends a branch to the lateral side of the fifth toe.

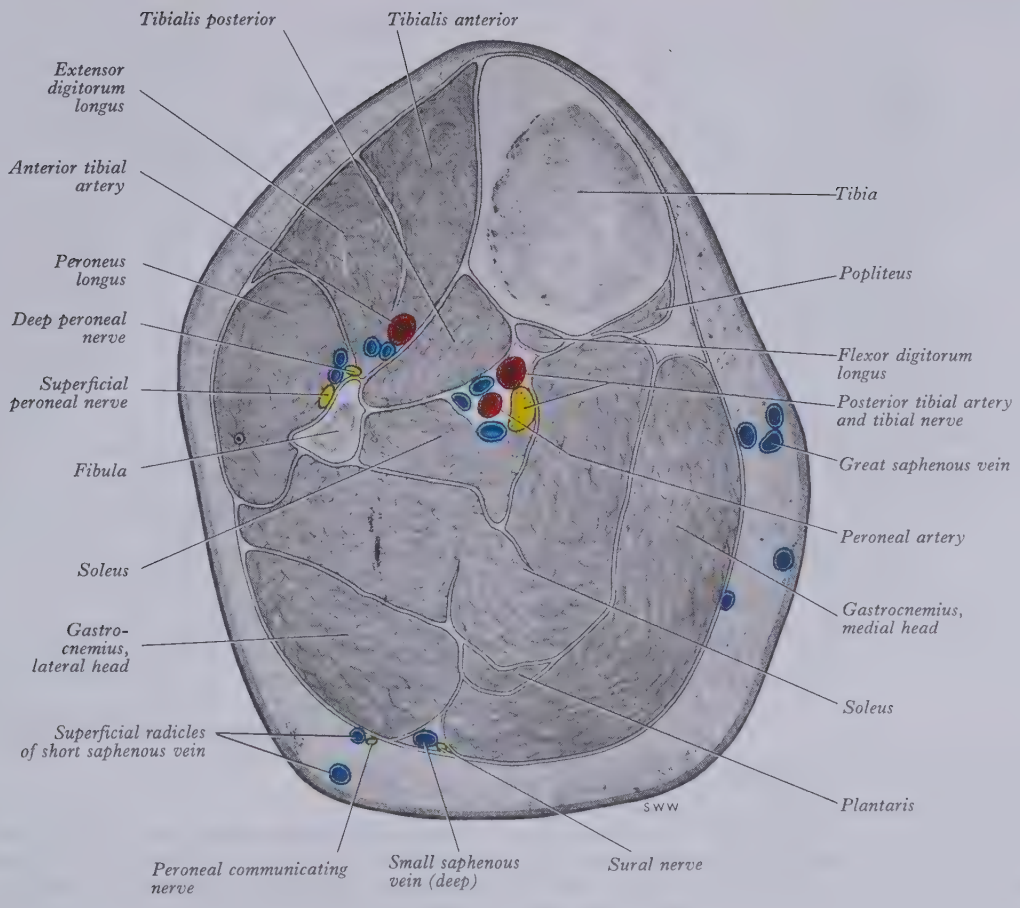
The first dorsal metatarsal artery arises just before the arteria dorsalis pedis enters the sole; it runs distally on the first dorsal interosseous; at the cleft between the first and second toes it divides, one branch passing under the tendon of extensor hallucis longus and supplying the medial side of the hallux and one bifurcating to supply the adjoining sides of hallux and the second toe.

The Posterior Tibial Artery (**6**.134,135,138)



This begins at the distal border of the popliteus, between the tibia and fibula, descending medially in the flexor compartment to divide midway between the medial malleolus and the medial tubercle of calcaneus, under abductor hallucis, into the *medial* and *lateral plantar arteries*.

Relations. The artery is successively *posterior* to tibialis posterior, flexor digitorum longus, tibia and ankle joint. Proximally, gastrocnemius, soleus and the deep transverse fascia of the leg are *superficial* and distally only the skin and fascia. It is parallel with and about 2.5 cm anterior to the medial border of the tendo calcaneus; terminally it is *deep* to the flexor retinaculum and abductor hallucis. It is accompanied by two veins and the tibial nerve, the latter first medial, but soon crossing posterior, and then largely posterolateral. The arrangement of structures passing from the leg to the sole is described on p. 651.



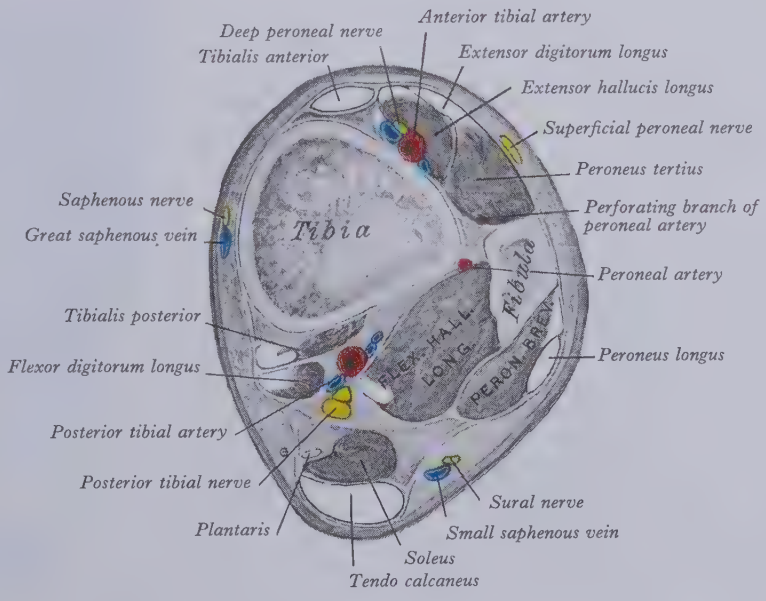
Surface Anatomy. The posterior tibial artery corresponds to a line joining a point 1–2 cm lateral to the calf's midline at the fibular neck's level, extending downwards and medially to the midpoint between the medial malleolus and the heel (medial calcaneal tubercle).

Branches are: circumflex fibular, peroneal, nutrient, medial and lateral plantar.

The circumflex fibular artery (sometimes from the *anterior* tibial artery) passes laterally round the fibula's neck through the soleus to anastomose with the lateral inferior genicular, medial

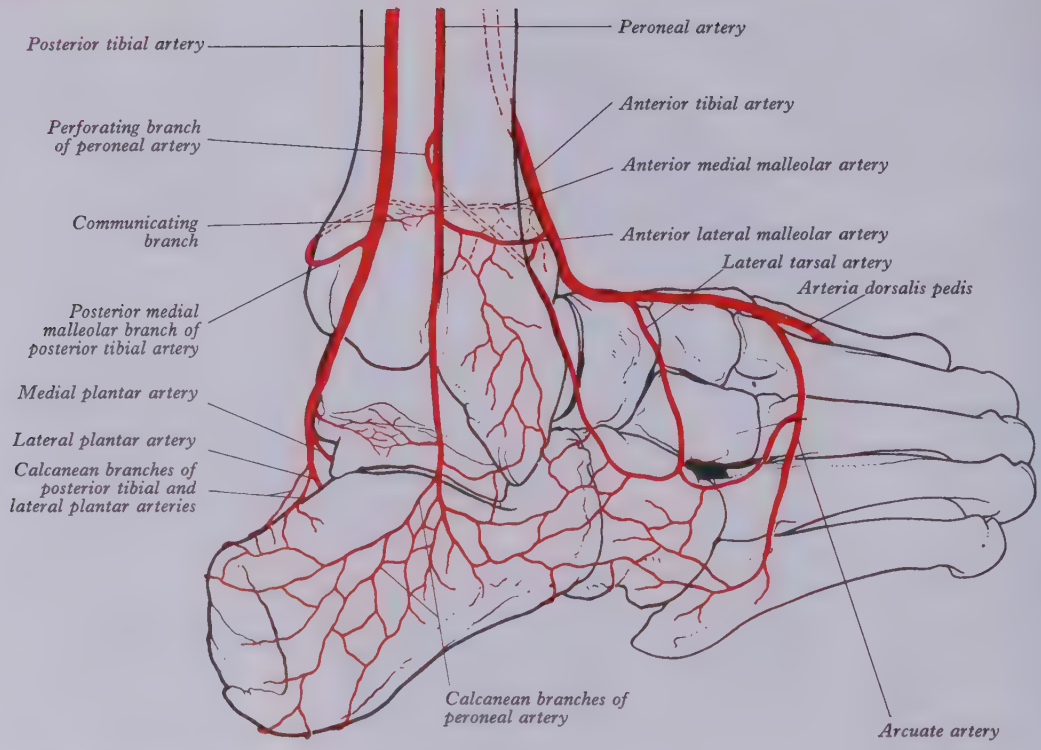
6.137 The right anterior tibial and dorsalis pedis arteries. A large part the tibialis anterior has been excised and the extensor hallucis longus retracted laterally to expose the anterior tibial artery.

6.138 Transverse section through the right leg, about 10 cm below the knee joint: inferior (distal) aspect. At a slightly lower level the flexor digitorum longus intervenes between the soleus and the fascia on the posterior surface of the tibialis posterior.



genicular and anterior tibial recurrent arteries. It supplies bone and articular structures.

The peroneal artery (**6**.134), arising about 2.5 cm distal to popliteus, passes obliquely to the fibula, descending along its medial crest in a fibrous canal between tibialis posterior and flexor hallucis longus or in the latter. Reaching the inferior tibiofibular syndesmosis it divides into the calcanean branches, ramifying on the lateral and posterior surfaces of the calcaneus. *Proximally* it is covered by the soleus and deep transverse fascia, between this and the deep muscles; *distally* it is overlapped by flexor hallucis longus.



Variations. The artery may spring earlier from the posterior tibial, or even the popliteal, sometimes 7 or 8 cm *distal* to popliteus. It is more often enlarged and either joins and reinforces the posterior tibial artery or replaces it in the distal leg and foot.

Muscular branches supply soleus, tibialis posterior, flexor hallucis longus and peronei. A *nutrient artery* runs proximally into the fibula. A *perforating branch* traverses the interosseous membrane about 5 cm proximal to the lateral malleolus to enter the extensor compartment, where it anastomoses with the anterior lateral malleolar artery; descending anterior to the inferior tibiofibular syndesmosis, it supplies the tarsus, anastomosing with the lateral tarsal artery. This branch is sometimes enlarged and may replace the arteria dorsalis pedis. A *communicating branch* connects it about 5 cm proximal to the ankle to a *communicating branch* of the posterior tibial. The *calcanean* or terminal branches anastomose with the anterior lateral malleolar and calcanean branches of the posterior tibial artery.

The nutrient artery of the tibia arises from the posterior tibial near its origin; supplying a few muscular rami it descends into bone immediately distal to the soleal line. It is one of the largest of the nutrient arteries. **Muscular branches** are distributed to the soleus and deep flexors of the leg. **The communicating branch** of the posterior tibial runs posteriorly across the tibia about 5 cm above its distal end, deep to flexor hallucis longus, to join a communicating branch of the peroneal. **Medial malleolar branches** pass round the tibial malleolus to the medial malleolar network. **Calcanean branches** arise just

6.139 Transverse section through the right leg, about 6 cm above the tip of the medial malleolus: superior (proximal) aspect.

6.140 The arterial anastomoses of the ankle, tarsus and metatarsus.

proximal to the terminal division of the posterior tibial; they pierce the flexor retinaculum to supply the fat and skin behind the tendo calcaneus and in the heel and muscles on the tibial side of the sole; they anastomose with medial malleolar arteries and calcanean branches of the peroneal.

The medial plantar artery (**6**.141,142), the smaller terminal branch of the posterior tibial, passes distally along the medial side of the foot with the medial plantar nerve lateral to it. At first deep to abductor hallucis, it runs distally between this and flexor digitorum brevis, supplying both. Near the first metatarsal base,

 6.141 The plantar arteries of the right foot.

its calibre, diminished by muscular branches, is further diminished by a *superficial stem* and it then passes to reach the medial border of the hallux where it anastomoses with a branch of the first plantar metatarsal artery (vide infra). Its superficial stem trifurcates and supplies three *superficial digital branches* accompanying the digital branches of the medial plantar nerve to join the first to third plantar metatarsal arteries.

Surface Anatomy. The trunk of the artery begins midway between the medial malleolus and heel (medial calcaneal tubercle) extending towards the first interdigital cleft as far as the navicular bone.

The lateral plantar artery (**6**.141), the larger terminal branch of the posterior tibial, passes distally and laterally to the *fifth* metatarsal base, the lateral plantar nerve medial to it. (Note that the plantar nerves lie *between* the plantar arteries.) Turning medially, with the nerve's deep branch, to the interval between the first and second metatarsal bases, it unites with the arteria dorsalis pedis to complete the *plantar arch*. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius; running distally to the fifth metatarsal base it passes between flexor digitorum brevis and abductor digiti minimi and is covered by the plantar aponeurosis, superficial fascia and skin.

Branches. *Muscular branches* supply the adjoining muscles; *superficial branches* emerge along the lateral intermuscular septum to supply the skin and subcutaneous tissue lateral in the sole; *anastomotic branches* run to the lateral border, joining branches of the lateral tarsal and arcuate arteries. Sometimes a *calcanean* branch pierces abductor hallucis to supply the skin of the heel.

6.142 The plantar arteries: superficial dissection.

The Plantar Arch

This is deeply situated, extending from the fifth metatarsal base to the proximal end of the first interosseous space. Convex distally, it is plantar to the bases of the second to fourth metatarsal bones and corresponding interossei but dorsal to the oblique part of adductor hallucis.

Branches. Three perforating and four plantar metatarsal branches, and numerous rami supply the skin, fasciae and muscles in the sole. *Three perforating branches* ascend through the proximal ends of the second to fourth intermetatarsal spaces, between the heads of the dorsal interosseous muscles, anastomosing with the dorsal metatarsal arteries. *Four plantar metatarsal arteries* (**6**.141) extend distally between the metatarsal bones in contact with the interossei. Each divides into two *plantar digital arteries*, supplying the adjacent digital aspects. Near its division each plantar metatarsal sends dorsally a *distal perforating branch* to join a dorsal metatarsal artery. The *first plantar metatarsal* artery springs from the junction between the lateral plantar and dorsalis pedis arteries, sending a digital branch to the medial side of the hallux. The lateral digital branch for the fifth toe arises directly from the lateral plantar artery near the fifth metatarsal base.

Surface Anatomy. Beginning between the heel and medial malleolus, the lateral plantar artery crosses obliquely to a point 2.5 cm medial to the fifth metatarsal's tuberosity and with a slight distal convexity reaches the proximal end of the first inter-metatarsal space.

Applied Anatomy. Haemorrhage from the plantar arch is difficult to stem, due to the depth of the vessel and its important close relations. It must be treated like the palmar arches (p. 764).

THE VENOUS SYSTEM

Veins are divisible into three main systems: pulmonary, systemic and portal.

Pulmonary veins contain oxygenated blood, returning from the lungs to the heart. **Systemic veins** return venous blood to the heart from much of the rest of the body. *Superficial veins* are located in superficial fascia and are variable in disposition. *Deep veins* are beneath the deep fascia and are usually enclosed in connective tissue sheaths with accompanying arteries, the latter assisting venous return (p. 691). Smaller arteries are accompanied by *venae comitantes*, paired veins flanking them; larger arteries usually accompany single veins. Some however, run separately. Systemic veins are usually more variable than arteries; anastomoses are less frequent between larger veins. In many regions, such as the pelvis and vertebral column, veins form extensive plexuses devoid of valves. These plexuses are the basis of anastomosis between the veins of the trunk; they may also act as reservoirs of variable capacity. At many points, such as the junctional regions between the trunk and limbs and near joints, valved *connecting veins* join superficial and deep systemic veins.

The portal vein receives tributaries draining venous blood from almost the whole subdiaphragmatic intestinal tract and associated extrinsic glands and spleen: the whole of this blood passes through the hepatic circulation before returning to general systemic venous channels.

Pulmonary Veins

Pulmonary veins return oxygenated blood to the left atrium. Usually four, two from each lung and destitute of valves, they commence in capillary networks in the alveolar walls. By repeated junctions tributary veins finally form a single trunk in each lobe, i.e. three in the right lung, and two in the left. The right middle and superior lobar veins usually join so that two veins, superior and inferior, leave each lung; they perforate the fibrous pericardium and open separately and posterosuperiorly into the left atrium (**6**.31,35). Occasionally the three right lobar veins remain separate. Sometimes the two left pulmonary veins form a single trunk. Occasionally the two left pulmonary veins, each draining a lobe, may be augmented by an *accessory lobar vein* from each lobe and these may unite to form a *third* left pulmonary vein (Corry & Valentine 1959).

In the pulmonary hilum (pp. 1275, 1284) the superior pulmonary vein is antero-inferior to the pulmonary artery,

the inferior being the most inferior hilar structure and also slightly posterior. The principal bronchus is posterior to the pulmonary artery. On the right the superior pulmonary vein passes posterior to the superior vena cava, the inferior behind the right atrium. On the left both pass anterior to the descending thoracic aorta. In the pericardium, they are partly covered by serous pericardium. Between the terminations of the right and left veins is, centrally, the oblique pericardial sinus and, laterally, directed medially and upwards, smaller, variable pulmonary venous pericardial recesses (p. 696).

The Systemic Veins

Systemic veins form three groups: (1) *cardiac veins*, (2) veins of the upper limbs, head, neck and thorax, all draining to the *superior vena cava*, (3) veins of the lower limbs, abdomen and pelvis, all draining to the *inferior vena cava*.

CARDIAC VEINS

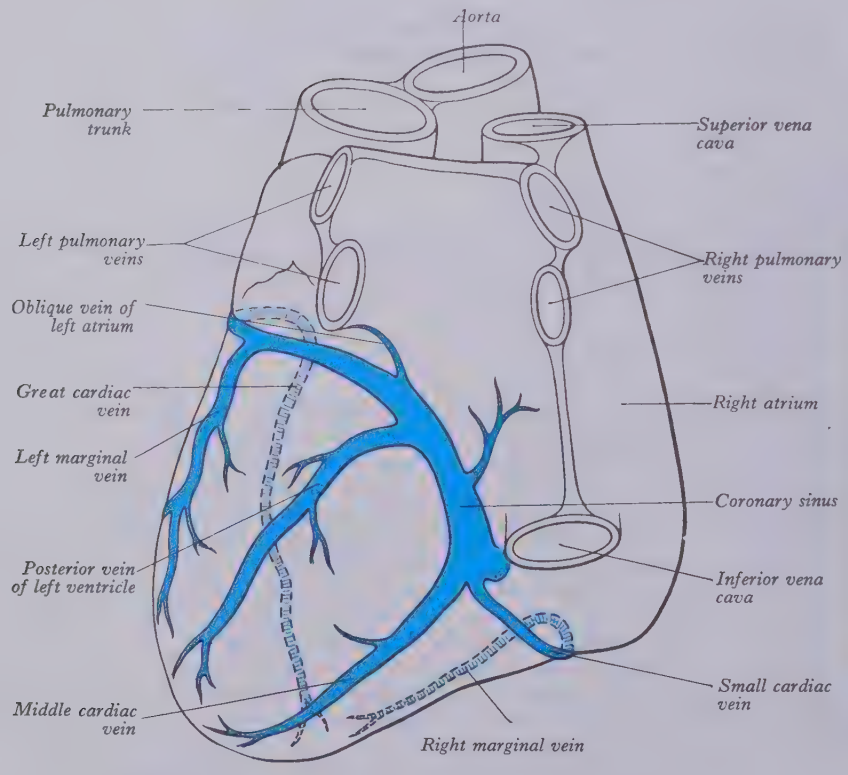
Veins draining the heart may be grouped as: (1) the *coronary sinus* and tributaries, returning blood to the right atrium from the whole heart (including its septa) except the anterior region of the right ventricle and small, variable parts of both atria and left ventricle; (2) the *anterior cardiac veins* draining an anterior part of the right ventricle and a region around the right cardiac border when the right marginal vein joins this group, ending principally in the right atrium; (3) the *venae cordis minimae* (Thebesian veins), opening into the right atrium and ventricle and, to a lesser extent, the left atrium and sometimes left ventricle.

CORONARY SINUS

Most cardiac veins drain to the wide coronary sinus, about 2 or 3 cm long, lying posterior in the coronary sulcus (atrioventricular groove) between the left atrium and ventricle (**6**.31,143A,B). It ends in the right atrium between the inferior vena caval opening and the right atrioventricular orifice, its opening displaying a semilunar *valve of the coronary sinus* (**6**.32,37). Its tributaries are the great, small and middle cardiac veins, the posterior vein of the left ventricle and the oblique vein of the left atrium, all except the last having valves at their orifices.

The great cardiac vein (**6**.143A,B) begins at the cardiac apex, ascends in the anterior interventricular sulcus to the coronary sulcus and follows this to the left and round posterior to the heart to enter the beginning of the coronary sinus. It receives tributaries from left atrium and both ventricles, including the large *left marginal vein* ascending the left aspect ('obtuse border') of the heart.

The small cardiac vein (**6**.143A,B) is posterior in the coronary sulcus between the right atrium and ventricle and opens into the coronary sinus near its atrial end. It receives blood from the back of the right atrium and ventricle; the *right marginal vein* passes right, along the inferior cardiac margin ('acute border'), and may join the small cardiac vein in the coronary sulcus but more often opens directly into the right atrium.



The middle cardiac vein (**6**.115) begins at the cardiac apex, runs back in the posterior interventricular groove to end in the coronary sinus near its atrial end.

The posterior vein of the left ventricle (**6**.143A,B) is on the diaphragmatic surface of the left ventricle a little left of the middle cardiac vein; it usually opens into the centre of the coronary sinus but sometimes into the great cardiac vein.

The oblique vein of the left atrium, a small vessel, descends obliquely on the back of the left atrium to join the coronary sinus near its left extremity; it is continuous above with the *ligament of the left vena cava* (p. 696); the two structures are remnants of the left common cardinal vein.

ANTERIOR CARDIAC VEINS

The *anterior cardiac veins* drain the anterior part of the right ventricle. Usually two or three, sometimes even five (Baroldi & Scomazzoni 1967), they ascend in subepicardial tissue to cross the right part of the atrioventricular sulcus, passing deep or superficial to the right coronary artery. They end in the right atrium, near the sulcus, separately or in variable combinations. A

6.143A The principal veins of the heart.

6.143B A coloured resin cast of the coronary sinus and its tributaries. Of course, the venae cordis minimae and anterior cardiac veins are not filled. Compare with **6**.143A. Specimen by D H Tompsett, Department of Anatomy, Royal College of Surgeons of England.

subendocardial collecting channel, into which all may open, has been described (James 1961). **The right marginal vein** courses along the inferior ('acute') cardiac margin, draining adjacent parts of the right ventricle, and usually opens separately into the right atrium but may join the anterior cardiac veins or, less often, the coronary sinus. Because it is commonly independent it is often grouped with the venae cordis minimae but, since it is larger in calibre, it is comparable with the anterior cardiac veins or even wider. It is perhaps better considered one of the latter, which also sometimes drain with it into the coronary sinus. Mechanik (1934) described all cardiac veins as draining into the coronary sinus in the early fetal period.

VENAE CORDIS MINIMAE

The existence of *venae cordis minimae*, opening into all cardiac cavities, has been confirmed by many subsequent to their first recording by Thebesius (1708); they are more difficult to demonstrate than larger cardiac vessels. Their numbers and size are highly variable. Aho (1950) demonstrated 'minimal' veins of up to 2 mm in diameter opening into the right atrium and about 0.5 mm into the right ventricle. He found venae minimae numerous in the right atrium and ventricle, occasional in and often absent from the left atrium, and rare in the left ventricle. Grant & Regnier (1926) considered venae minimae as derived from the intertrabecular spaces of developing mammalian hearts.

Cardiac Venous Anastomoses

Most investigators accept widespread anastomosis at all levels of cardiac venous circulation, on a scale exceeding that of the arteries and amounting to a veritable venous plexus, according to some (Baroldi & Scomazzoni 1967). Not only are adjacent veins often connected but connections also exist between tributaries of the coronary sinus and those of the anterior cardiac veins (Mierzwa & Kozielec 1975). Regions of abundant anastomoses are the apex and its anterior and posterior aspects. Like coronary arteries (p. 731) cardiac veins connect with extracardiac vessels, chiefly the vasa vasorum of the large vessels continuous with the heart.

Variation in Cardiac Veins

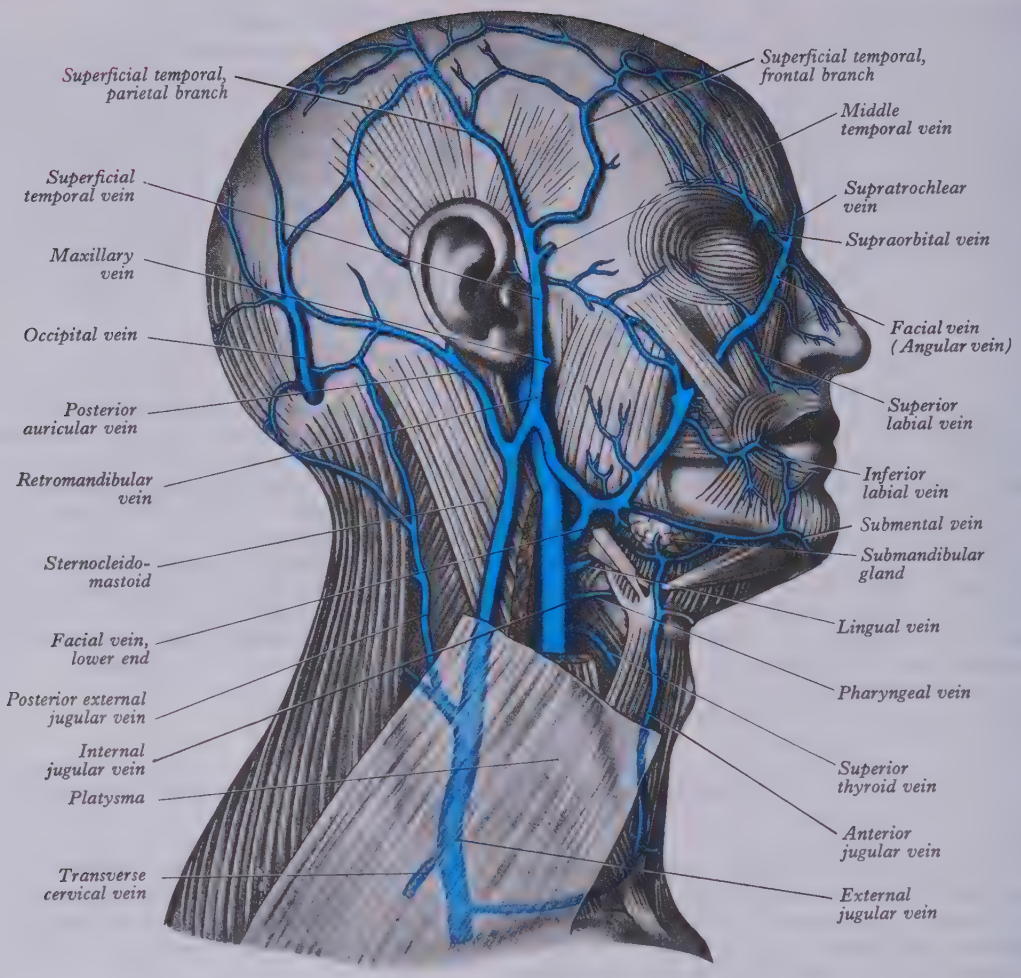
Attempts to categorize variations in cardiac venous circulation (Aho 1950) into 'types' have not produced any accepted pattern. Major variations concern the general directions of drainage. The coronary sinus may receive *all* cardiac veins (except the venae minimae), including the anterior cardiac veins (33%), which may be reduced by diversion of some into the small cardiac vein and then to the coronary sinus (28%); the remainder (39%) represent the 'normal' pattern, as described above. Baroldi & Scomazzoni (1967) distinguished two major variants: a majority (70%) in which the small cardiac vein is independent, small or absent and a less frequent pattern (30%) in which this vein, though variable in size, connects with both coronary and anterior cardiac 'systems'.

VEINS OF THE HEAD AND NECK

Veins of the head and neck may be grouped as: (1) veins of the exterior the of head and face, (2) cervical veins, (3) diploic, meningeal, intracranial veins and dural venous sinuses.

This classification is particularly significant at cranial level, where veins, like arteries, are arranged as a three-layered system: (*a*) vessels of the scalp, (*b*) dural vessels and (*c*) cerebral and cerebellar vessels. But the arteries and veins differ, largely in interconnections between the three layers. Arteries of the scalp and dura, both from the *external* carotid, intercommunicate to a limited extent, as do corresponding veins; but the latter, though quite variable, usually communicate much more extensively (emissary veins, p. 804). Dural or meningeal arteries, on the other hand, are independent of cerebral and cerebellar arteries, the latter being derived from the *internal* carotid, whereas dural venous sinuses share a drainage to the internal jugular vein which is also common to veins of the cerebrum and cerebellum. It is possible to hypothecate a *fourth* venous tier, the diploic veins; since these, however, drain into dural veins, they are here grouped with them, following Browder & Kaplan (1976). It is to be noted that intracranial veins communicate at many points with extracranial vessels by the emissary and other veins (p. 804).

In accounts of venous sinuses they are usually described as simple arrangements with a single lumen. Developmentally they emerge as venous *plexuses*; and it is clear, from angiographic studies and corrosion casts, that *most sinuses* preserve a *plexiform* arrangement to a variable degree. Browder & Kaplan (1976), examining human venous sinuses in hundreds of corrosion casts, have observed vascular plexuses adjoining, in particular, the superior and inferior sagittal and straight sinuses and, with a lesser incidence, the transverse sinuses. Details show much individual variation; departures from 'average' patterns are frequent in earlier years, e.g. the falx cerebelli may in infancy contain large plexiform channels and venous lacunae, augmenting the occipital sinus. Such variations cannot be detailed in a general text; in any case they must be established for the individual by angiography when clinical necessity arises; but the wide variation possible in the structure of cranial venous sinuses, with their plexiform nature and wide connections with cerebral and cerebellar veins, must be emphasized. Another kind of connection may be noted here; experiment shows (Rowbotham & Little 1962, Browder & Kaplan 1976) that parts of sinuses (and even diploic veins) can be filled by forcible internal carotid injection, suggesting the existence of arteriovenous shunts. Browder & Kaplan, by injection of the middle meningeal arteries, established a connection between these and the superior sagittal sinus at sites still unknown.



External Veins of the Head and Face

As with most superficial veins these are subject to variations, far too numerous to illustrate. Some major features are, however, relatively constant; a common pattern is shown in **6**.144.

The supratrochlear vein starts on the forehead from a venous network connected to the frontal tributaries of the superficial temporal vein. Veins from this form a single trunk, descending near the midline parallel with its fellow to the radix nasi, across which they are joined by a *nasal arch* draining the dorsum nasi. The veins then diverge, each joining a *supraorbital vein* to form the *facial vein* near the *medial canthus*. Supratrochlear veins may join, dividing again on the radix nasi to form the two facial veins.

The supraorbital vein begins near the zygomatic process of the frontal bone, connecting with radicles of the superficial and middle temporal veins. Passing *medially* above the orbital opening under orbicularis oculi, it pierces this to form the *facial vein* by joining the supratrochlear near the medial canthus. A branch through the supraorbital notch joins the superior ophthalmic vein, receiving in the notch veins from the frontal sinus and frontal diploë.

The facial vein, receiving the supratrochlear and supraorbital veins, descends obliquely near the side of the radix nasi, receding from the ala, and then turns posterolaterally below the orbital opening, passing downwards and backwards behind the facial artery, being less tortuous. It passes under zygomaticus major, risorius and platysma and then descends on to the anterior border and then the surface of masseter, crosses the body of the mandible and runs obliquely back under the platysma but superficial to the submandibular gland, digastric and stylohyoid. A little anteroinferior to the mandibular angle it is joined by the anterior division of the retromandibular vein; descending superficial to the lingual artery's loop, the hypoglossal nerve and external and internal carotid arteries, it enters the internal jugular near the greater cornu of the hyoid bone (i.e. in the upper angle of the

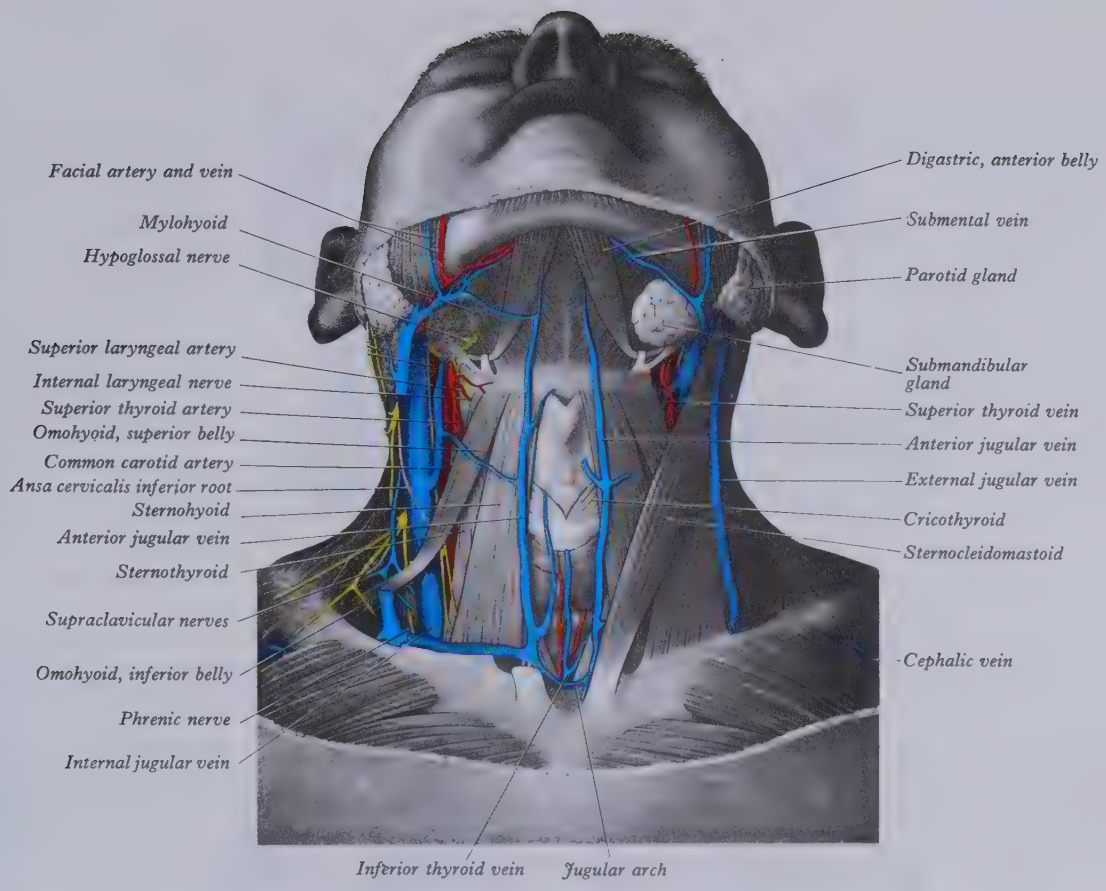
6.144 The veins of the right side of the head and neck. Parts of the right sternocleidomastoid and platysma have been excised to expose the trunk of the internal jugular vein. The external jugular vein is visible through the lower part of the platysma.

carotid triangle). Near its end a large branch often descends along the anterior border of sternocleidomastoid to the anterior jugular vein. Its uppermost segment, above its junction with the superior labial vein (vide infra), is often termed the *angular vein*.

Tributaries. Near its beginning the facial vein connects with the superior ophthalmic directly and via the supraorbital; it is thus connected to the cavernous sinus. It receives veins of the ala nasi and, lower, a large *deep facial vein* from the pterygoid venous plexus and also the inferior palpebral, superior and inferior labial, buccinator, parotid and masseteric veins. Below the mandible, submental, tonsillar, external palatine (paratonsillar) and submandibular veins join it and sometimes the vena comitans of the hypoglossal nerve, and the pharyngeal and superior thyroid veins.

Applied Anatomy. The facial vein has no valves. It connects, as noted, with the cavernous sinus by two routes: through the ophthalmic vein or its supraorbital tributary, or by the deep facial vein to the pterygoid plexus and hence the cavernous sinus. Infection may thus spread from the face to the intracranial venous sinuses.

The superficial temporal vein (6.144) begins in a widespread network joined across the scalp to the contralateral vein and to the ipsilateral supratrochlear, supraorbital, posterior auricular and occipital veins, all draining the same network. Anterior and posterior tributaries unite above the zygoma to form the superficial temporal, joined here by the *middle temporal vein*. It crosses the posterior root of the zygoma and enters the parotid gland to join the maxillary vein, to form the *retromandibular vein*.



Tributaries are the parotid veins, rami from the temporomandibular joint, anterior auricular veins, and *transverse facial vein*. The middle temporal vein, after receiving the *orbital vein* which is formed by the lateral palpebral veins, passes back between layers of temporal fascia, piercing this to join the superficial temporal vein.

The pterygoid venous plexus is partly between temporalis and the lateral pterygoid, and partly between the pterygoids. Sphenopalatine, deep temporal, pterygoid, masseteric, buccal, dental, greater palatine and middle meningeal veins and a branch or branches from the inferior ophthalmic are all tributaries. The plexus connects by the *deep facial vein* with the facial and with the cavernous sinus through the sphenoidal emissary foramen, foramen ovale and foramen lacerum. Its deep temporal tributaries often connect with tributaries of the anterior diploic (p. 798) and thus with the middle meningeal veins.

The maxillary vein, a short trunk, accompanies the first part of the maxillary artery; it is the confluence of veins from the pterygoid plexus, passing back between the sphenomandibular ligament and mandibular neck, uniting with the superficial temporal to form the retromandibular vein.

The retromandibular vein descends in the parotid gland, between the external carotid artery and superficially the facial nerve. It divides into an anterior branch going forwards to join the facial and a posterior branch joining the posterior auricular to form the *external jugular vein*. Occasionally it is not connected to the external jugular, which is then small, the anterior jugular often being enlarged.

The posterior auricular vein (6.144) begins in a parieto-occipital network also draining into tributaries of the occipital and superficial temporal veins. It descends behind the auricle to join

6.145 Anterior view of the veins of the neck.

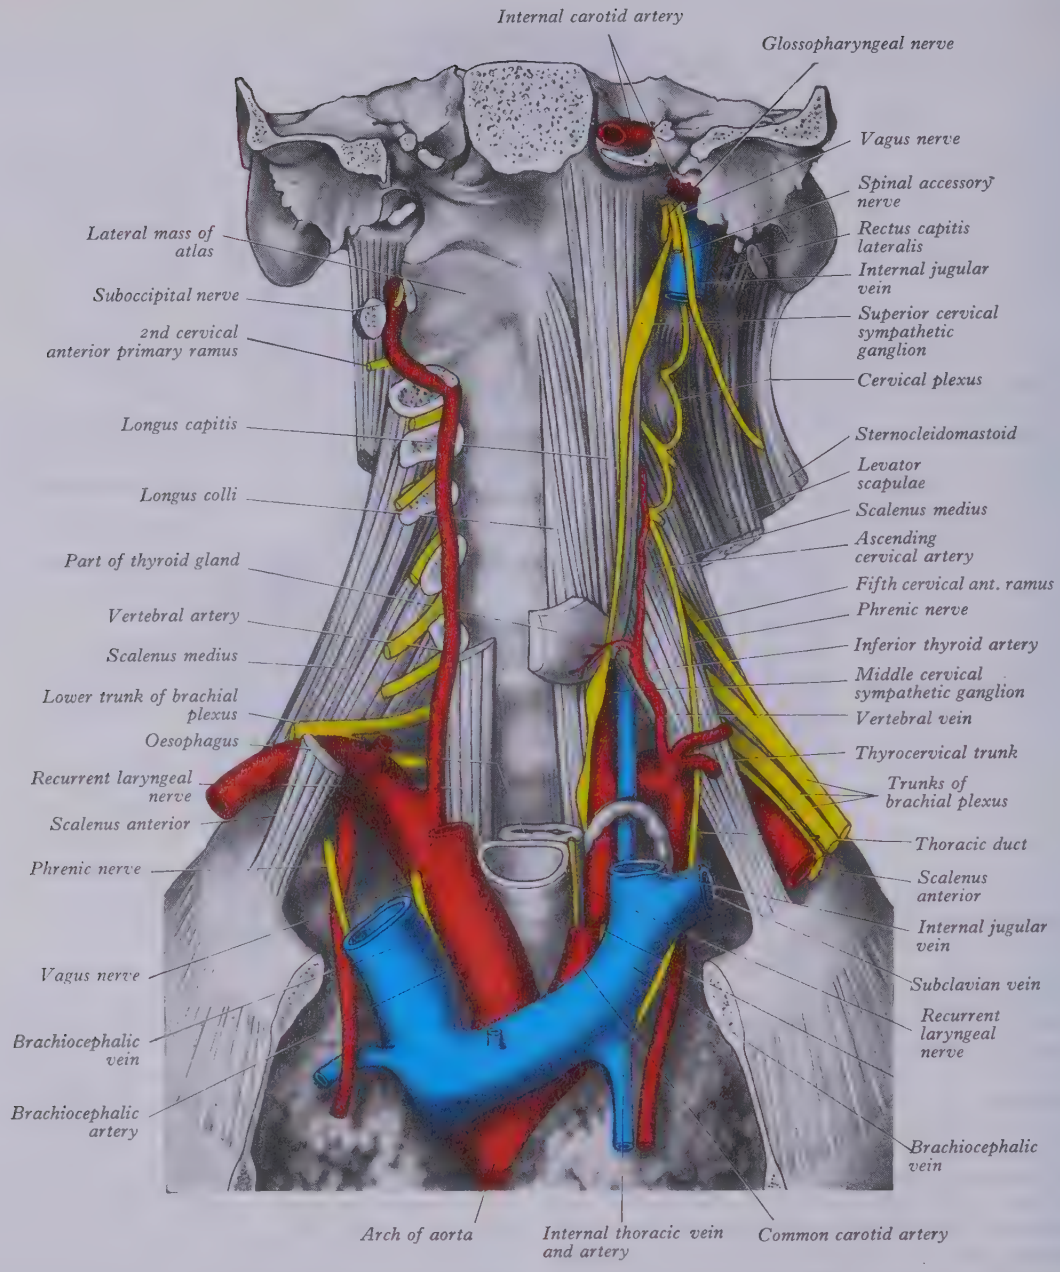
the posterior division of the retromandibular vein in or just below the parotid gland, to form the external jugular. It receives a stylomastoid vein and tributaries from the cranial surface of the auricle.

The occipital vein (**6**.144) begins in a posterior network in the scalp, pierces the cranial attachment of trapezius, turns into the suboccipital triangle and joins the deep cervical and vertebral veins. It may follow the occipital artery to end in the internal jugular; sometimes it joins the posterior auricular and hence the external jugular vein. Parietal and mastoid emissary veins link it with the superior sagittal and transverse sinuses. The occipital diploic vein sometimes joins it (p. 794).

Veins of the Neck (6.144,145,161)

These are divisible into those either *superficial* or *deep* to the deep fascia but these are not entirely separate. Superficial veins, tributaries (some with specific names, given below) of the external jugular, drain a much smaller volume of tissue than the deep veins, which drain all but the subcutaneous structures, mostly into the internal jugular vein (but some into the vertebral veins).

The external jugular vein (**6**.144) largely drains the scalp and face but also some deeper parts. The union of the posterior division of the retromandibular and posterior auricular veins begins near the mandibular angle just below or in the parotid gland, descending from the angle to the mid-clavicle. It crosses obliquely, superficial to sternocleidomastoid, to the subclavian triangle, where it traverses the deep fascia to end in the subclavian vein, lateral or anterior to scalenus anterior. Its wall is adherent to the rim of the fascial opening. It is covered by platysma, superficial fascia and skin, separated from sternocleidomastoid by deep cervical fascia; it crosses the transverse cervical nerve and is parallel with the great auricular nerve, ascending posterior to its upper half. In size the vein is inversely proportional to other veins in the neck; it is occasionally double. It has valves at its entrance into the subclavian vein and about 4 cm above the clavicle, between which it is often dilated, as a so-called *sinus*. The valves do not prevent regurgitation.



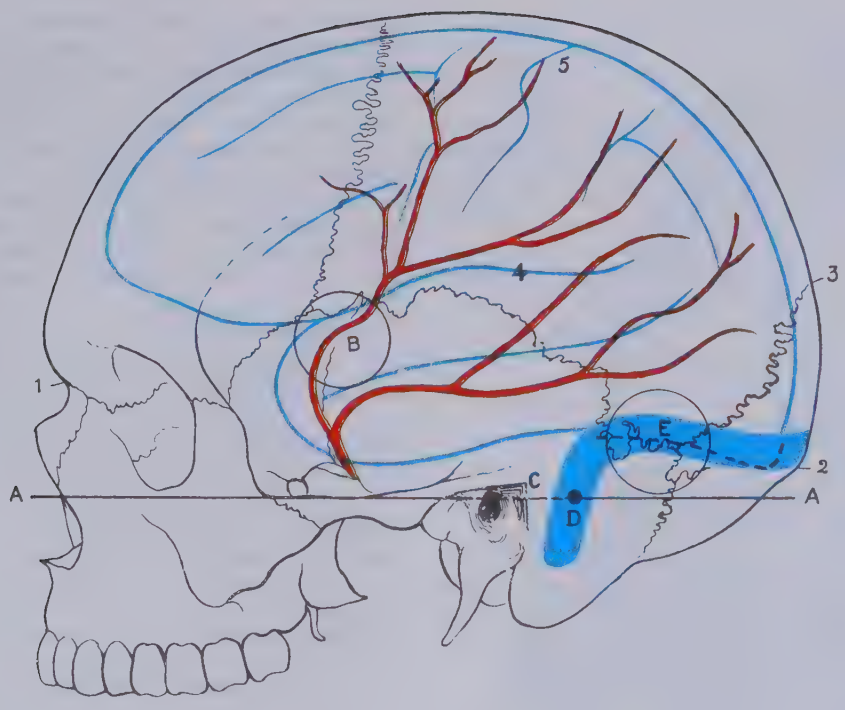
Tributaries. In addition to formative tributaries, the external jugular receives the posterior external jugular and, near its end, transverse cervical, suprascapular and anterior jugular veins; in the parotid gland it is often joined by a branch from the internal jugular. The occipital vein occasionally joins it.

The posterior external jugular vein begins in the occipital scalp and drains the skin and the superficial muscles posterosuperior in the neck. It usually joins the middle part of the external jugular.

The anterior jugular vein (**6**.144,145) starts near the hyoid bone by the confluence of the superficial submandibular veins. It descends between the midline and the anterior border of sternocleidomastoid; turning laterally, low in the neck, posterior (deep) to the muscle but superficial to the hyoid depressors, it joins the end of the external jugular vein or the subclavian vein directly. In size it is usually inverse to the external jugular. It communicates with the internal jugular, receiving the laryngeal veins and sometimes a small thyroid vein. There are usually two anterior jugular veins, united just above the manubrium by a large transverse *jugular arch*, receiving the inferior thyroid tributaries. They have no valves and may be replaced by a midline trunk.

Surface Anatomy. Usually the *external jugular vein* is visible as it crosses the sternocleidomastoid; to assist visibility it can be distended by expiring against resistance or by gentle supraclavicular digital pressure. Similarly the *anterior jugular vein* can often be made visible in the upper two-thirds of the neck. The end of the facial vein runs from a point, where the anterior border of the masseter meets the inferior mandibular border, to the greater hyoid cornu.

The internal jugular vein (**6**.144,145) collects blood from the skull, brain, superficial parts of face and much of the neck. It begins at the cranial base in the posterior compartment of the jugular foramen, continuous with the sigmoid sinus. At its origin



6.146 A dissection to show the prevertebral region and the superior mediastinum. On the right the costal elements of the upper six cervical vertebrae have been removed to expose the cervical part of the vertebral artery. On the left most of the deep relations of the common carotid artery and the internal jugular vein are exposed. Details of the terminal parts of the left lymphatic trunks have been omitted.

is its *superior bulb*, which is below the posterior part of the tympanic floor. The vein descends in the carotid sheath (p. 582), uniting with the subclavian, posterior to the sternal end of the clavicle, to form the brachiocephalic vein. It is also dilated near its end as its *inferior bulb*, above which it contains a pair of valves. *Posterior* to the vein, from above, are: the rectus capitis lateralis, transverse process of atlas, levator scapulae, scalenus medius and cervical plexus, scalenus anterior, phrenic nerve, thyrocervical trunk, vertebral vein and first part of subclavian artery; on the left it also crosses anterior to the thoracic duct (**6**.146). *Medial* to the vein are the internal and common carotid arteries and the vagus nerve between vein and arteries but posterior to them. *Superficially* the vein is overlapped above, then covered below by sternocleidomastoid and crossed by the posterior belly of the digastric and the superior belly of omohyoid. Superior to the digastric, the parotid gland and styloid process are superficial, the accessory nerve, posterior auricular and occipital arteries crossing the vein. Between the digastric and the omohyoid, the sternocleidomastoid arteries and inferior root of the ansa cervicalis cross it, but the nerve often passes between the vein and the common carotid. Below the omohyoid, it is covered by the infrahyoid muscles and the sternocleidomastoid and it is crossed by the anterior jugular vein. Deep cervical lymph nodes lie along the vein, mainly on its superficial aspect. At the root of the neck the right internal jugular is separated from the common carotid, but the left usually overlaps its artery. At the base of the skull the internal carotid artery is *anterior*, separated from the vein by the *ninth to twelfth cranial nerves*.

Surface Anatomy. The vein is represented in surface projection by a broad band from the ear's lobule to the medial end of the clavicle; its inferior bulb is in the interval (depression) between the sternal and clavicular heads of the sternocleidomastoid (i.e. the bulb bulges into the *lesser supraclavicular fossa*; a needle may be inserted here with precision).

Tributaries are: the inferior petrosal sinus, facial, lingual, pharyngeal, superior and middle thyroid veins, sometimes the occipital. It may communicate with the external jugular vein. The thoracic duct opens near the union of the left subclavian and internal jugular veins; the right lymphatic duct is at the same site on the right.

6.147 The relations of the brain, the middle meningeal artery and the transverse and sigmoid sinuses to the surface of the skull. 1. Nasion. 2. Inion. 3. Lambda. 4. Lateral cerebral sulcus. 5. Central sulcus. AA = Frankfurt plane, which traverses the lower margin of the orbital opening and the upper margin of the external acoustic meatus. B = area (including the pterion) for trephining over the frontal branch of the middle meningeal artery and the cerebral Sylvian point. C = Suprameatal triangle, D = sigmoid sinus, E = area for trephining over the transverse sinus, exposing the dura mater of both cerebrum and cerebellum. The outline of the cerebral hemisphere and its major sulci are indicated in blue; the course of the middle meningeal artery is in red.

The inferior petrosal sinus leaves through the anterior part of the jugular foramen, crosses lateral or medial to the ninth to eleventh cranial nerves and joins the superior jugular bulb.

The lingual veins follow two routes: (1) *Dorsal lingual veins* drain the dorsum and sides of the tongue and join the *lingual veins* accompanying the lingual artery between the hyoglossus and genioglossus. Near the greater cornu of the hyoid bone they join the internal jugular. (2) The *deep lingual vein* begins near the tip and runs back near the mucous membrane on the tongue's inferior surface. Near the anterior border of hyoglossus it joins a *sublingual vein*, from the salivary gland, to form the *vena comitans nervi hypoglossi* which runs back between the mylohyoid and hyoglossus with the hypoglossal nerve to join the facial, internal jugular or lingual vein.

The pharyngeal veins begin in a *pharyngeal plexus* external to the pharynx. After receiving meningeal veins and a vein from the pterygoid canal, they end in the internal jugular but sometimes in the facial, lingual or superior thyroid vein.

The superior thyroid vein (**6**.144,145), formed by deep and superficial tributaries corresponding to the arterial branches, accompanies the artery and receives the superior laryngeal and crico-thyroid veins, ending in the internal jugular or facial vein.

The middle thyroid vein (**6**.145) drains the lower part of the gland and also receives veins from the larynx and trachea. It crosses anterior to the common carotid artery to join the internal jugular vein behind the superior belly of omohyoid.

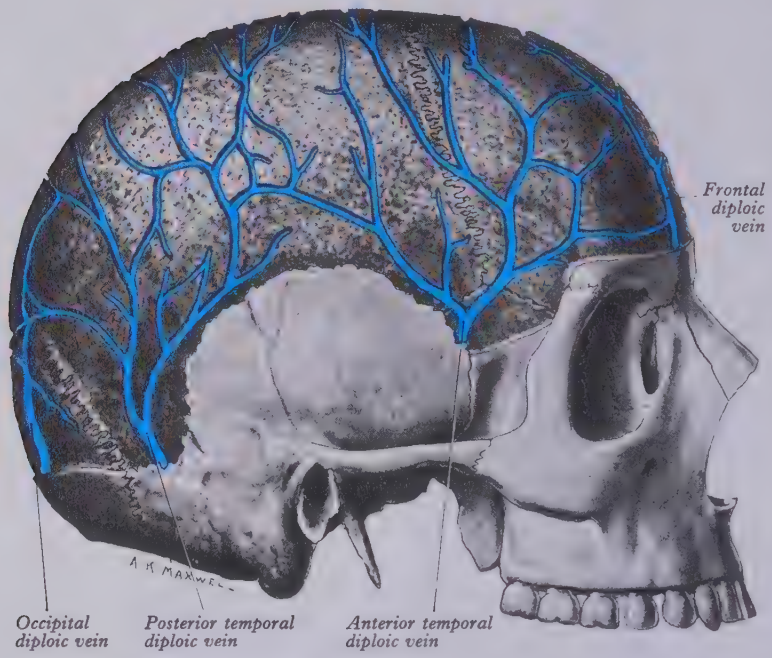
Facial and occipital veins are described on pp. 793, 794, inferior thyroid veins on p. 808.

Applied Anatomy. When the superior jugular bulb thromboses (e.g. in otitis media), the glossopharyngeal, vagus and accessory nerves may be involved. The internal jugular vein may be endangered during removal of tuberculous or neoplastic lymph nodes.

Venous pulsation may be visible in the external jugular at the root of the neck. There are no valves in the brachiocephalic veins or the superior vena cava; hence the right atrial systole causes a wave of distension up these vessels, which may appear as a feeble flicker over the external jugular vein. This atrial systolic impulse is much increased when the right atrium is abnormally distended or hypertrophied, as in disease of the mitral valve.

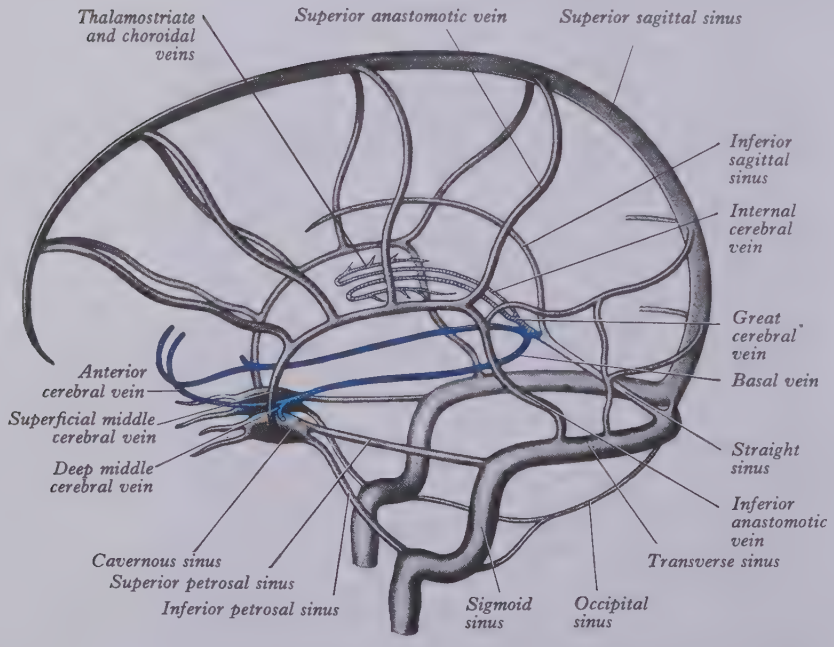
The vertebral vein is formed in the suboccipital triangle by many small tributaries from internal vertebral plexuses which leaves the vertebral canal above the posterior atlantal arch. They join small veins from local deep muscles to form a vessel which enters the foramen in the atlantal transverse process to descend, as a plexus around the vertebral artery, through successive transverse foramina. This ends as the vertebral vein, emerging from the sixth cervical transverse foramen, whence it descends, at first anterior then anterolateral to the vertebral artery, to open superoposteriorly into the brachiocephalic vein; the opening has a paired valve. The vertebral vein descends behind the internal jugular, passing in front of the first part of the subclavian artery (**6**.146). A small *accessory vertebral vein* usually descends from the vertebral plexus, traverses the seventh cervical transverse foramen and turns forwards between the subclavian artery and the cervical pleura to join the brachiocephalic vein.

Tributaries. The vein connects with the sigmoid sinus by a vessel in the posterior condylar canal, when this exists. It also receives branches from the occipital vein, prevertebral muscles, internal and external vertebral plexuses. It is joined by anterior vertebral and deep cervical veins (vide infra) and sometimes near its end by the first intercostal vein.



The anterior vertebral vein starts in a plexus around the upper cervical transverse processes, descends near the ascending cervical artery between attachments of scalenus anterior and longus capitis and opens into the end of the vertebral vein.

The deep cervical vein accompanies its artery between the semispinales capitis et cervicis. It begins in the suboccipital region from communicating branches of the occipital and veins from suboccipital muscles and also from plexuses around the cervical spines. It passes forwards between the seventh cervical transverse process and the neck of the first rib to end in the lower part of the vertebral vein.



Cranial and Intracranial Veins

DIPLOIC VEINS

These veins occupy channels in the diploë of some cranial bones (**6**.148) and are devoid of valves. They are large, with dilatations at irregular intervals; their thin walls are merely endothelium supported by elastic tissue. Radiographically they may appear as relatively transparent bands 3 or 4 mm wide. Absent at birth, they begin to develop with the diploë at about two years. They communicate with meningeal veins, dural sinuses and pericranial veins. Recognizably regular channels are: (1) *a frontal diploic vein*, emerging from bone in the supraorbital foramen to join the supraorbital vein; (2) *an anterior temporal (parietal) diploic vein*, confined chiefly to the *frontal* bone, which pierces the greater wing of the sphenoid to end in the sphenoparietal sinus or anterior deep temporal vein; (3) *a posterior temporal (parietal) diploic vein*, in the parietal bones, descending to the parietal mastoid angle to join the transverse sinus through a foramen at the angle or mastoid foramen; (4) *an occipital diploic vein*, the largest, confined to the occipital bone, opening into occipital veins or the transverse sinus near the confluence of sinuses or into an occipital emissary vein. Numerous small diploic veins emerge near the superior sagittal sinus to end in its venous lacunae (p. 800).

6.148 The veins of the diploë, displayed by the removal of the outer table of the skull.

6.149 Schema of the venous sinuses of the dura mater and their connections with the cerebral veins. The more deeply placed cerebral veins are shown in blue and those inside the brain are shown in *interrupted* blue.

MENINGEAL VEINS

Meningeal veins begin from plexiform vessels in the dura mater and drain into efferent vessels in the outer dural layer which connect with lacunae of the superior sagittal sinus and with other cranial sinuses, including those accompanying the middle meningeal arteries (p. 740), and with diploic veins.

CEREBRAL AND CEREBELLAR VEINS

Veins of the brain (p. 1085) have no valves; their thin walls have no muscular tissue. They pierce the arachnoid mater and the inner dural layer to open into the cranial venous sinuses. They comprise cerebral and cerebellar veins and veins of the brain stem.

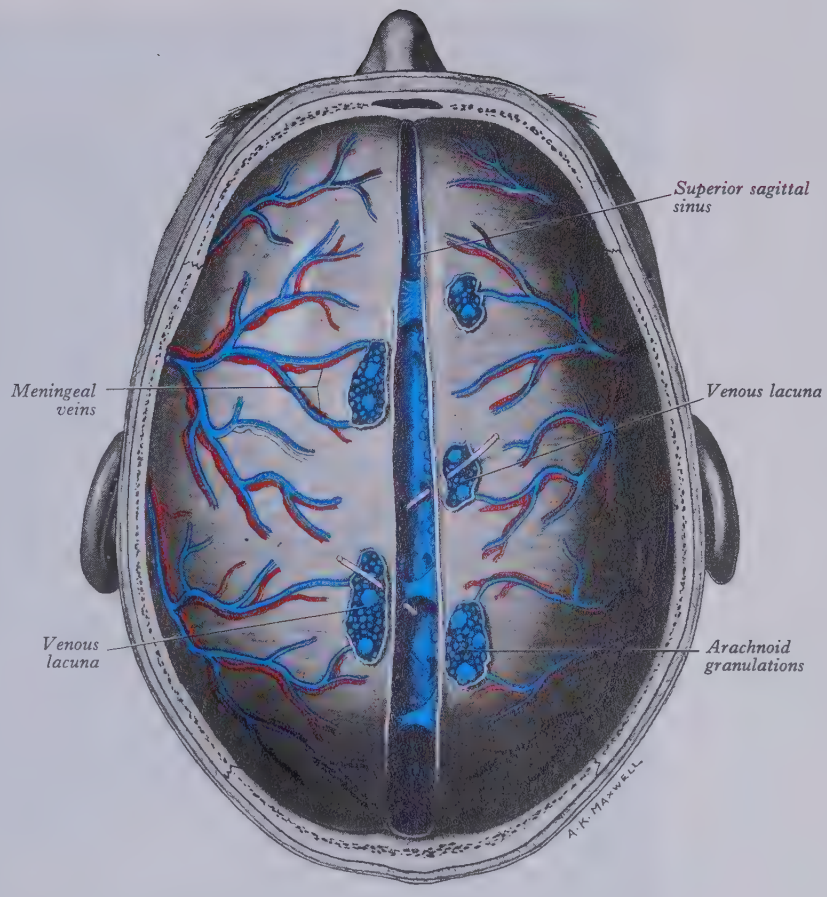
The cerebral veins (**6**.149), external and internal, drain the surfaces and interior of the hemispheres. **The external cerebral veins** form *superior, middle* and *inferior* groups.

The superior cerebral veins, eight to twelve to each hemisphere, drain their superolateral and medial surfaces and mainly follow the sulci, though some cross the gyri. Ascending to the superomedial border, they receive small veins from the medial surface and open into the superior sagittal sinus; anterior veins open almost at right angles; the larger, posterior veins are directed obliquely forwards against the current in the sinus. This may resist the collapse of thin-walled cerebral veins which might result from a rise of intracranial pressure; but another factor is the backward growth of the cerebral hemispheres and the consequent displacement of vessels during development.

The superficial middle cerebral vein begins on the lateral surface, following the posterior ramus and stem of the lateral sulcus to end in the cavernous sinus. A *superior anastomotic vein* runs posterosuperiorly between the middle cerebral vein and the superior sagittal sinus, thus connecting the superior sagittal and cavernous sinuses. An *inferior anastomotic vein* courses over the temporal lobe, connecting the middle cerebral vein to the transverse sinus.

The inferior cerebral veins are small. Those on the frontal orbital surface join the superior cerebral veins and thus drain to the superior sagittal sinus; those on the temporal lobe anastomose with basal and middle cerebral veins, draining to the cavernous, superior petrosal and transverse sinuses.

The basal vein begins at the anterior perforated substance by the union of: (1) a small *anterior cerebral vein*, accompanying the anterior cerebral artery; (2) *a deep middle cerebral vein* receiving tributaries from the insula and neighbouring gyri and running in the lateral cerebral sulcus; and (3) *striate veins* emerging from the anterior perforated substance. The basal vein passes back round the cerebral peduncle to the great cerebral vein (**6**.149), receiving tributaries from the interpeduncular fossa, inferior cornu of the lateral ventricle, parahippocampal gyrus and midbrain.

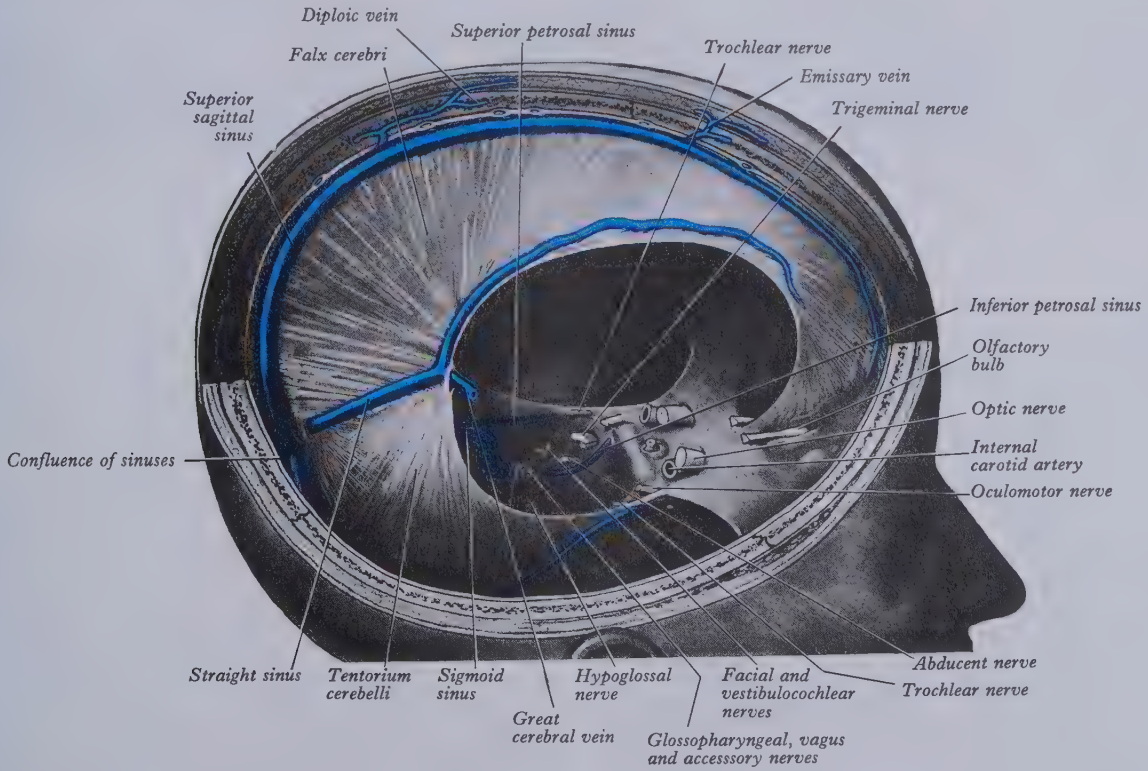


The internal cerebral vein drains the deep parts of its hemisphere; it is formed near the interventricular foramen primarily by the *thalamostriate* and *choroid veins*. Numerous smaller veins from surrounding structures also converge here; each runs back parallel to its fellow between the layers of the tela choroidea of the third ventricle and below the splenium, where they join to form the median *great cerebral vein* (**6**.149).

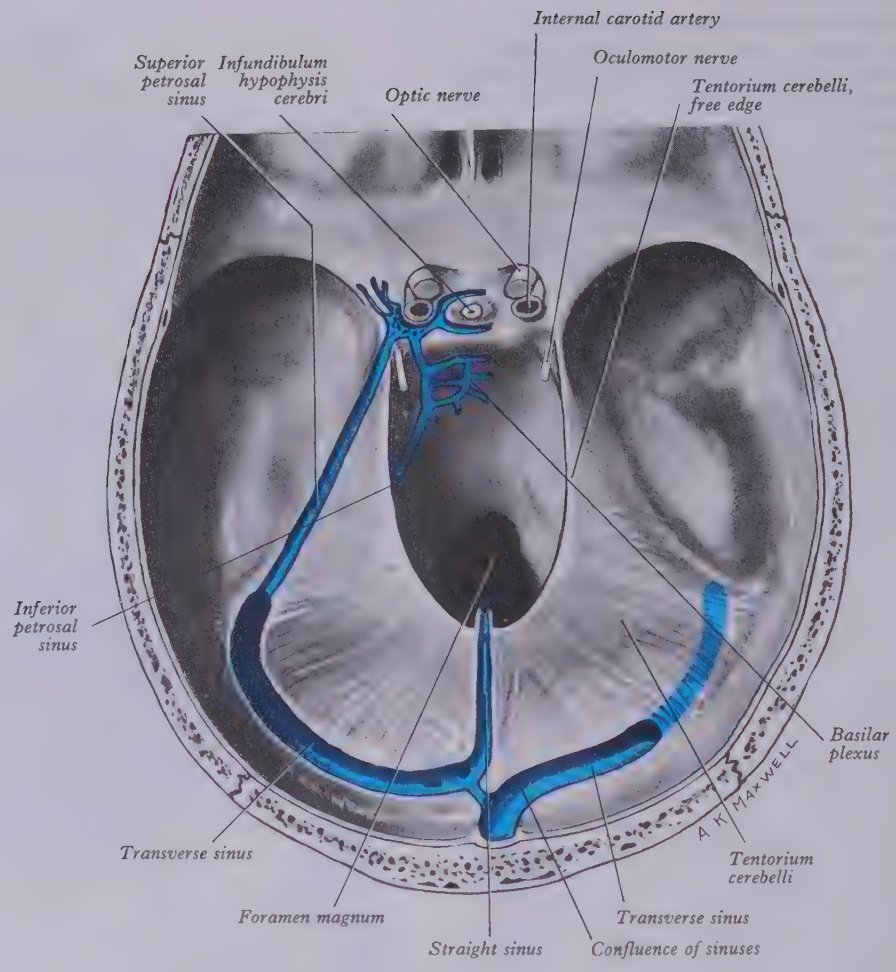
The thalamostriate vein runs anteriorly between the caudate nucleus and thalamus, receives many veins from both and unites behind the anterior column of the fornix with the choroid vein to form the internal cerebral. The *choroid vein* runs along (curves or 'spirals' along) the whole choroid plexus, receiving veins from the hippocampus, fornix, corpus callosum and adjacent structures.

The great cerebral vein starts by union of the two internal cerebral veins as a short median vessel *curving sharply up* around the splenium to open into the anterior end of the straight sinus, after receiving the right and left basal veins.

The cerebellar veins course on the cerebellar surface, comprising superior and inferior sets. Some *superior cerebellar veins* run anteromedially across the superior vermis to the straight sinus or great cerebral vein; others run laterally to the transverse and superior petrosal sinuses. *Inferior cerebellar veins* include a small median vessel running backwards on the inferior vermis to enter the straight or (either) sigmoid sinus; laterally coursing vessels join the inferior petrosal and occipital sinuses.



Veins of the brain stem form a superficial venous plexus *deep* to the arteries. Veins of the midbrain may reach the great cerebral or basal vein. Over the pons they tend to form a lateral vein on each side which, with upper medullary veins, may enter the petrosal sinuses, transverse sinus, cerebellar veins or the venous plexus of the (sphenoidal) foramen ovale. A median pontine vein may exist and join one of the basal veins. Veins of the inferior medulla oblongata communicate with spinal veins and drain into the adjacent venous sinuses or along variable radicular veins following the last four cranial nerves to the inferior petrosal or occipital sinuses or the upper part of the internal jugular vein. Anterior and posterior median medullary veins may run along the anterior medial fissure or posterior median sulcus and are then continuous with the spinal veins in corresponding positions (pp. 948, 1085).



6.150 The superior sagittal sinus laid open after removal of the cranial vault. Some of the fibrous bands which cross the sinus are clearly seen; from two of the venous lacunae, bristles are passed into the sinus.

CRANIAL DURAL VENOUS SINUSES

Dural sinuses are venous channels, draining blood from the brain and cranial bones, and lying between two layers of dura mater. They are lined by endothelium continuous with that in veins; they have no valves and their walls are devoid of muscular tissue. Although most accounts describe sinuses as largely simple, smooth channels, a complex 'cavernous' or plexiform nature has been emphasized by Browder & Kaplan (1976), at least in some sites (p. 802). They may be divided into: (1) a posterosuperior group and (2) an antero-inferior group on the cranial base.

6.151 The dura mater, its processes and venous sinuses: right aspect. The cavernous and sphenoparietal sinuses are not represented.

6.152 The tentorium cerebelli and venous sinuses: superior aspect. Representation of the cavernous sinuses (or 'plexuses', see text) and their extensions is greatly simplified.

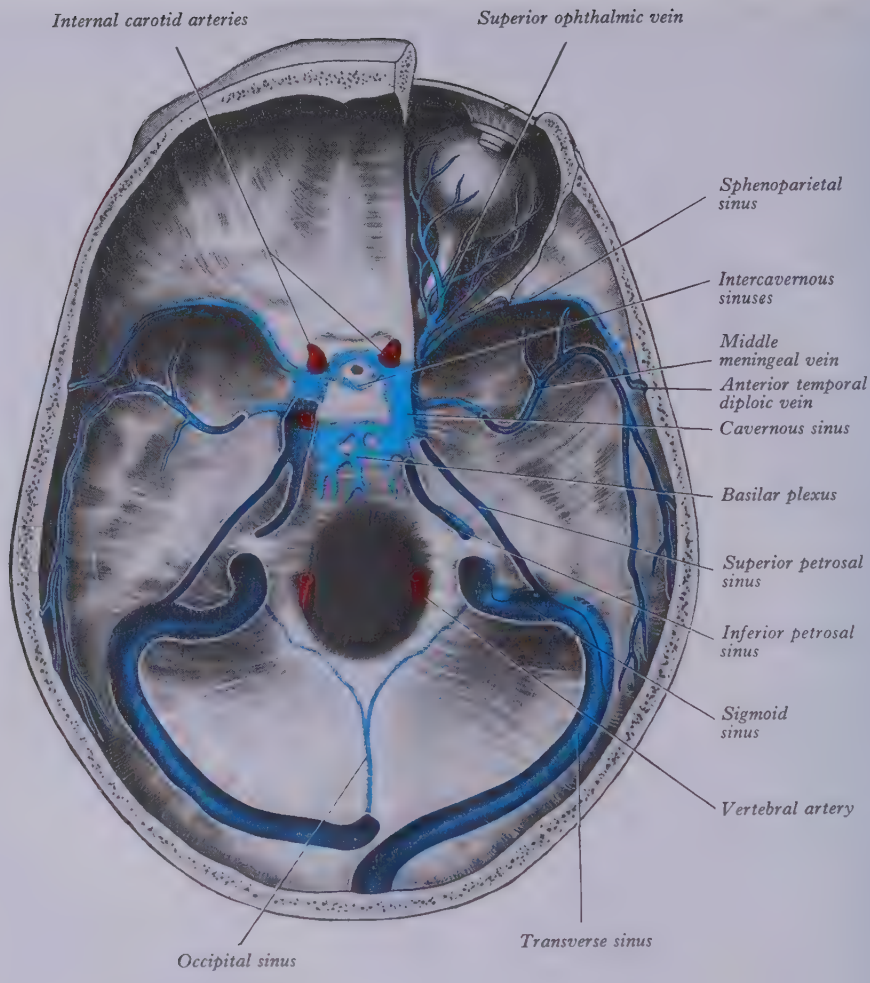
1. *The posterosuperior group of venous sinuses* comprises the superior and inferior sagittal, straight, transverse, petrosquamous, sigmoid and occipital sinuses.

The superior sagittal sinus (**6**.149,150,151) occupies the attached, convex margin of the falx cerebri. It is said to begin near the crista galli by receiving a vein from the nasal cavity when the foramen caecum is patent; but Kaplan et al (1973) found no such tributary in 201 specimens; in only 9% did the sinus extend as far as the foramen; the first tributaries were cortical veins from adjacent frontal poles, the *ascending frontal veins* of Krayenbuhl (1967). The sinus usually begins a few millimetres posterior to the foramen caecum and runs back, grooving the internal surface of the frontal bone, the adjacent margins of both parietals and the squamous occipital bone. Near the internal occipital protuberance it deviates, usually to the right, continuing as a transverse sinus. Triangular in cross-section, it gradually enlarges backwards. Its interior shows the openings of superior cerebral veins, projecting arachnoid granulations, and many fibrous bands across its inferior angle; it also communicates by small orifices with irregular *venous lacunae*, situated in the dura mater near the sinus, usually three on each side: a small frontal, a large parietal and an occipital intermediate in size. In the elderly, lacunae tend to become confluent as one elongated lacuna on each side. Fine fibrous bands cross them and numerous arachnoid granulations project into them. The superior sagittal sinus receives the superior cerebral veins and, near the posterior end of the sagittal suture, veins from the pericranium passing through the parietal foramina; the lacunae drain the diploic and meningeal veins.

The complexity of these lateral lacunae and of the sinus itself have been obscured by over-simplification in general texts; but this complexity has often been emphasized (LeGros Clark 1920, Balo 1950) and studies of corrosion casts (Browder & Kaplan 1976) and cerebral angiography have revived earlier descriptions. Lateral lacunae are often so complex as to be almost plexiform and rarely the simple venous spaces usually depicted. All more recent observers have described plexiform arrays of small veins adjoining the sagittal, transverse and straight sinuses. LeGros Clark and Balo regarded these masses as cavernous tissue, which commonly adjoin all sinuses inter-communicating at their confluence. Ridges of such 'spongy' venous tissue often project into the lumina of the superior sagittal and transverse sinuses. Their function can only be conjectured (p. 1090). The superior sagittal sinus is also invaded, in its intermediate third, by variable bands and projections from its dural walls, even extending as horizontal shelves dividing its lumen into superior and inferior channels. Such variable features make it impossible to give a simple description of this or other venous sinuses, whose variations have been detailed by Browder & Kaplan (1974) in a large series of corrosion casts; individual variations can only be shown by angiography.

The confluence of the sinuses (**6**.152) is a term for the dilated posterior end of the superior sagittal sinus, situated to one side (usually right) of the internal occipital protuberance, where it turns to become a transverse sinus. It also *connects* with the occipital and contralateral transverse sinus. The size and degree of communication of the channels meeting at the confluence are variable. (Consult Browder & Kaplan 1974 for statistics of 215 specimens.) In more than half of the specimens all venous channels converging towards the occiput do interconnect, including straight and occipital sinuses. In many instances, however, communication is nil or tenuous. Any sinus involved may be reduplicated, narrowed or widened near the confluence. Variation is too great for useful description.

6.153 Internal carotid arteriogram (right), venous phase: lateral view. (Same subject as in **6**.77 and **6**.78, p. 743.) 1. Superior cerebral veins. Note the anterior course at entry into the superior sagittal sinus. 2. An inferior cerebral vein ending in the straight sinus. 3. Region of venous anastomoses.



Applied Anatomy. Connections between the superior sagittal sinus and veins of the nose, scalp and diploë explain the occasional spread of infective thrombosis in these parts.

The inferior sagittal sinus (**6**.151), in the posterior half or two-thirds of the free margin of the falx cerebri, increases in size posteriorly, ending in the straight sinus. It receives veins from the falx and sometimes from the medial cerebral surfaces.

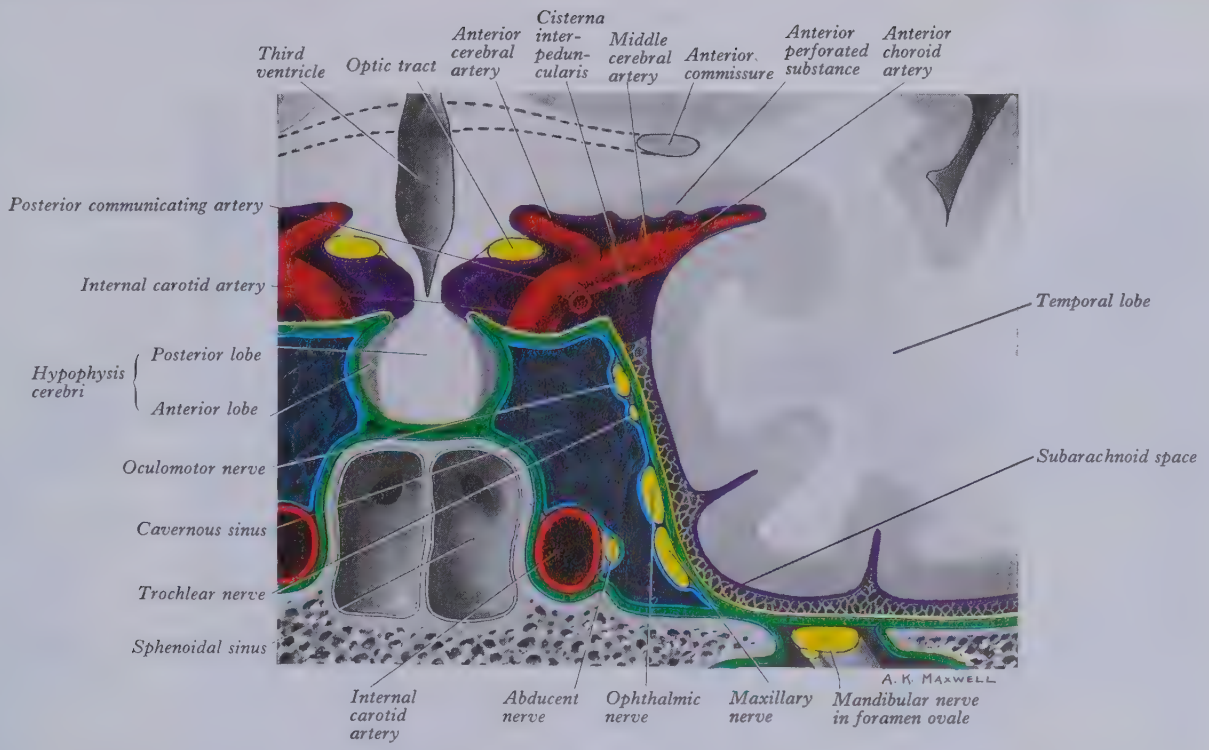
The straight sinus (**6**.151,152) lies in the junction of the falx cerebri with the tentorium cerebelli. Triangular in cross-section, it has a few transverse bands. It runs *postero-inferiorly*, continuing the inferior sagittal sinus into that transverse sinus which is not, or only tenuously, continuous with the superior sagittal sinus. It may communicate terminally, but quite variably, at the confluence. Its tributaries include some superior cerebellar veins and the great cerebral; the site of the latter's opening is marked by a dilatation. A small body projects into the floor of the sinus at its junction with the great cerebral vein. This contains a sinusoidal plexus of vessels; it may become engorged and act as a valve controlling outflow from the great cerebral vein, affecting the secretion of cerebrospinal fluid in the lateral ventricles. As noted, other masses of cavernous tissue are related to other dural sinuses; engorgement possibly influences their blood flow but structural data make this unlikely (vide supra).

The transverse sinuses (**6**.152,154) begin at the internal occipital protuberance, one (right) directly continuous with the superior sagittal sinus, the other with the straight sinus. Each curves anterolaterally to the posterolateral part of the petrous temporal bone, where it turns down as a sigmoid sinus. It is in the attached margin of the tentorium cerebelli, first on the occipital's squama, then on the parietal's mastoid angle. It has a gentle curve, convex upwards, and increases in size as it proceeds forwards. Transverse sinuses are triangular in section and usually unequal in size, the one draining the superior sagittal sinus being the larger. Where they continue as sigmoid sinuses, they are joined by the superior petrosal sinuses; they receive the inferior cerebral, inferior cerebellar, diploic and inferior anastomotic veins (p. 798).

Each petrosquamous sinus runs back in a groove, which sometimes becomes a canal posteriorly, along the junction of the squamous and petrous parts of the temporal bone, opening behind into the transverse sinus. Anteriorly it connects with the

6.154 The sinuses at the base of the skull. The sinuses coloured dark blue have been opened up. See text and **6**.156, 157 for alternative views on the construction of the cavernous sinuses.

retromandibular vein through a postglenoid or squamosal foramen (pp. 377, 378). The sinus may be absent; it may drain entirely into the retromandibular vein.



The sigmoid sinuses (**6**.154) are continuations of the transverse sinuses, beginning where these leave the tentorium cerebelli. Each sigmoid sinus curves inferomedially in a groove on the mastoid temporal bone, crosses the occipital's jugular process and turns forwards to the superior jugular bulb, lying posterior in the jugular foramen. Anteriorly, a thin plate of bone alone separates its upper part from the mastoid antrum and air cells. It connects with pericranial veins via mastoid and condylar emissary veins.

The occipital sinus (**6**.154), the smallest of the sinuses, lies in the attached margin of the falx cerebelli, occasionally paired. It commences near the foramen magnum in several small channels, one joining the end of the sigmoid sinus; it connects with the internal vertebral plexuses and ends in the confluence of sinuses.

2. *The antero-inferior group of venous sinuses* includes: cavernous, intercavernous, inferior petrosal, sphenoparietal, superior petrosal and basilar sinuses and middle meningeal 'veins'.

The cavernous sinuses (**6**.149,154,155,156,157) lie on the sides of the body of the sphenoid bone; their name indicates their internal structure. It has been asserted that a distended adult sinus contains a few trabeculae, mostly in its periphery near the entry of its tributaries and that these are incorporations of plexiform tributaries during developmental expansion. When the sinus is collapsed, as is usual in cadavers, its cavity is encroached upon by the nerves and arachnoid granulations in its wall, creating a spurious resemblance to cavernous tissue (Butler 1957). From corrosion casts, however, Parkinson (1973) concluded that the sinus is usually a plexus (as it is during development), a finding in accord with some earlier descriptions; Pernkopf (1963) depicted the 'sinus' as a venous plexus (see **6**.156, 157). Browder & Kaplan (1976), from examination of many casts prepared in cadavers, described the sinus as 'reticulated'. It is not clear whether they meant *plexiform* or *cavernous*. The sinus extends from the superior orbital fissure to the apex of the petrous temporal bone, with an average length of 2 cm and width of 1 cm. The internal carotid artery, with a sympathetic plexus, passes forwards through the sinus, as does the abducent nerve, inferolateral to the artery; the oculomotor and trochlear nerves and ophthalmic and maxillary divisions of the trigeminal (**6**.155) are usually said to be *in the thickness* of its lateral wall; but they are of such diameters that they project into the sinus; while they may be surrounded by dural connective tissue, they are usually covered medially by little more than endothelium (McGrath 1977). The sphenoidal air sinus and hypophysis cerebri are medial; the trigeminal cave is near the inferoposterior part of its lateral wall, extending posteriorly beyond it and enclosing the trigeminal ganglion. The uncus is also lateral.

Tributaries are: the superior ophthalmic vein, a branch from the inferior ophthalmic vein (or the whole vessel), the superficial middle cerebral vein, inferior cerebral veins, and sphenoparietal sinus; the central retinal vein and frontal tributary of the middle meningeal sometimes drain to it. The sinus drains to the transverse sinus via the superior petrosal sinus, to the internal jugular via the inferior petrosal sinus and a plexus of veins on the internal carotid, to the pterygoid plexus by veins traversing the emissary sphenoidal foramen, foramen ovale and foramen lacerum, and to the facial vein via the superior ophthalmic. The two sinuses are

6.155 Coronal, slightly oblique section through the middle cranial fossa, showing the cavernous and cerebral portions of the internal carotid artery and the cavernous sinus: pia mater—mauve; arachnoid mater— white; layers of dura mater—green (the mesothelium of the dura mater is not indicated); endothelium of cavernous sinus—blue.

connected by anterior and posterior intercavernous sinuses and the basilar plexus. All connections are valveless; the direction of flow in them is reversible.

Propulsion of blood in the sinus is partly due to pulsation of the internal carotid artery. It is also influenced by gravity and hence by the position of the head.

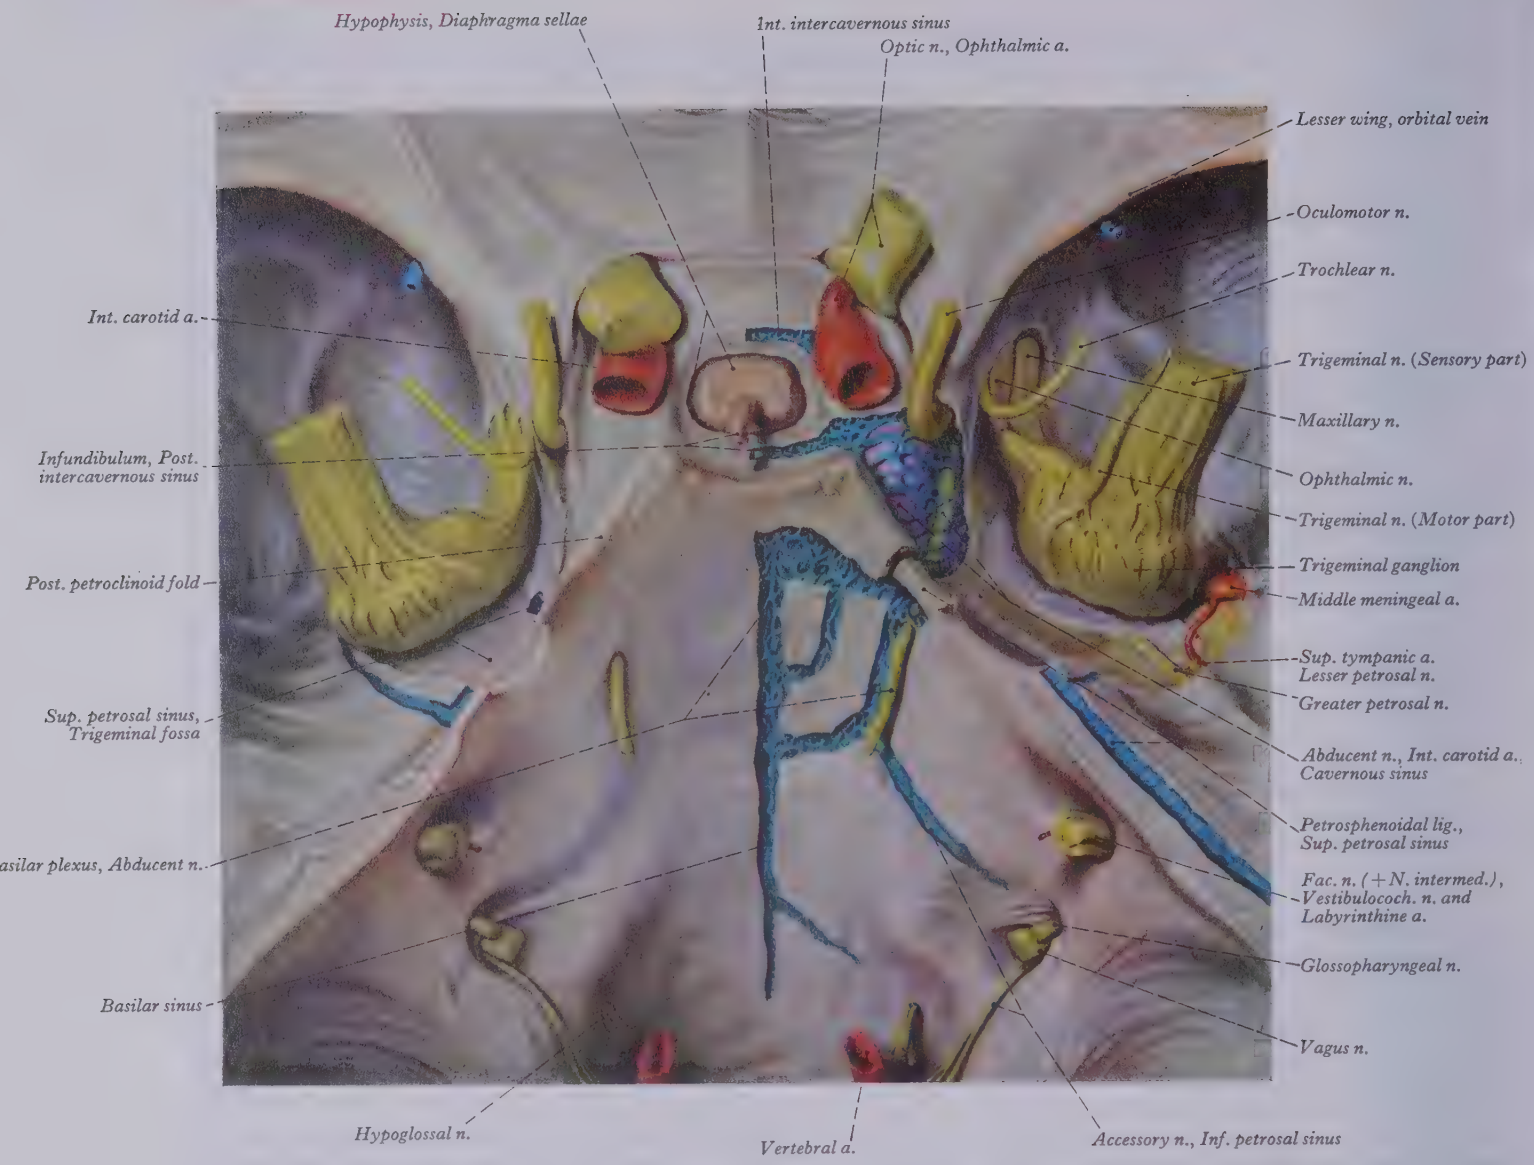
Applied Anatomy. An arteriovenous leak may occur between the cavernous sinus and internal carotid artery, causing a pulsating orbital swelling. Ligation of the internal or common carotid artery has sometimes alleviated the condition. Suppuration in the upper nasal cavities and paranasal sinuses or near the medial canthus may lead to septic thrombosis of the cavernous sinuses.

The ophthalmic veins (**6**.154,158), superior and inferior, devoid of valves, link the facial and intracranial veins.

The *superior ophthalmic vein* forms posteromedial to the upper lid from two tributaries connecting anteriorly with the facial and supraorbital veins (p. 793). It runs with the ophthalmic artery, receiving corresponding tributaries, and traverses the superior orbital fissue to end in the cavernous sinus. The *inferior ophthalmic vein* begins in a network near the anterior region of the orbital floor and medial wall, receiving veins from the rectus inferior, obliquus inferior, lacrimal sac and eyelids; it runs back above the rectus inferior and often joins the superior ophthalmic vein but may reach the cavernous sinus. It connects with the pterygoid venous plexus by small rami through the inferior orbital fissure.

The central retinal vein first traverses the optic nerve, leaving it to pursue a long course in the subarachnoid space before entering the cavernous sinus or superior ophthalmic vein. It receives a central vein which drains the nerve while still within it.

The sphenoparietal sinuses (**6**.154) are inferior to the periosteum of the lesser wings of the sphenoid bone, near their posterior edges. Each receives small veins from the adjacent dura mater and sometimes the frontal ramus of the middle meningeal vein; curving medially it opens into the anterior part of the cavernous sinus. It often receives connecting rami, in its middle course, from the superficial middle cerebral vein, sometimes veins from the temporal lobe and the anterior temporal diploic vein. When these connections are well developed it is a large channel.



The intercavernous sinuses, anterior and posterior, interconnect the cavernous sinuses in the anterior and posterior attached borders of the diaphragma sellae; they thus complete a venous *circular sinus* (**6**.154). Small, irregular sinuses inferior to the hypophysis cerebri drain into them. Such *inferior intercavernous sinuses* were studied by Kaplan et al (1976), who emphasized their size and plexiform nature, features important in a surgical trans-nasal approach to the hypophysis.

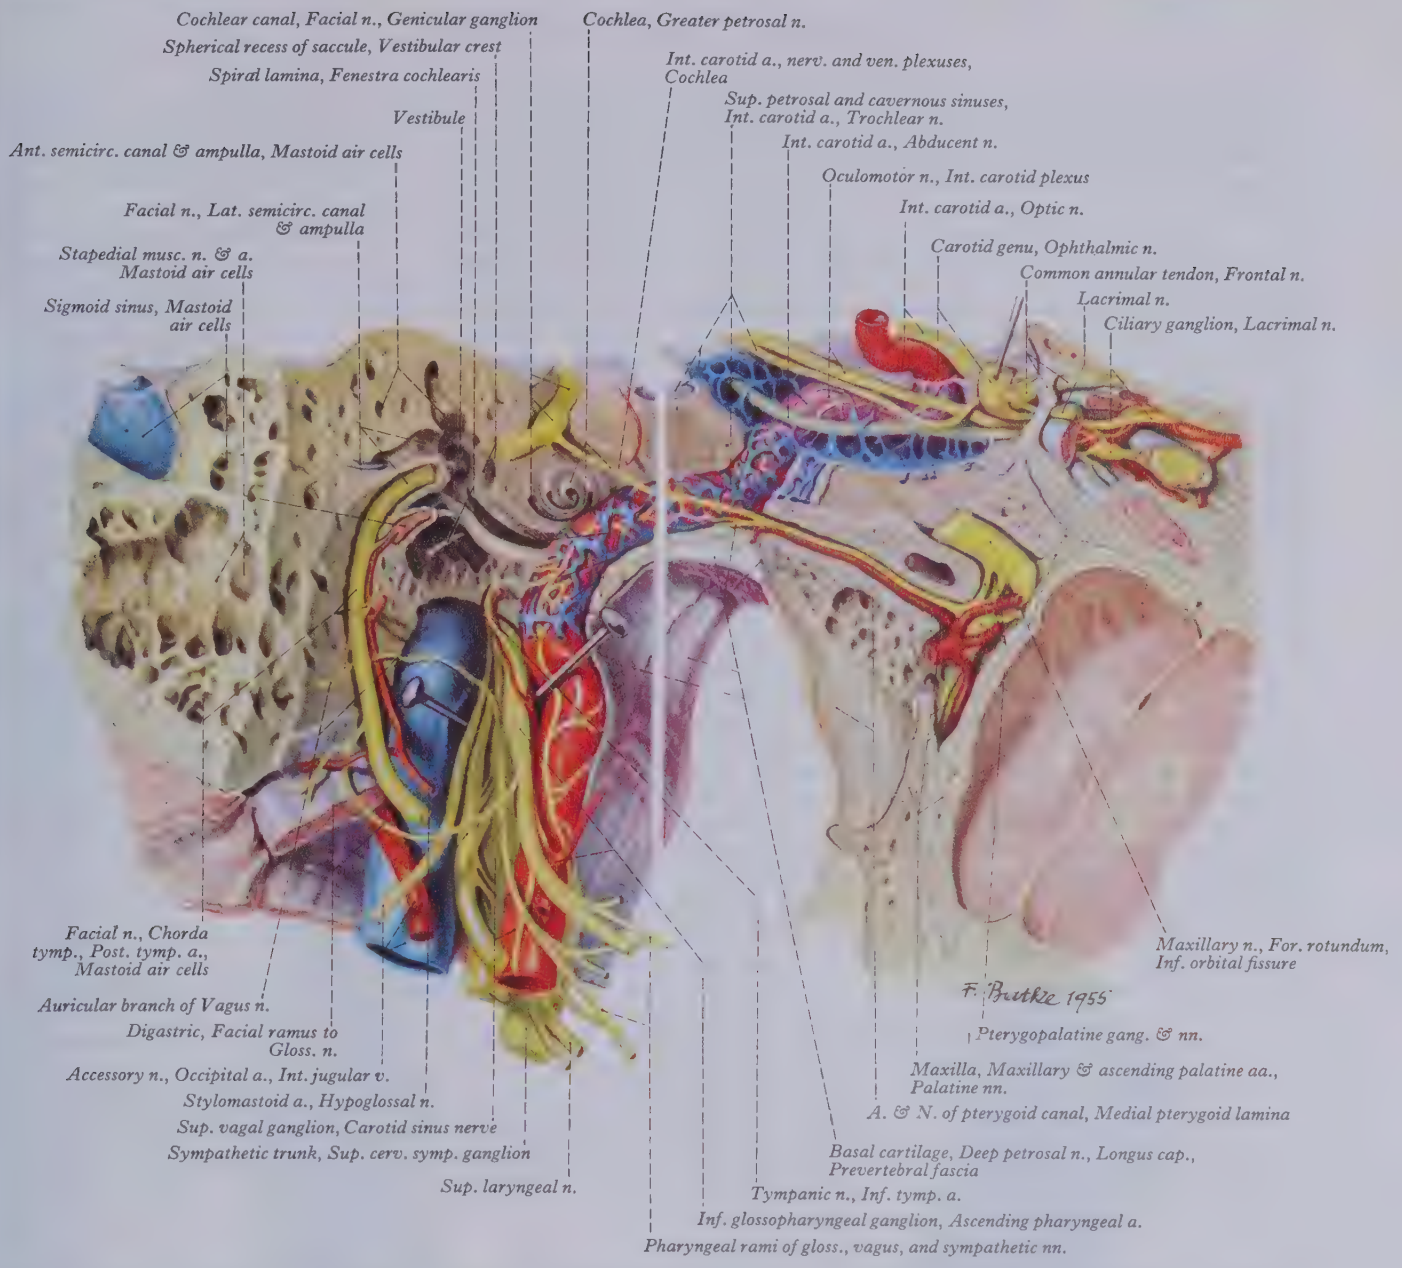
The superior petrosal sinuses (**6**.154), small and narrow, drain the cavernous to the transverse sinuses. Leaving the posterosuperior part of the cavernous sinus, each runs posterolaterally in an attached margin of the tentorium cerebelli, crossing above the trigeminal nerve to a groove on the superior border of the petrous temporal bone; each ends by joining a transverse sinus where this curves down to become the sigmoid. It receives cerebellar, inferior cerebral and tympanic veins. It connects with the inferior petrosal sinus and basilar plexus.

The inferior petrosal sinuses drain the cavernous sinuses to the internal jugular veins. Each (**6**.154) begins postero-inferiorly at its cavernous sinus and runs back in a groove between the petrous temporal and basilar occipital bones. Traversing the anterior part of the jugular foramen it ends in the superior jugular bulb. It receives *labyrinthine veins* via the cochlear canaliculus and the vestibular aqueduct and tributaries from the medulla oblongata, pons and inferior cerebellar surface. According to Browder & Kaplan (1976) the sinus is more often a plexus and sometimes drains by a vein in the hypoglossal canal to the suboccipital vertebral plexus.

Relations of structures in the *jugular foramen* are as follows: the inferior petrosal sinus is anteromedial with a meningeal branch of the ascending pharyngeal artery, and the sinus descends obliquely backwards; the sigmoid sinus is situated at the lateral and posterior part of the foramen with a meningeal branch of the occipital artery; between the sinuses are in succession, posterolaterally: the glossopharyngeal, vagus and accessory nerves (p. 1118).

The basilar venous plexus (**6**.154) consists of interconnecting channels between layers of dura mater on the clivus; it interconnects the inferior petrosal sinuses and joins with the internal vertebral venous plexus. It also usually connects with the

6.156 The middle cranial fossa, viewed from above to show the termination of the internal carotid artery, its branches and the cavernous sinus. Note the plexiform nature of the 'sinus', which communicates with similar venous plexuses in the hypophysial fossa and over the clivus. These have been exposed by partial removal of the dura mater. (See also **6**.157.)



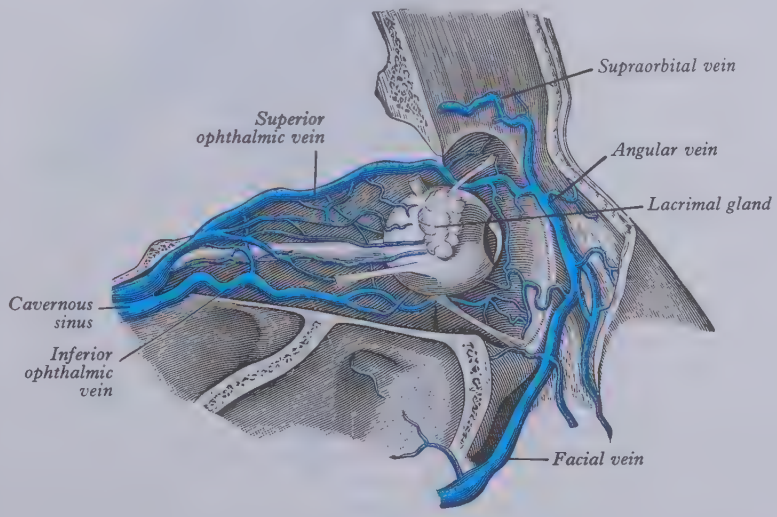
cavernous and superior petrosal sinuses at its anterior end. When marginal sinuses (p. 805) are large they communicate anteriorly with the plexus; an almost complete *circular venous channel* may then surround the foramen magnum, connecting the basilar plexus intracranially to the inferior petrosal, sigmoid and occipital sinuses and to variable extracranial vertebral plexuses in the suboccipital region.

The middle meningeal veins (or sinuses) (**6**.154) communicate above with the superior sagittal sinus through its venous lacunae; *below* they converge and unite as *frontal* and *parietal trunks*, which accompany branches of the middle meningeal arteries in grooves on the internal parietal surfaces; but the veins are closer to bone and sometimes occupy separate grooves. The veins' situation has been said to make them liable to tears in fractures (Wood Jones 1911). Their termination is variable. The parietal trunk may traverse the foramen spinosum to the pterygoid venous plexus; the frontal may also reach the plexus via the foramen ovale or may end in the sphenoparietal or cavernous sinus. Besides meningeal tributaries they receive small inferior cerebral veins and connect with the diploic and superficial middle cerebral veins. Browder & Kaplan (1976) state that middle meningeal 'veins' are histologically *sinuses*, in places almost surrounding the middle meningeal arteries; they also report frequent arachnoid granulations in them.

Surface Anatomy. The *superior sagittal sinus* runs from the glabella (p. 342) to the inion (**3**.126). Narrow anteriorly, it widens to about 1 cm. The *transverse sinus* begins at the inion and runs laterally, with slight upward convexity, to the base of the mastoid process, from which the *sigmoid sinus* passes down just anterior to the posterior mastoid border to a point about 1 cm above its tip.

EMISSARY VEINS

Emissary veins traverse cranial apertures and make connections between venous sinuses and extracranial veins. Some are constant, others sometimes absent. (1) A *mastoid emissary vein* in the mastoid foramen unites the sigmoid sinus with the posterior auricular or occipital vein. (2) A *parietal emissary vein* traverses the parietal foramen to connect the superior sagittal sinus with the veins of the scalp. (3) The *venous plexus of the hypoglossal canal*, occasionally a single vein, connects the sigmoid sinus to the internal jugular vein. (4) A *posterior condylar emissary vein* connects the sigmoid sinus with veins in the suboccipital triangle via the condylar canal. (5) A plexus of emissary veins (*venous plexus of foramen ovale*) links the cavernous sinus to the pterygoid plexus via the foramen ovale. (6) Two or three small veins traverse the foramen lacerum connecting the cavernous sinus with the pharyngeal veins and pterygoid plexus. (7) A vein in the emissary sphenoidal foramen (of Vesalius) connects the same vessels.



6.157 An oblique vertical section through the cranial base to display in lateral view the right internal carotid artery and the continuity of the venous plexus around the intra-osseous and cavernous parts of the artery.

(**6.156** and 157 are from Pernkopf 1963, by kind permission of W B Saunders and Urban & Schwarzenberg.)

(8) The *internal carotid venous plexus*, passing through the carotid canal, connects the cavernous sinus to the internal jugular vein. (9) The petrosquamous sinus (p. 801) connects the transverse sinus with the external jugular vein. (10) A vein may traverse the foramen caecum (patent in about 1% of adult skulls) connecting nasal veins with the superior sagittal sinus. (11) An *occipital emissary vein* usually connects the confluence of sinuses with the occipital vein through the occipital protuberance, receiving also the occipital diploic vein. (12) The occipital sinus connects with variably developed veins around the foramen magnum (so-called *marginal sinuses*) and thus with the vertebral venous plexuses, an alternative venous drainage when the jugular vein is blocked or tied. (13) The ophthalmic veins are potentially emissary, since they connect intracranial to extracranial veins; but parietal emissary veins, included here, are usually minute and do not appear to connect with veins of the scalp in corrosion casts.

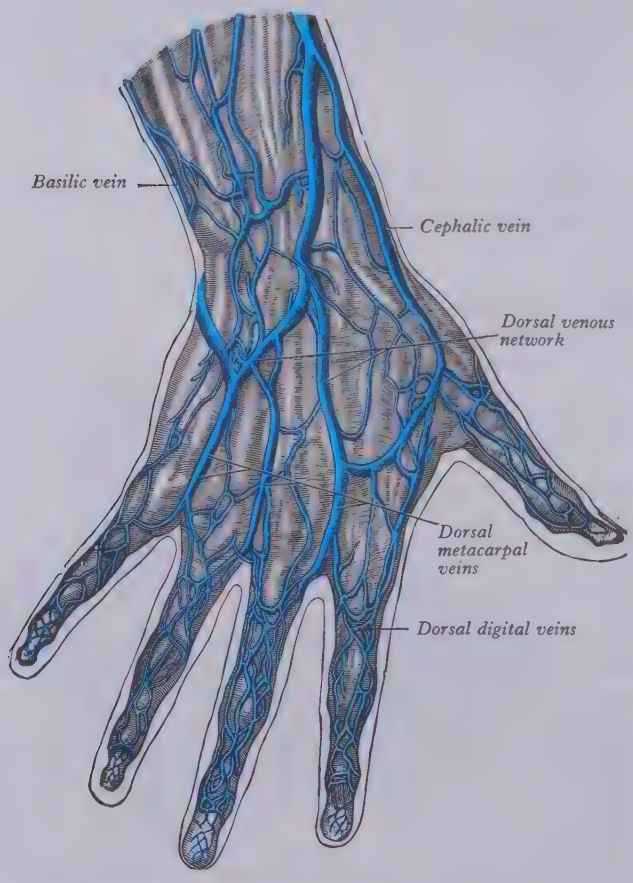
These connections are significant in the spread of infection from extracranial foci to venous sinuses. Ligature of the internal jugular vein, to limit the spread of some oral and pharyngeal pathologies, depends on the adequacy of the collateral drainage.

6.158 The veins of the right orbit: lateral aspect.

VEINS OF THE UPPER LIMBS

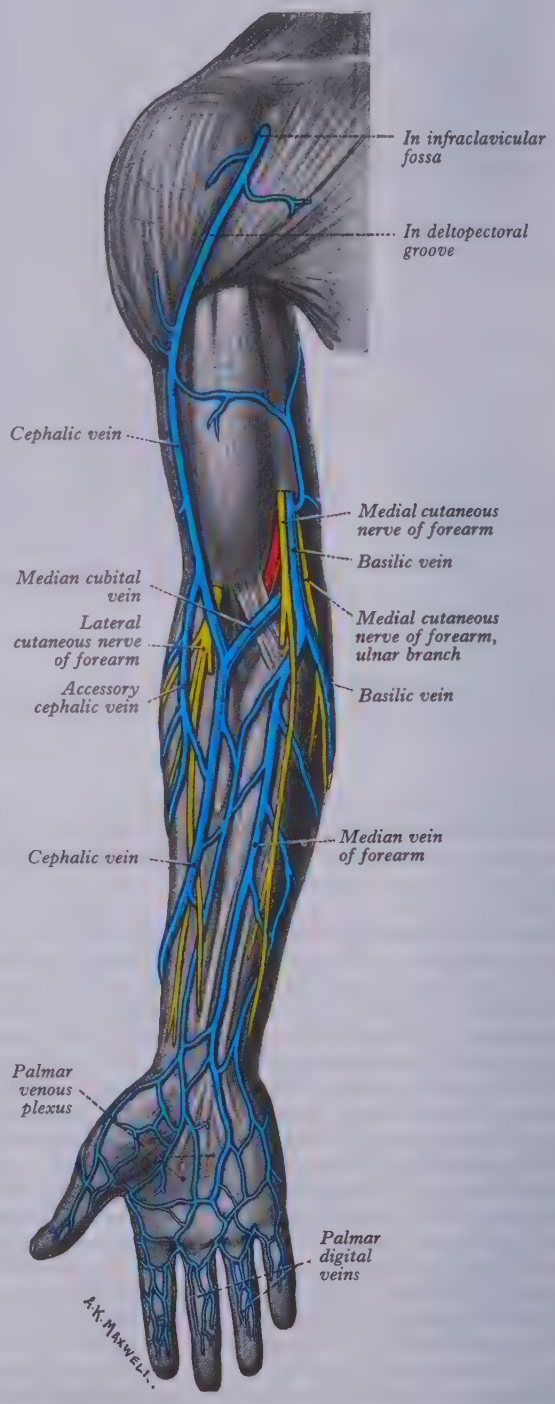
Veins are conveniently grouped as *superficial* and *deep* but these are widely interconnected. The superficial veins are subcutaneous in the superficial fascia; deep veins accompany arteries among the muscles of the limb. Both groups have valves, which are more numerous in deep veins.

SUPERFICIAL VEINS OF THE UPPER LIMB (6.159,160)



Superficial veins include the cephalic, basilic, median cubital and additional antebrachial veins and their tributaries.

Dorsal digital veins pass along the sides of the fingers, joined by oblique branches; they unite from the adjacent sides of digits into three *dorsal metacarpal veins* (6.159), which form a *dorsal venous network* over the metacarpus; this is joined *laterally* by a dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the pollex and is prolonged proximally as the cephalic vein. *Medially* a dorsal digital vein from the ulnar side of minimus joins the network, which drains proximally into the basilic vein. A vein often connects the central parts of the network to the cephalic near mid-forearm. (See also the accessory cephalic vein, and other antebrachial variants below.)



Palmar digital veins connect to the *dorsal* by oblique *intercapitular veins* passing between metacarpal heads; they also drain to a plexus *superficial* to the palmar aponeurosis, extending over both thenar and hypothenar regions.

The cephalic vein (6.159,160), commonly formed over the 'anatomical snuff box', curves proximally from the radial end of the dorsal plexus round the forearm's radial side to its ventral aspect, receiving veins from both aspects. Distal to the elbow a branch, the *median cubital vein*, joined by a ramus from the deep veins, diverges proximomedially to reach the basilic vein. The cephalic ascends in front of the elbow superficial to a groove between the brachioradialis and biceps, crosses superficial to the lateral cutaneous nerve of the forearm, ascends lateral to the biceps and between pectoralis major and the deltoid, where it adjoins the deltoid branch of the thoraco-acromial artery. Entering the infraclavicular fossa to pass behind the clavicular head of pectoralis major, it pierces the clavipectoral fascia, crosses the axillary artery and joins the axillary vein just below clavicular level. It may connect with the external jugular by a branch *anterior* to the clavicle. Sometimes the median cubital vein is large, transferring most blood from the cephalic to the basilic vein, the proximal cephalic vein then being absent or much diminished.

An *accessory cephalic vein*, arising in a dorsal forearm plexus or from the ulnar side of the dorsal venous network in the hand, joins the cephalic distal to the elbow. It may spring from the cephalic

6.159 The veins of the dorsum of the hand.

6.160 The superficial veins of the right upper extremity: anterior aspect.

proximal to the carpus and rejoin it later. A large oblique vein often connects the basilic and cephalic veins dorsally in the forearm.

The basilic vein (6.160) begins medially in the hand's dorsal venous network, ascending posteromedially in the forearm and inclining forwards to the anterior surface distal to the elbow. Joined by the median cubital vein, it ascends superficial to and between the biceps and pronator teres; filaments of the medial cutaneous nerve of the forearm pass here, in front and behind it. It ascends medial to biceps and perforates the deep fascia about midway in the arm, continuing medial to the brachial artery to the lower border of teres major, there becoming the axillary vein. (Its relation to the brachial veins is variable, vide infra.)

The median vein of the forearm (6.160) drains the superficial palmar venous plexus. It ascends anterior in the forearm to join the basilic or median cubital vein; it may divide distal to the elbow to join both.

Surface Anatomy. Superficial veins are usually visible until they pierce the deep fascia. Larger ones are obvious when the limb is dependent and its muscles contracted, driving blood from the deep to the superficial veins.

Applied Anatomy. Blood sampling, blood transfusion and intravenous injection are commonly done near the elbow or more distally in the forearm; the largest vein is usually the median cubital. The cubital veins are also used for cardiac catheterization for many purposes. Equally useful for such procedures is the cephalic vein where it is superficial to the distal end of the radius in the 'anatomical snuffbox'. The cephalic vein, a little proximal to the snuff box, is the site with many advantages for an indwelling cannula or fine tube when a lengthy period is contemplated; the position of the arm, forearm and hand is optimal for this purpose.

DEEP VEINS OF THE UPPER LIMB

Deep veins (venae comitantes) accompany arteries, usually in pairs, flanking the artery and connected by short transverse links. Since much blood from the upper limb is returned by the superficial veins, the deep ones are relatively small.

Deep veins of the hand. Superficial and deep palmar arterial arches are accompanied by *superficial* and *deep palmar venous arches*, receiving the corresponding branches. Thus *common palmar digital veins* join the superficial arch and *palmar metacarpal veins* join the deep arch. Deep veins accompanying the dorsal metacarpal arteries first receive perforating branches from the palmar metacarpal veins and then end in the radial veins and the dorsal venous network.

Deep veins of the forearm run with the radial and ulnar arteries draining respectively the deep and superficial palmar venous arches; they unite near the elbow as paired *brachial* veins. The radial veins are smaller, receiving the deep dorsal veins of the hand; ulnar veins drain the deep palmar venous arch, connecting with superficial veins near the wrist; near the elbow they receive the anterior and posterior interosseous artery companion veins; a large branch connects them to the *median cubital vein*.

Brachial veins flank the brachial artery, with tributaries similar to the arterial branches; near the lower margin of *subscapularis* they join the axillary vein, the medial one, however, often joining the basilic before it becomes the axillary.

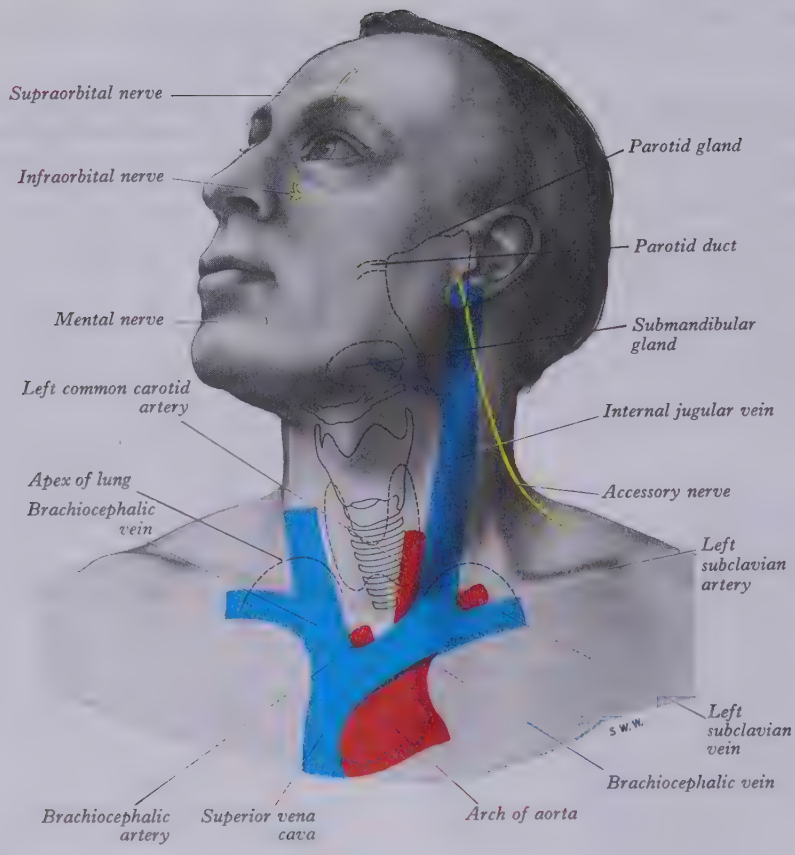
These deep veins have numerous anastomoses with each other *and* with the superficial veins.

The axillary vein, the continuation of the basilic, begins at the lower border of *teres major*, and ascends to the outer border of the first rib, where it becomes the subclavian. Near subscapularis the brachial veins joins it and, near its costal end, the cephalic; other tributaries follow the axillary arterial branches. It is medial to the axillary artery, which it partly overlaps; between them are the medial pectoral nerve, medial cord of the brachial plexus, the ulnar nerve and the medial cutaneous nerve of the forearm. The medial cutaneous nerve of the arm is medial to the vein; the lateral group of axillary lymph nodes is posteromedial. It has a pair of valves near its distal end; valves also occur near the ends of the cephalic and subscapular veins.

The subclavian vein (6.87), continuing the axillary, extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular to form the brachiocephalic vein. *Anterior* are the clavicle and subclavius, *posterosuperior* the subclavian artery, separated by the scalenus anterior and phrenic nerve; *inferior* are the first rib and pleura. The vein usually has a pair of valves about 2 cm from its end. Its tributaries are the external jugular, dorsal scapular and sometimes the anterior jugular; occasionally a small branch ascends in front of the clavicle from the cephalic vein. At its junction with the internal jugular the left subclavian receives the thoracic duct, the right subclavian vein and the right lymphatic duct.

Surface Anatomy. The vein can be projected as a broad band, convex upwards, from just medial to the mid-clavicular point to the medial edge of the clavicular attachment of sternocleidomastoid.

VEINS OF THE THORAX



The brachiocephalic (innominate) veins, two large vessels at the junction of the neck and upper thorax, are the united trunks of the internal jugular and subclavian veins. Both are devoid of valves.

The right brachiocephalic vein (6.161), about 2.5 cm long, begins posterior to the sternal end of the right clavicle, descending almost vertically to join the left brachiocephalic in forming the superior vena cava posterior to the lower border of the first right costal cartilage, near the right sternal border. It is anterolateral to the brachiocephalic artery and right vagus nerve. The right pleura, phrenic nerve and internal thoracic artery are posterior to it above, becoming lateral below. Its tributaries are the right vertebral, internal thoracic, inferior thyroid and sometimes the first right posterior intercostal veins.

The left brachiocephalic vein (6.161), about 6 cm long, begins posterior to the sternal end of the left clavicle, anterior to the cervical pleura. It descends *obliquely to the right*, posterior to the upper half of the manubrium sterni, to the sternal end of the first right costal cartilage, uniting here with the right brachiocephalic to form the superior vena cava. It is separated from the left sternoclavicular joint and manubrium by the sternohyoid and sternothyroid, the thymus or its remains and areolar tissue; terminally it is overlapped by the right pleura. It crosses *anterior* to the left internal thoracic, subclavian and common carotid arteries, left phrenic and vagus nerves, trachea and brachiocephalic artery. The aortic arch is inferior to it. The vein's tributaries are the left vertebral, internal thoracic, inferior thyroid, superior intercostal, sometimes the first left posterior intercostal, thymic and pericardial veins.

Surface Anatomy. The brachiocephalic veins can be projected as broad bands 1.5 cm wide from the sternal ends of the clavicles to the parasternal lower border of the first right costal cartilage.

Variations. The brachiocephalic veins may enter the right atrium separately, the right vein descending like a normal superior vena cava; a *left superior vena cava* may have a slender connection with the right and then cross the left side of the aortic arch to pass anterior to the left pulmonary hilum before turning to enter the right atrium. It replaces the oblique atrial vein and coronary sinus

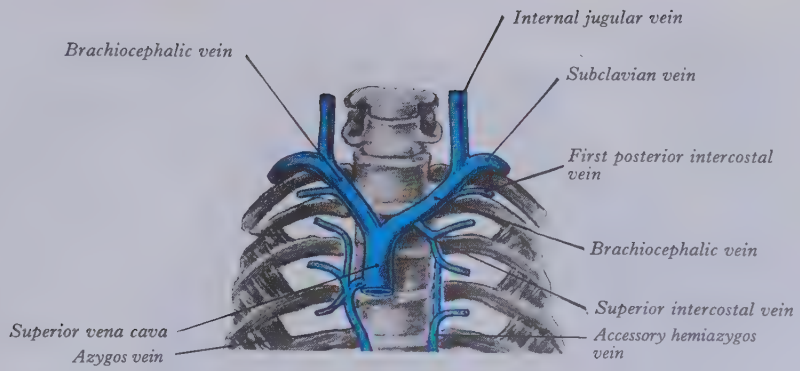
6.161 The surface projections of some of the important structures in the face, neck and upper part of the thorax. The apices of the lungs, the thyroid, submandibular and parotid glands and the parotid duct are indicated in interrupted dotted outline; the hyoid bone, the thyroid and cricoid cartilages and the rings of the trachea are shown in continuous outline.

and receives all the latter's tributaries. This abnormality, due to persistence of an early fetal condition, is normal in birds and some mammals. The left brachiocephalic vein sometimes projects above the manubrium (more frequently in childhood), crossing the suprasternal fossa in front of the trachea.

Internal thoracic (mammary) veins (**6**.66,90) are venae comitantes to the inferior half of the internal thoracic artery; they have several valves. Near the third costal cartilages the veins unite to ascend medial to the artery, ending in their brachiocephalic vein. Tributaries correspond to branches of the artery (p. 754), and include a pericardiacophrenic vein.

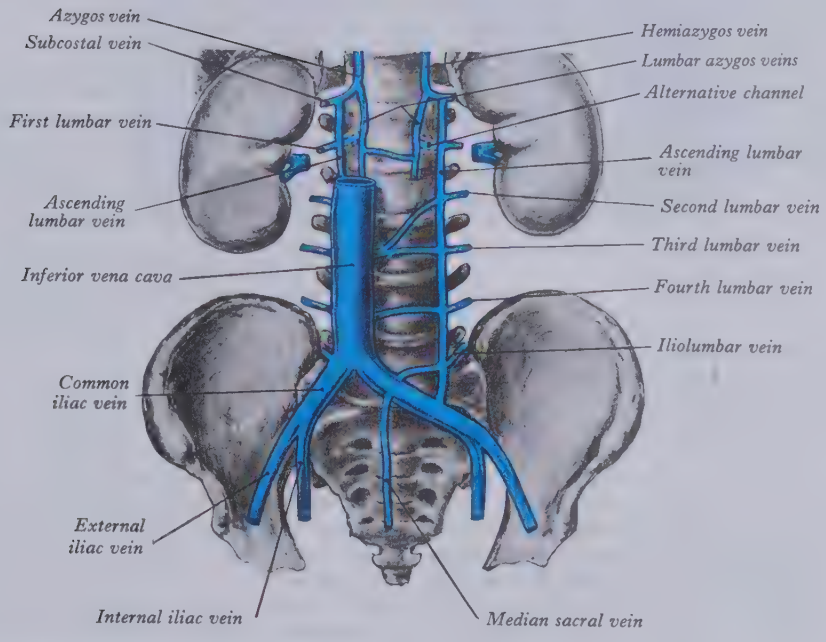
Inferior thyroid veins (**6**.66) arise in a glandular venous plexus, which also connects with the middle and superior thyroid veins. These veins form a *pretracheal plexus* from which the left inferior vein descends to join the left brachiocephalic, the right descending obliquely across the brachiocephalic artery to the right brachiocephalic vein, at its junction with the superior vena cava; the inferior thyroid veins often open in common into the vena cava or left brachiocephalic vein. They drain the oesophageal, tracheal and inferior laryngeal veins and have valves at their terminations.

The left superior intercostal vein (**6**.162) drains the second and third (sometimes fourth) left posterior intercostal veins, ascending obliquely forwards across the left aspect of the aortic arch, lateral to the left vagus, medial to the left phrenic nerve, to open into the left brachiocephalic vein. It usually receives the left bronchial veins, sometimes the left pericardiacophrenic; it connects inferiorly with the accessory hemiazygos vein.



The superior vena cava (**6**.60,63,64,65,66) returns blood from the superior half of the body. It is about 7 cm in length, formed by the junction of the brachiocephalic veins, and has no valves. It begins behind the lower border of the first right costal cartilage near the sternum, descends vertically behind the first and second intercostal spaces, ending in the upper right atrium behind the third right costal cartilage; its inferior half is within the fibrous pericardium, which it pierces level with second costal cartilage. Covered anterolaterally by serous pericardium from which projects a *retrocaval recess* (p. 696), it is slightly convex to the right.

Relations. *Anterior* are the anterior margins of the right lung and pleura, the pericardium intervening below; these separate the vein from the internal thoracic artery and first and second intercostal spaces, and second and third costal cartilages; *posteromedial* are the trachea and right vagus nerves and *posterolateral* the right lung and pleura; *posterior* is the right pulmonary hilum. *Right lateral* are the right phrenic nerve and pleura, *left lateral* the brachiocephalic artery and ascending aorta, the latter overlapping it.

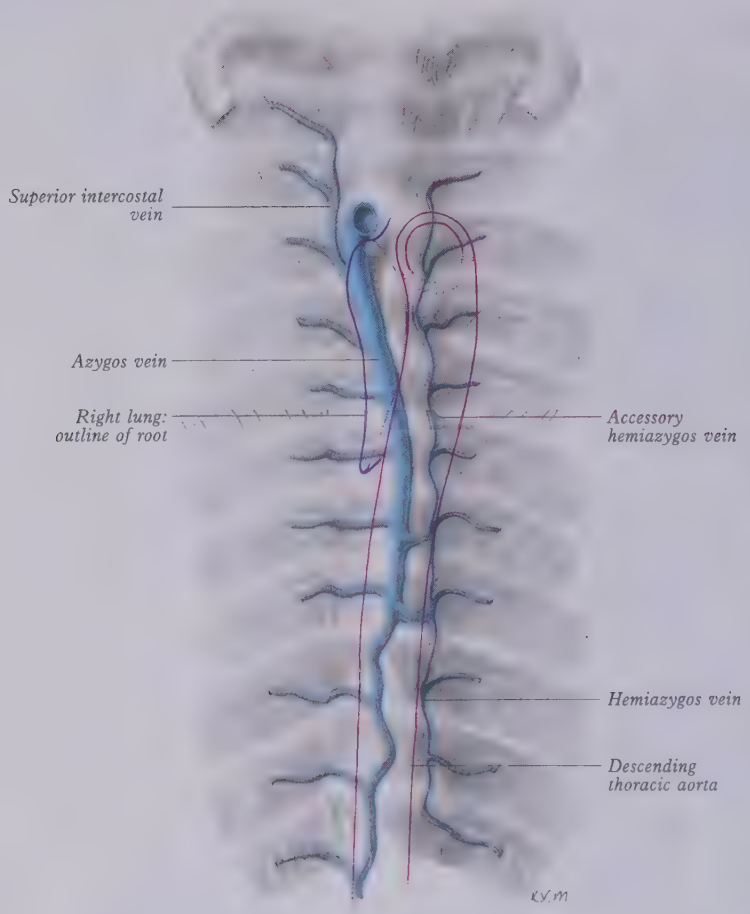


Surface Anatomy. The superior vena cava, 2 cm wide, is partly behind but projects well beyond the right sternal margin, from the lower border of the first to the lower border of the third right costal cartilage. Its lateral border is visible in anteroposterior radiographs.

Tributaries: the azygos vein and small veins from the pericardium and other mediastinal structures.

The azygos vein (**6**.162A,B,163,164) is inconstant in origin (Gladstone 1929). An origin from the posterior aspect of the inferior vena cava, at or below the level of the renal veins, is to be expected from its development. Such a *lumbar azygos vein* frequently occurs, ascending anterior to the upper lumbar vertebrae. The vein may pass behind the right crus of the diaphragm or pierce it. It may traverse the aortic opening on the right of the cisterna chyli. Anterior to the twelfth thoracic vertebral body it is joined by a large vessel formed by the right ascending

Much variation occurs in the transthoracic parts of the azygos and hemiazygos veins, in terms of numbers of radicles, levels of transmedian crossing, etc. Schemata are usually misleading. That depicted by painting in 6.162B is the most common condition.



6.162A Schema showing the superior and inferior extremities of the azygos system of veins and their principal associated veins. The intervening parts have been omitted because schemata of this region are often topographically misleading.

lumbar and right subcostal veins, which passes forward and right of the twelfth thoracic vertebra behind the right crus. This common trunk may, in the absence of a lumbar azygos, form the azygos itself. Whatever its origin, the azygos vein ascends in the posterior mediastinum to the fourth thoracic vertebra, arching forward above the right pulmonary hilum to end in the superior vena cava, before the latter pierces (enters) the pericardium. It is *anterior* to the lower eight thoracic vertebral bodies (vide infra), anterior longitudinal ligament and right posterior intercostal arteries. *Right lateral* are the right greater splanchnic nerve, lung and pleura; *left lateral* in most of its course are the thoracic duct and aorta and, where it arches forward, the oesophagus, trachea and right vagus. In the lower thorax it is covered *anteriorly* by a recess of the right pleural sac and oesophagus, emerging from behind the latter to ascend behind the right hilum (**6**.164). In the lower thorax it should be noted that the azygos vein closely follows the right posterolateral aspect of the descending thoracic aorta for a variable distance (Dr M.C.E. Hutchinson, personal communication), thus *often reaching* and even *crossing* left of the midline; aortic pulsations might thus assist venous return in azygos and hemiazygos veins (cf. p. 691).

Tributaries. The azygos vein drains: the right posterior intercostal veins except the first, the veins from the second to fourth intercostal spaces usually via a right superior intercostal vein, the hemiazygos and accessory hemiazygos veins, oesophageal, mediastinal and pericardial veins and, near its end, right bronchial veins. When it begins as a lumbar azygos, the common trunk formed by the right ascending lumbar and subcostal veins is its largest tributary. Imperfect valves occur in the azygos vein, some tributaries having complete valves.

The hemiazygos starts on the left like the azygos; ascending anterior to the vertebral column to the eighth thoracic level, it

6.162B A frequent (perhaps the commonest) course followed by the intrathoracic azygos, hemiazygos and accessory hemiazygos veins. Outlines of the root of the right lung and descending thoracic aorta are included. Dissection by M C E Hutchinson, Guy's Hospital Medical School, London.

crosses the column posterior to the aorta, oesophagus and thoracic duct to end in the azygos vein. Its tributaries are the lower three posterior intercostal veins, a common trunk formed by the left ascending lumbar and subcostal veins and oesophageal and mediastinal rami. Its lower end often connects with the left renal vein.

The accessory hemiazygos vein descends to the left of the vertebral column, receiving veins from the fourth (or fifth) to eighth intercostal spaces and sometimes the left bronchial veins. It crosses the seventh thoracic vertebra to join the azygos vein. It sometimes joins the hemiazygos, their common trunk opening into the azygos vein.

The azygos veins vary much in their mode of origin, course, tributaries, anastomoses and termination. For a survey consult Grzybiak et al (1975), who consider the accessory hemiazygos most variable, draining into the left brachiocephalic, azygos or hemiazygos. The arrangement shown in **6**.162B represents a common pattern. In about 1 or 2% according to Anson (1963) there are left and right independent azygos veins (the early embryonic form) and occasionally a single azygos without hemiazygos tributaries, in a midline position. In more than 95% a main 'right-sided' azygos and at least some representative of hemiazygos veins exist. The latter vary, one or other being absent or poorly developed. Retro-aortic trans-vertebral connections from hemiazygos and accessory hemiazygos veins to the azygos are also extremely variable; there may be from one to five, or more; when either hemiazygos is absent, intercostal veins involved cross vertebral bodies to end in the azygos. These trans-vertebral routes are often very short, since the azygos vein is more commonly *anterior* to the vertebral column (Anson 1963, Dr. M.C.E. Hutchinson, personal communication) and often passes *left* of the midline in part of its course.

Posterior intercostal veins (**6**.106,164) accompany their arteries in eleven pairs. Approaching the vertebral column each vein receives a posterior tributary returning blood from the dorsal muscles and skin and vertebral venous plexuses. On both sides the first posterior intercostal vein ascends anterior to the first rib's neck, arching forward above the pleural dome to end in the ipsilateral brachiocephalic or vertebral vein. On the right the second, third and often fourth form a *right superior intercostal vein* joining the arch of the azygos vein. Veins from the lower spaces drain directly to it. On the left the second and third (sometimes fourth) form a left superior intercostal vein (p. 869). Veins from the fourth (or fifth) to eighth spaces end in the accessory hemiazygos vein, veins from the lower three spaces in the hemiazygos.

Posterior intercostal veins are so called to distinguish them from small *anterior intercostal veins* which are tributaries of the internal thoracic and musculophrenic veins.

Applied Anatomy. In obstruction of the upper inferior vena cava, the azygos and hemiazygos veins and vertebral venous plexuses are the main collateral channels maintaining venous circulation, by connecting superior and inferior venae cavae and communicating with the common iliac by ascending lumbar veins and with many tributaries of the inferior vena cava.

Bronchial veins, usually two on each side, drain blood from larger bronchi and from hilar structures. The right bronchial veins join the end of the azygos, the left join the left superior intercostal or hemiazygos vein. Some blood carried to the lungs by bronchial arteries returns via the pulmonary veins (see p. 1285).

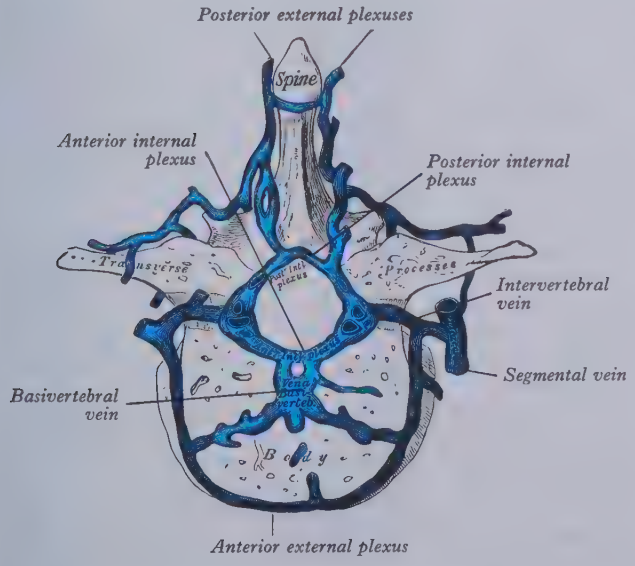
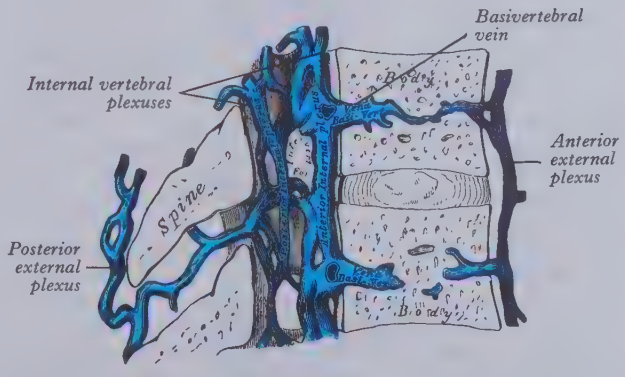
VEINS OF THE VERTEBRAL COLUMN (6.165,166)

These form intricate plexuses along the entire column, external and internal to the vertebral canal. Both groups are devoid of valves, anastomose freely with each other and join the intervertebral veins. Interconnections are widely established between these plexuses and longitudinal veins early in fetal life (Loginova 1972).



External vertebral venous plexuses, most developed in the cervical region, are anterior and posterior, anastomosing freely. *Anterior external plexuses* are anterior to the vertebral bodies, communicating with basivertebral and intervertebral veins and receiving tributaries from vertebral bodies. *Posterior external plexuses* lie posterior to vertebral laminae and around spines, transverse and articular processes. They anastomose with the internal plexuses and join the vertebral, posterior intercostal and lumbar veins.



6.164 The right aspect of the mediastinum. The right lung and most of the right pleura have been removed and a large opening made into the pericardial sac to expose the heart. In this specimen the fourth right posterior intercostal vein did not join the superior intercostal vein.

Internal vertebral venous plexuses occur between the dura mater and vertebrae, receiving tributaries from the bones, red bone marrow and spinal cord. They form a denser network than the external plexuses and are arranged vertically as four interconnecting longitudinal vessels, two in front, two behind.

Anterior internal plexuses are large plexiform veins on the posterior surfaces of vertebral bodies and intervertebral discs, flanking the posterior longitudinal ligament; under this they are connected by transverse branches, into which the large *basivertebral veins* open. *Posterior internal plexuses*, on each side in front of the vertebral arches and ligamenta flava, anastomose with the posterior external plexuses by veins passing through and between the ligaments. The internal plexuses interconnect by venous rings near each vertebra. Around the foramen magnum they form a dense network connecting with: vertebral veins, occipital and sigmoid sinuses, basilar plexus, venous plexus of the hypoglossal canal and the condylar emissary veins.

6.165 Transverse section through the body of a thoracic vertebra showing the vertebral venous plexuses and basivertebral veins.

6.166 Median sagittal section through two thoracic vertebrae showing the vertebral venous plexuses and basivertebral veins.

The basivertebral veins emerge from the posterior foramina of vertebral bodies. They are large and tortuous channels in bone, like those in cranial diploë. The trabecular bone in vertebral bodies contains much haemopoietic tissue. The basivertebral veins also drain into the anterior external vertebral plexuses through small openings in the vertebral bodies. Posteriorly they form one or two short trunks opening into the transverse branches uniting anterior internal vertebral plexuses. They enlarge in advanced age.

Intervertebral veins accompany the spinal nerves through intervertebral foramina, draining the spinal cord and internal and external vertebral plexuses, and ending in the vertebral, posterior intercostal, lumbar and lateral sacral veins. Whether the basivertebral or intervertebral veins contain effective valves is uncertain but experiment strongly suggests that their blood flow can be reversed (Batson 1957). This may explain how pelvic neoplasms, in particular, may metastasize in vertebral bodies, the cells spreading into the internal vertebral plexuses by connections with the pelvic veins when blood flow is temporarily reversed by raised intra-abdominal pressure or postural alterations.

Veins of the spinal cord lie in the pia mater, forming a tortuous venous plexus. In this there are: (1) two *median longitudinal veins*, one near the anterior median fissure, the other behind the posterior median septum; (2) two *anterolateral* and two *posterolateral longitudinal veins* respectively behind the ventral and dorsal spinal nerve roots. They drain to internal vertebral plexuses, and thence to intervertebral veins. Near the skull they unite into two or three small veins joined to the vertebral veins and ending in inferior cerebellar veins or the inferior petrosal sinuses.

VEINS OF THE LOWER LIMBS

Veins of the lower limbs can be subdivided, like those of the upper, into *superficial* and *deep* groups, the superficial being subcutaneous in the superficial fascia, the deep veins (beneath the deep fascia) accompanying major arteries. Both have valves, more numerous in deep veins and also more numerous than in the upper limb.

SUPERFICIAL VEINS OF THE LOWER LIMB (6.167,168)

The principal named superficial veins are the great (long) and small (short) saphenous; their numerous tributaries are mostly (but not wholly) unnamed; named vessels will be noted. (For variations consult Kosinski 1926.) As in the upper limb the vessels will be described centripetally from peripheral to major drainage channels.

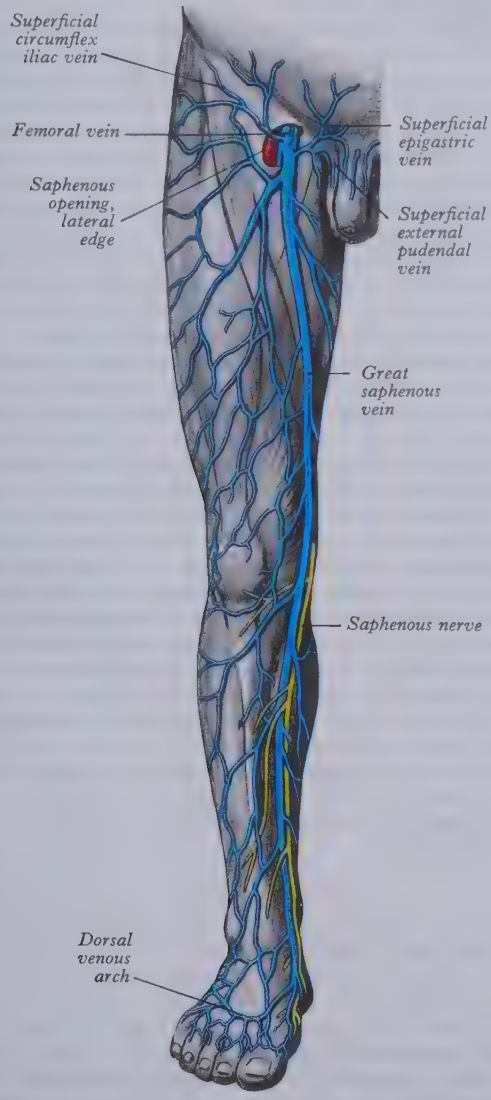
Dorsal digital veins receive, in the clefts between the toes, rami from the plantar digital veins and then join to form *dorsal metatarsal veins*, which are united across the proximal parts of the metatarsal bones in a *dorsal venous arch*. Proximal to this is an irregular *dorsal venous network* receiving tributaries from deep veins and continuous proximally with a venous network in the leg. At each side of the foot this network connects with *medial* and *lateral marginal veins*, both formed mainly by veins from more superficial parts of the sole. In the sole superficial veins form a *plantar cutaneous arch* across the roots of the toes and also drain into the medial and lateral marginal veins. Proximal to the plantar arch is a *plantar cutaneous venous plexus*, especially dense in the fat of the heel; this connects with the plantar cutaneous venous arch and other deep veins, but drains mainly into the marginal veins.

The great (long) saphenous vein (6.167) starts inferiorly (below) as a continuation of the medial marginal vein and ends in the femoral vein a short distance distal to the inguinal ligament (vide infra), being thus the body's longest vein. It ascends about 2.5–3 cm *anterior* to the tibial malleolus, crosses the distal third of the medial surface of the tibia obliquely to its medial border, then ascends a little behind the border to the knee; proximally it is posteromedial to the medial tibial and femoral condyles, then ascends the medial aspect of the thigh; after traversing the saphenous opening (p. 638) it finally enters the femoral vein. The so-called 'centre' of the opening is often said to be 2.5–3.5 cm inferolateral to the pubic tubercle; and the vein is then held to be represented by a line drawn from this to the femoral adductor tubercle. However, the saphenous opening, as noted elsewhere, varies greatly in size and disposition and its imagined centre has proved a poor indicator of the saphenofemoral junction. Royle et al (1981) made a careful quantitative study in 167 flush ligations in 136 subjects noting, in particular, the relative positions of the pubic tubercle, the venous junction and the inguinal skin crease. They concluded that a correctly placed incision for flush saphenofemoral ligation should be made 1 cm above, and parallel to, the inguinal skin crease, centring the incision at a point 4 cm lateral to and level with the pubic tubercle.

In its course through the thigh the great saphenous vein has branches of the medial femoral cutaneous nerve accompanying it: at the knee the saphenous branch of the descending genicular artery and, in the leg and foot, the saphenous nerve, are anterior to it. The vein is often duplicated, especially distal to the knee. It has from 10 to 20 valves, which are more numerous in the leg than the thigh. One is present just before it pierces the cribriform fascia, another at its junction with the femoral vein. In almost its entire extent the vein lies in superficial fascia, but it has many connections with the deep veins, especially in the leg (vide infra).

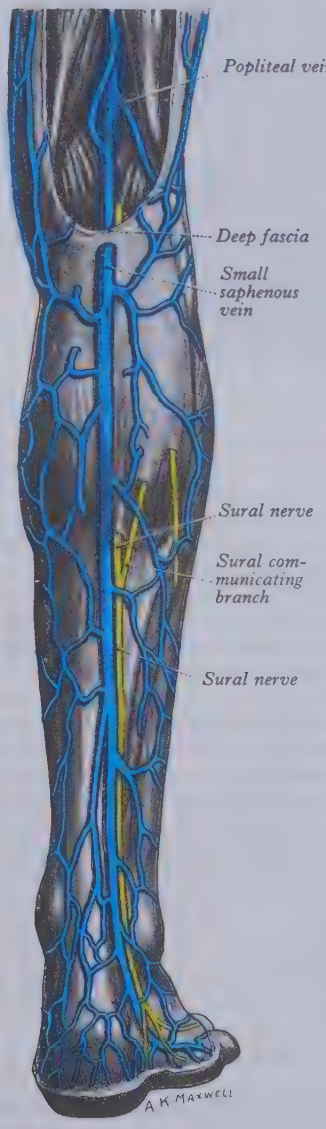
Tributaries. At the ankle it drains the sole by medial marginal veins. In the leg it often connects with the small saphenous vein and with deep veins through *perforating veins*. Just distal to the knee it usually has three large tributaries: one from the front of the leg, a second from the tibial malleolar region (connecting with some of the 'perforating' veins) and a third from the calf (communicating with the small saphenous vein). The second of these forms below in a fine network or 'corona' of delicate veins over the medial malleolus and then ascends the medial aspect of the calf as the *'posterior arch vein'* of Dodd & Cockett (1956); the clinical importance of its connections with posterior tibial venae comitantes by a series of perforating (communicating) veins was emphasized by Platz & Adelmann (1976), who proposed the term *'vena arcuata cruris posterior'*. The clinical significance of the latter should be reaffirmed, with relevant points concerning other venous channels in the leg (D Negus, 1988, personal communication). Although Platz & Adelmann (1976) mentioned 3–6 perforating veins, it has been indicated that three are most usual, being equally spaced between the medial malleolus and the mid-calf; more than three was termed 'most uncommon' and an arch vein perforator above mid-calf 'extremely rare'. The posterior crural arch vein was first illustrated by Leonardo da Vinci and his name is often applied to the vein in some surgical circles.

Above the posterior crural arch vein, perforating veins join the great saphenous or one of its main tributaries at two main sites. The first is at a level in the upper calf indicated by its name, the *tibial tubercle perforator (Boyd's perforator)*; the second is in the lower/intermediate third of the thigh where it perforates the deep fascial roof of the subsartorial canal to join the femoral vein (*Hunterian perforator*).



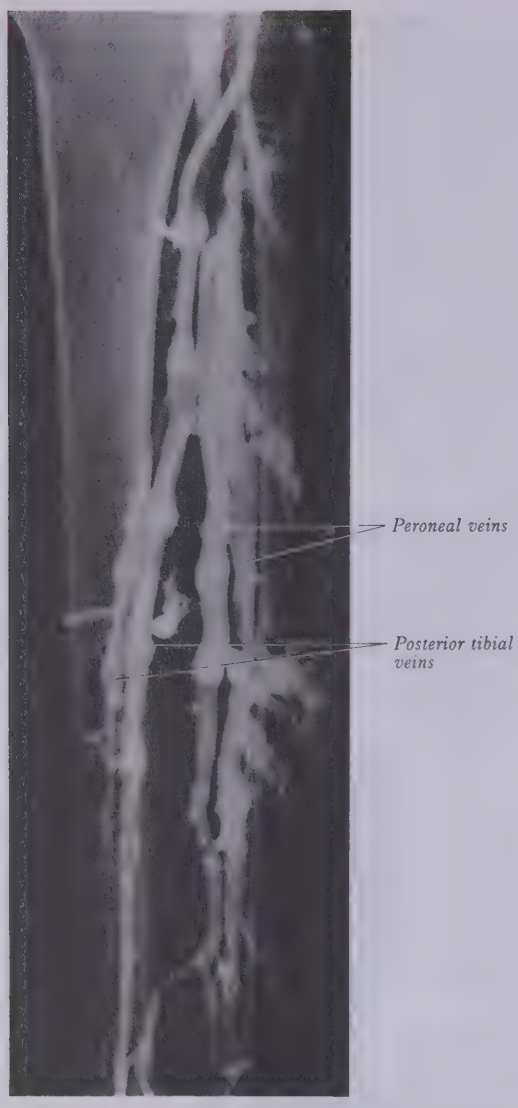
In the thigh the great saphenous vein receives many tributaries; some open independently, whilst others converge to form large named channels that frequently pass towards the basal half of the femoral triangle before joining the great saphenous near its termination. These may be grouped thus: one or more large posteromedial tributaries, one or more large anterolateral tributaries, four or more peri-inguinal veins. *The posteromedial vein of the thigh*, large and sometimes double, drains a large superficial tissue volume in the region indicated by its name; it has (as have the

other tributaries) radiological and surgical significance. One of its lower radicles is often continuous with the small saphenous vein. The posteromedial vein is sometimes (perhaps unhelpfully) named the *accessory saphenous vein* with greater emphasis on its variability of form and level of junction with the great saphenous. Some restrict the term *accessory* to a lower (more distal) posteromedial branch when two (or more) are present. Another large vessel, the *anterolateral vein of the thigh (anterior femoral cutaneous vein)*, usually commences from an anterior network of veins in the distal thigh and crosses the apex and distal half of the femoral triangle to reach the great saphenous vein. As the latter traverses its saphenous opening (**6**.167), it is joined by the superficial epigastric, superficial circumflex iliac and superficial external pudendal veins. Their mode of union varies. Superficial epigastric and circumflex iliac veins drain the inferior abdominal wall, the latter also receiving tributaries from the proximolateral region of the thigh; superficial external pudendal veins drain part of the scrotum, one being joined by the superficial dorsal vein of the penis. The deep external pudendal vein joins the great saphenous in its opening.



A *thoraco-epigastric vein* lies along the anterolateral aspect of the trunk and connects the superficial epigastric or femoral vein to the lateral thoracic veins, thus connecting femoral and axillary veins and hence superior and inferior vena caval fields of drainage. It is held to be in line with the primitive mammary ('milk') ridge which extends from the axilla to the pubic region (p. 177).

The small (short) saphenous vein (**6**.168) begins posterior to the lateral malleolus, as a continuation of the lateral marginal vein. In the distal (inferior or lower) third of the calf it ascends lateral to the tendo calcaneus, lying on the deep fascia and covered only by superficial fascia and skin. Inclining medially to the midline of the calf it enters an intra-deep fascial compartment (or tunnel) within which it ascends on the gastrocnemius, only emerging *between* the deep fascia and gastrocnemius gradually at about the junction of the intermediate and proximal thirds of the calf (well *below* the lower limit of the popliteal fossa). Continuing its ascent it passes between the heads of the gastrocnemius, then proceeds to its termination in the popliteal vein, 3–7.5 cm above the knee joint in the popliteal fossa. (These fascial relations are of considerable surgical significance when small saphenous vein ligation is contemplated. Figure **6**.168 from an earlier edition is somewhat misleading and should be examined in close conjunction with this textual description.



The small saphenous vein connects with deep veins on the dorsum of the foot, receives many cutaneous tributaries in the leg and sends several rami proximally and medially to join the great saphenous vein. Sometimes a communicating branch from it ascends medially to the accessory saphenous vein (vide supra); this may be the main continuation of the small saphenous. In the leg the small saphenous lies near the sural nerve. It has 7–13 valves, one near its termination. Its mode of ending is variable; it may join the great saphenous vein in the proximal thigh or it may bifurcate, one branch joining the great saphenous, the other the

6.167 The great saphenous vein and its tributaries.

popliteal or deep posterior femoral veins; sometimes it ends distal to the knee in the great saphenous or deep sural muscular veins.

Applied Anatomy. In a standing position, venous return from the lower limb depends largely on muscular activity (p. 691), especially contraction of the calf muscles, known as the 'calf pump', whose efficiency is aided by the tight sleeve of deep fascia. '*Perforating*' *veins* have been noted that connect the great saphenous with the deep veins, particularly near the ankle, distal calf and perigenual regions. In these channels valves are arranged to prevent flow of blood from deep to superficial veins. At rest, pressure in a superficial vein is equal to the height of the column of blood extending therefrom to the heart. When calf muscles contract, blood is pumped proximally in the deep veins but is normally prevented from flowing into superficial veins by the valves in the perforating veins; during relaxation blood can be aspirated from superficial into deep veins. If the valves in the perforating veins become incompetent, these veins become 'high pressure leaks' during muscular contraction; this transmission of high pressure in deep veins to superficial veins results in dilatation and venous stagnation in the latter, producing varicosities, devitalization of tissues and ultimately varicose ulceration. In operative treatment of severe varicose veins and ulcers, perforating veins *must* be ligatured. Similar perforating connections occur in the anterolateral region and varicosities may also occur here (Cockett 1956, Green et al 1958). Veins connecting the great saphenous to the femoral vein, in the adductor canal, may also become varicose (Dodd & Cockett 1956, Dodd 1959).

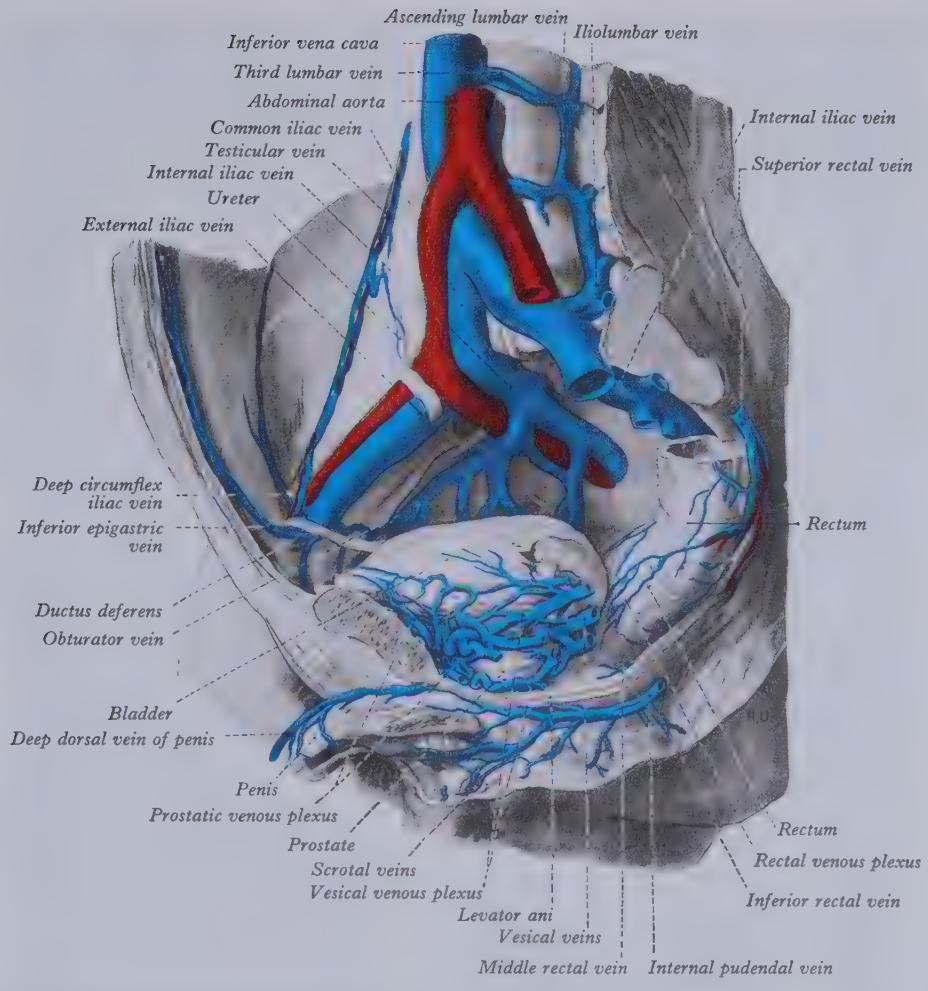
DEEP VEINS OF THE LOWER LIMB

These accompany the arteries and their branches; they have numerous valves (**6**.169). *Plantar digital veins* arise from plexuses in the plantar regions of the toes, connecting with dorsal digital veins and uniting into four *plantar metatarsal veins*; these run in the intermetatarsal spaces and connect by perforating veins with dorsal veins, then continue to form the *deep plantar venous arch*, accompanying the plantar arterial arch. From this *medial* and *lateral plantar veins* run near the corresponding arteries and, after communicating with the great and small saphenous veins, form behind the medial malleolus the posterior tibial veins.

Posterior tibial veins accompany the posterior tibial artery, receiving veins from sural muscles, especially the venous plexus in the soleus, connections from superficial veins and the *peroneal veins*. The latter, running with their artery, receive rami from the soleus and superficial veins.

Anterior tibial veins are continuations of the venous companions of the dorsal pedal artery. They leave the extensor region between the tibia and fibula, through the proximal end of the interosseous membrane, uniting with the posterior tibial veins to form the *popliteal vein* at the distal border of the popliteus.

The popliteal vein ascends through the fossa to an aperture in the adductor magnus, where it becomes the femoral vein. Distally it is medial to the artery; between the heads of gastrocnemius it is superficial (dorsal) to it; proximal to the knee joint it is posterolateral. Its tributaries are: the small saphenous vein, veins corresponding to branches of the popliteal artery and muscular veins, including a large one from each head of gastrocnemius. There are usually four valves in the popliteal vein.



The femoral vein accompanies its artery, beginning at the adductor opening as the continuation of the popliteal, and ending posterior to the inguinal ligament as the external iliac. In the distal adductor canal, it is posterolateral to the femoral artery; more proximally in the canal, and in the distal femoral triangle (i.e. its apex), it is posterior to it; at the triangle's base it is medial (**6**.127, 130). The vein occupies the middle compartment of the femoral sheath, between the femoral artery and canal, fat in the latter allowing expansion of the vein. It has many muscular tributaries: about 4–12 cm distal to the inguinal ligament the vena profunda femoris joins it posteriorly and then the great saphenous vein, which enters anteriorly. Lateral and medial circumflex femoral veins are usually tributaries. There are usually four or five valves in the femoral vein, the most constant being one just distal to the entry of the profunda femoris and one near the inguinal ligament.

The **vena profunda femoris** is anterior to its artery, its tributaries corresponding; through these it connects distally with the poplital and proximally inferior gluteal veins. It sometimes drains medial and lateral circumflex femoral veins. It has a valve just before its end.

VEINS OF THE ABDOMEN AND PELVIS

The External Iliac Vein

The proximal continuation of the femoral vein is the external iliac: it thus begins posterior to the inguinal ligament, ascends the pelvic brim and ends anterior to the sacro-iliac joint by joining the *internal iliac* to form the *common iliac vein*. On the right, it is first medial to the external iliac artery, gradually inclining behind it as it ascends; on the left, it is wholly medial. Medially it is crossed by the ureter and internal iliac artery, and is elsewhere covered by parietal peritoneum. In males it is crossed by the ductus deferens,

6.170 The veins of the right half of the male pelvis (after Spalteholz).

in females by the round ligament and ovarian vessels. Lateral is the psoas major, except where the artery intervenes. The vein is usually valveless, but may contain a single value.

Tributaries: inferior epigastric, deep circumflex iliac and pubic veins.

The inferior epigastric vein is the union of the venae comitantes of the inferior epigastric artery, which connect above with the superior epigastric veins; it joins the external iliac about 1 cm proximal to the inguinal ligament. **The deep circumflex iliac vein** is formed from venae comitantes of the corresponding artery; it joins the external iliac about 2 cm proximal to the inguinal ligament after crossing anterior to the external iliac artery. **The pubic vein**, connecting the external iliac with the obturator vein in the obturator foramen, ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery. It sometimes replaces the normal obturator vein.

The Internal Iliac Vein

Veins converge superiorly in the great sciatic foramen to form the internal iliac vein, which ascends posteromedial to the internal iliac artery to join the external iliac vein, forming the common iliac at the pelvic brim, anterior to the lower part of the sacro-iliac joint. It is covered anteromedially by parietal peritoneum.

Tributaries: (1) gluteal, internal pudendal and obturator veins, with origins outside the pelvis; (2) lateral sacral veins, anterior to the sacrum; (3) middle rectal, vesical, uterine and vaginal veins, originating in the venous plexuses of pelvic viscera.

The superior gluteal veins, venae comitantes of the superior gluteal artery, receive rami corresponding to branches of the artery; entering the pelvis via the greater sciatic foramen, above piriformis, they join the internal iliac vein, frequently as a single trunk.

The inferior gluteal veins, venae comitantes of the inferior gluteal artery, begin proximally and posterior in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins; they enter the pelvis low in the greater sciatic foramen, joining to form a vessel opening into the distal (lower) part of the internal iliac vein. They connect with the *superficial gluteal veins* by perforating veins (Doyle 1970) similar to those in the calf (p. 812). These *gluteal perforating veins* are, indeed, even more numerous than the sural ones. In addition to a probable venous 'pumping' role, they provide collaterals between the femoral and internal iliac veins.

The internal pudendal veins, venae comitantes of the internal pudendal artery, begin in the prostatic venous plexus (p. 816), accompany the artery and unite as a single vessel ending in the internal iliac vein. They receive veins from the penile bulb and the scrotal (or labial) and inferior rectal veins. The deep dorsal vein of the penis connects with the internal pudendal but ends mainly in the prostatic plexus.

The obturator vein begins in the proximal adductor region, enters the pelvis superiorly in the obturator foramen, and runs back and up on the lateral pelvic wall below the obturator artery covered by peritoneum; it then passes between the ureter and internal iliac artery to end in the internal iliac vein. Sometimes it is replaced by an enlarged pubic vein, which joins the external iliac (p. 814).

Lateral sacral veins accompany the lateral sacral arteries; they are interconnected by a *sacral venous plexus*.

The middle rectal vein varies in size; it begins in the rectal venous plexus, with tributaries from bladder, prostate and

seminal vesicle; it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein.

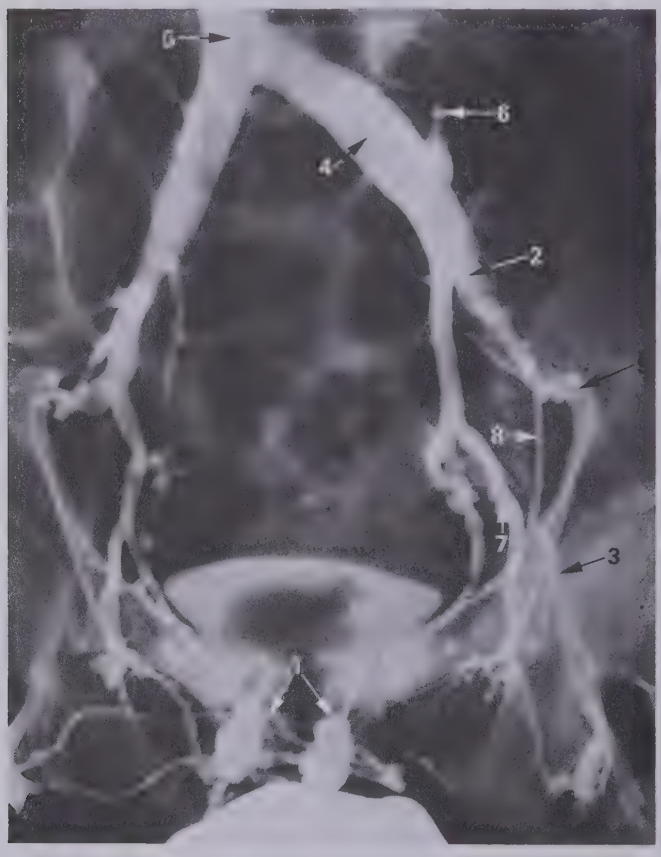
The rectal venous plexus surrounds the rectum, connecting anteriorly with the vesical plexus in males and the uterovaginal plexus in females. It consists of an *internal* part beneath the rectal and anal epithelium and an *external* part outside the muscular stratum. In the anal canal the internal plexus has longitudinal dilatations, connected by transverse branches in circles immediately above the anal valves. The dilatations are most prominent in the left lateral, right anterolateral and right posterolateral sectors. The internal plexus drains mainly to the superior rectal vein but connects widely with the external plexus. The external plexus is drained inferiorly by the inferior rectal vein into the internal pudendal, its middle part by a middle rectal vein into the internal iliac, its superior part by the superior rectal vein, which is the commencement of the inferior mesenteric (a tributary of the portal vein). Communication between portal and systemic venous systems is thus established in the rectal plexus.

Applied Anatomy. Veins of the internal rectal plexus are apt to become varicose, as *internal haemorrhoids*, especially in the sectors indicated above. The vessels are in very loose areolar tissue, less supported by surrounding structures than most veins, and are less able to resist increased blood pressure; the superior rectal and portal veins have no valves; rectal veins pass through muscular tissue and are liable to compression, especially during defecation; they are affected by every form of portal obstruction. The veins in the subcutaneous part of the external plexus may thrombose, the basis of one type of *external haemorrhoid*; rupture of these vessels may lead to acute perianal haematoma.

The prostatic venous plexus is posterior to the arcuate pubic ligament and lower part of symphysis pubis, anterior to the bladder and prostate (**6**.170). Its chief tributary is the deep dorsal vein of the penis; it also receives anterior vesical and prostatic rami, connecting with the vesical plexus and internal pudendal vein. It drains into vesical and internal iliac veins. The plexus is embedded in the lateral fascial prostatic sheath (p. 1434).

The vesical plexus envelops the lower bladder and, in males, the prostatic base, communicating with the prostatic plexus in males and the vaginal plexus in females. It is drained by several vesical veins which usually unite to enter the internal iliac vein.

The dorsal veins of the penis are unpaired, and are superficial and deep: The *superficial dorsal vein* drains the prepuce and penile skin; running back in subcutaneous tissue it inclines right or left, and opens into one of the external pudendal veins. The *deep dorsal vein* is inside the fibrous penile sheath; it receives blood from the glans penis and corpora cavernosa penis, coursing back in the midline between the paired dorsal arteries; near the radix penis it passes deep to the suspensory ligament and through a gap between the arcuate pubic ligament and anterior margin of the perineal membrane (inferior fascia of the urogenital diaphragm), dividing into right and left branches which enter the prostatic plexus after connecting below the symphysis pubis with the internal pudendal veins. The *dorsal vein of the clitoris*, after a similar course, ends in the vesical plexus.



Uterine plexuses extend lateral to the uterus in the broad ligaments, communicating with the ovarian and vaginal plexuses. They are drained by two uterine veins on each side, arising inferiorly in the plexuses, level with the external os and draining to the internal iliac veins.

Vaginal plexuses flank the vagina; they connect with uterine, vesical and rectal plexuses and are drained by vaginal veins, one each side, to the internal iliac veins.

Common iliac veins (**6**.170, 171) result from the union of external and internal iliac veins, anterior to the sacro-iliac joints. They ascend obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle to form the inferior vena cava. The *right common iliac vein*, the shorter, is nearly vertical, ascending posterior, then lateral to its artery. The right obturator nerve passes posterior, descending forward to its foramen. The *left common iliac vein*, longer and more oblique, is first medial to its artery, then posterior. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior rectal vessels. In the rest of its course it is covered only by peritoneum. Each vein receives iliolumbar and sometimes lateral sacral veins; the left common iliac drains the median sacral vein. There are no valves in these veins.

Median sacral veins accompany the corresponding artery anterior to the sacrum, joining into a single vein usually ending in the left common iliac but sometimes at the common iliac junction.

Variations. The left common iliac vein occasionally ascends *left* of the aorta to the level of the kidney where, receiving the left renal vein, it crosses *anterior* to the aorta to join the inferior vena cava. This vessel represents the persistent caudal half of the left postcardinal or supracardinal vein (p. 223).

Internal iliac vein. 3. External iliac vein (faintly outlined). 4. Common iliac vein. 5. Inferior vena cava. 6. Ascending lumbar vein. 7. Obturator vein. 8. Internal pudendal vein. 9. Gluteal vein. Radiograph supplied by M Lea Thomas.

The Inferior Vena Cava (**6**.107A,170,172)

This conveys blood to the right atrium from all structures below the diaphragm. It is formed by the junction of the common iliac veins anterior to the fifth lumbar vertebral body, a little to its right. It ascends anterior to the vertebral column, to the right of the aorta. Reaching the liver, it is contained in a deep groove on its posterior surface or sometimes in a tunnel completed by a band of liver tissue. It perforates the *tendinous* part of the diaphragm between its median and right 'leaves' and inclines slightly anteromedially. Passing through the fibrous pericardium and through a posterior inflexion of the serous pericardium it opens into the inferoposterior part of the right atrium. Anterior and left of its atrial orifice is a semilunar *valve of the inferior vena cava*, relatively less prominent in adults, but large and overtly functional in the fetus (p. 723). The vessel is otherwise devoid of valves.

Relations of the abdominal part. *Anteriorly* the inferior vena cava is overlapped at its commencement by the right common iliac artery and covered, below the horizontal part of the duodenum, by the posterior parietal peritoneum. It is crossed obliquely by the root of the mesentery and its contained vessels and nerves and by

6.172 Inferior vena cavogram in an adult male while performing the Valsalva manoeuvre. Supplied by Shaun Gallagher, Guy's Hospital; photography by Sarah Smith.

the right testicular or ovarian artery. It ascends behind the head of the pancreas and then the superior part of the duodenum, separated from it by the common bile duct and portal vein. Above the duodenum it is again covered by peritoneum of the posterior wall of the epiploic foramen (**8.99**), separating it from the right free border of the lesser omentum and its contents. Above this the liver is anterior.

Posterior are the lower three lumbar vertebral bodies, their intervening symphyses ('discs') and the anterior longitudinal ligament, the right psoas major, right sympathetic trunk, and third and fourth right lumbar arteries; superior to these are the right crus (partially separated by the medial part of the right suprarenal gland and the right coeliac ganglion) and the right renal, suprarenal and inferior phrenic arteries.

Right lateral are the right ureter, the descending part of the duodenum, the medial border of the right kidney and right lobe of the liver. *Left lateral* are the aorta and above this the right crus and caudate lobe.

Relations of the thoracic part. This part of the inferior vena cava is very short, partly inside and partly outside the pericardial sac. The *extrapericardial part* is separated from the right pleura and lung by the right phrenic nerve. The *intrapericardial part* is covered, except posteriorly, by inflected serous pericardium.

Surface Anatomy. The vein begins in, or just below, the transtubercular plane, its centre 2.5 cm right of the midline; about 2.5 cm wide, it ends behind the sternal end of the sixth right costal cartilage. A band from its lower end to a part of the inguinal ligament centred at a point 1 cm medial to the mid-inguinal point indicates the *common* and *external iliac veins* on each side.

Variations. Numerous anomalies occur and are attributable to arrests or errors in its complex formation. It is sometimes replaced, below the level of the renal veins, by two more or less symmetrical vessels, often associated with the failure of interconnection between the common iliac veins, and due to persistence on the left of a longitudinal channel (usually supra- or subcardinal) which normally disappears in early fetal life (p. 223). In complete visceral transposition, the inferior vena cava is left of the aorta.

Applied Anatomy. Thrombosis of the inferior vena cava leads to oedema of the legs and back, without ascites. Collateral venous circulation is soon established by enlargement of either

the superficial or deep veins, or both; the epigastric, circumflex iliac, lateral thoracic, thoraco-epigastric (p. 813), internal thoracic, posterior intercostals, external pudendal and lumbovertebral anastomotic veins connect it with the superior vena cava; deep connections are made through the azygos, hemiazygos and lumbar veins. Vertebral venous plexuses may also provide effective collateral circulation between the venae cavae (Batson 1957).

Tributaries: the common iliac, lumbar, right testicular or ovarian, renal, right suprarenal, inferior phrenic and hepatic veins.

Lumbar veins, four pairs, collect blood by dorsal tributaries from lumbar muscles and skin, and by abdominal tributaries from the walls of the abdomen, where they connect with the epigastric veins. Near the vertebral column they drain the vertebral plexuses and are connected by the **ascending lumbar vein**, a longitudinal vessel anterior to the roots of the lumbar transverse processes. The *third* and *fourth lumbar veins* pass forward on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava; the left veins pass behind the abdominal aorta and are therefore longer. *First* and *second lumbar veins* may join the inferior vena cava, ascending lumbar, or lumbar azygos veins; the first does not usually enter the inferior vena cava; it may turn down to join the second and so open into it indirectly, but more often ends in the ascending lumbar vein or passes forward over the first lumbar vertebral body to the lumbar azygos vein (p. 808). The second lumbar vein may join the inferior vena cava at or near the level of the renal veins; sometimes it joins the third lumbar vein or may end in the ascending lumbar. First and second lumbar veins are often connected to each other, to contralateral veins and to right and left lumbar azygos veins by a plexus on the upper lumbar vertebral bodies.

The ascending lumbar vein connects the common iliac, iliolumbar and lumbar veins. It is between the psoas major and roots of the lumbar transverse processes. Superiorly it joins the subcostal vein and the vessel so formed turns forward over the twelfth thoracic vertebral body and, passing deep to the crus, ascends as the azygos vein on the right and as the hemiazygos on the left. There is an angle on the vessel as it turns up; it is usually joined here by a small vessel from the back of the inferior vena cava (or left renal vein on the left). This little vein represents the azygos line (p. 224), already described as the *lumbar azygos vein* (p. 808). Sometimes the ascending lumbar vein ends in the first lumbar, which then skirts the first lumbar vertebra with the first lumbar artery to join the lumbar azygos vein, the subcostal vein then joining the azygos vein on the right and the hemiazygos on the left.

Testicular veins (**6**.107A) emerge posteriorly from the testis, drain the epididymis and unite to form the *pampiniform plexus*, a chief component of the spermatic cord, ascending anterior to the ductus deferens. Distal to the superficial inguinal ring the plexus is drained by three or four veins traversing the inguinal canal to the abdomen through the deep inguinal ring; they coalesce into two veins, which ascend anterior to the psoas major and ureter, behind the peritoneum, on each side of the testicular artery. These veins join and open into the inferior vena cava on the right at an acute angle just inferior to the level of the renal veins; the left testicular vein opens into the left renal vein at a right angle. The testicular veins contain valves; the left passes behind the lower descending colon and inferior margin of the pancreas and is crossed by the left colic vessels; the right passes behind the terminal ileum and horizontal part of the duodenum and is crossed by the root of the mesentery, ileocolic and right colic vessels.

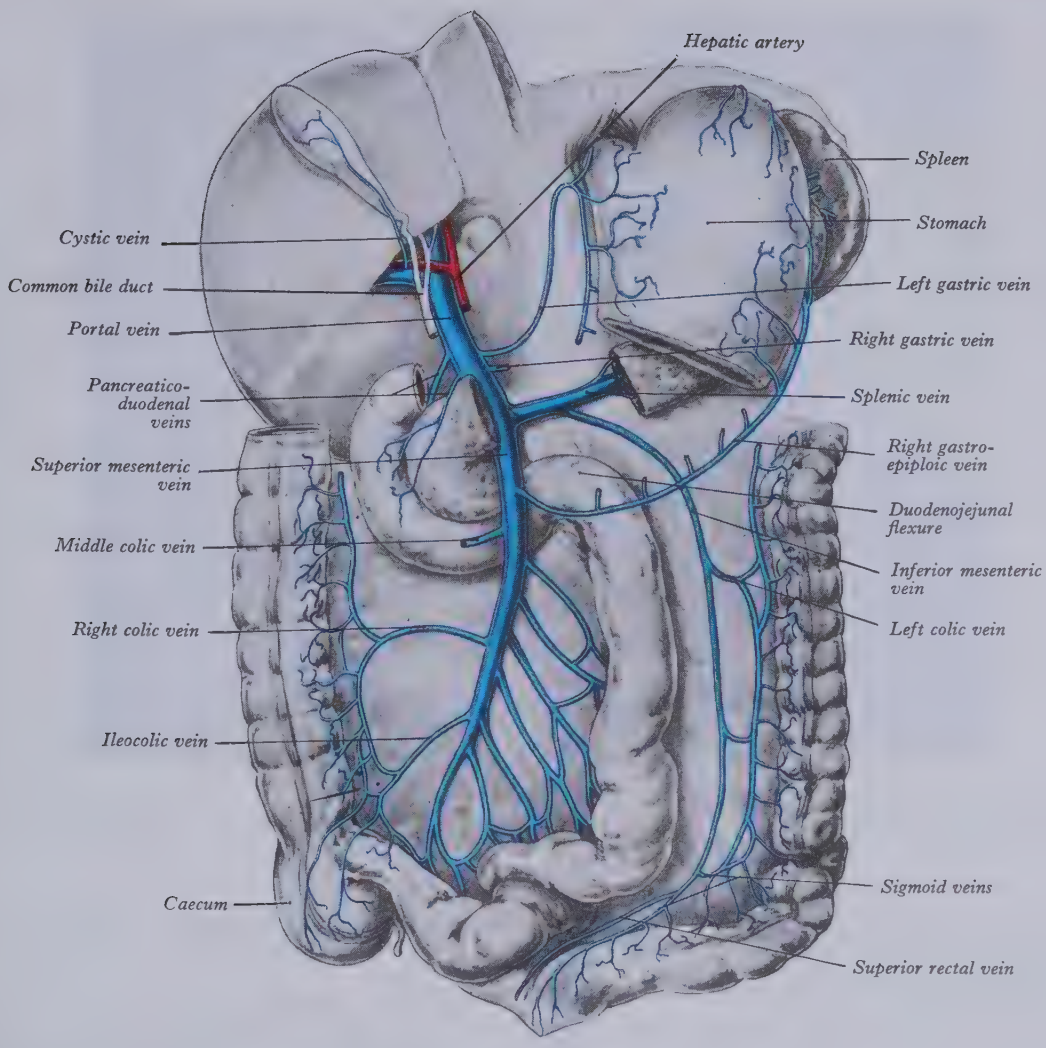
Applied Anatomy. The testicular veins are frequently varicose; varicocele, which is almost always on the left, is perhaps due to the orthogonal junction of the left testicular and renal veins. It is also overlaid by the descending colon and, when this is distended by constipation, its weight may impede venous return. After removal of a varicocele, venous return is by the small veins of the ductus deferens, cremaster and scrotal tissues.

Ovarian veins each form a plexus in the broad ligament near the ovary and uterine tube, communicating with the uterine plexus. Two veins issue from this and ascend across the external iliac artery with the ovarian artery. Their further course is like that of the testicular veins. Valves may occur in them. Like the uterine veins, they are much enlarged in pregnancy.

Renal veins, of large size and anterior to the renal arteries, open into the inferior vena cava almost at right angles. The *left* is three times the right in length (7.5 cm and 2.5 cm); it crosses the posterior abdominal wall posterior to the splenic vein and body of pancreas and, near its end, is *anterior* to the aorta, just *below* the origin of the superior mesenteric artery. The left testicular or ovarian vein enters it from below and the left suprarenal vein, usually receiving one of the left inferior phrenic veins, enters it above but nearer the midline. The left renal vein enters the inferior vena cava a little superior to the right. The *right renal vein* is behind the descending duodenum and sometimes the lateral part of the head of the pancreas.

Variations. The left renal vein may be double, one vein passing posterior, one anterior to the aorta to join the inferior vena cava, a condition named persistence of the 'renal collar' (p. 225); the anterior may be absent, representing persistence of the posterior limb of the renal collar combined with absence of an intersubcardinal anastomosis.

Suprarenal veins issue from each suprarenal hilum. The right is short, passing directly and horizontally into the posterior aspect of the inferior vena cava; the left descends medially anterior or lateral to the left coeliac ganglion, to pass posterior to the pancreatic body to reach the left renal vein.



Inferior phrenic veins follow the corresponding arteries on the inferior diaphragmatic surface; the right ends in the inferior vena cava; the left is often double, one branch ending in the left renal or suprarenal vein, the other passing anterior to the oesophageal opening to join the inferior vena cava.

Hepatic veins drain the liver, commencing as *intralobular veins*, draining the sinusoids of liver lobules (p. 1381); these lead to *sublobular veins*, which eventually unite into *hepatic veins*, emerging from the posterior hepatic surface to open *at once* into the inferior vena cava in its groove on the posterior hepatic surface. Hepatic veins are arranged in upper and lower groups. The *upper* are usually large veins, right, left and middle, the last from the caudate lobe; the *lower*, varying in number, are small and from the right and caudate lobes. The hepatic veins are contiguous with hepatic tissue and have no valves. Large *'accessory' hepatic veins* of the lower group, draining a variable volume of the right lobe, have been studied in 93 adult livers by corrosion casts; they are usually single, occasionally double, with an incidence of 15% (Sledzinski & Tyszkiewicz 1975).

The Hepatic Portal System

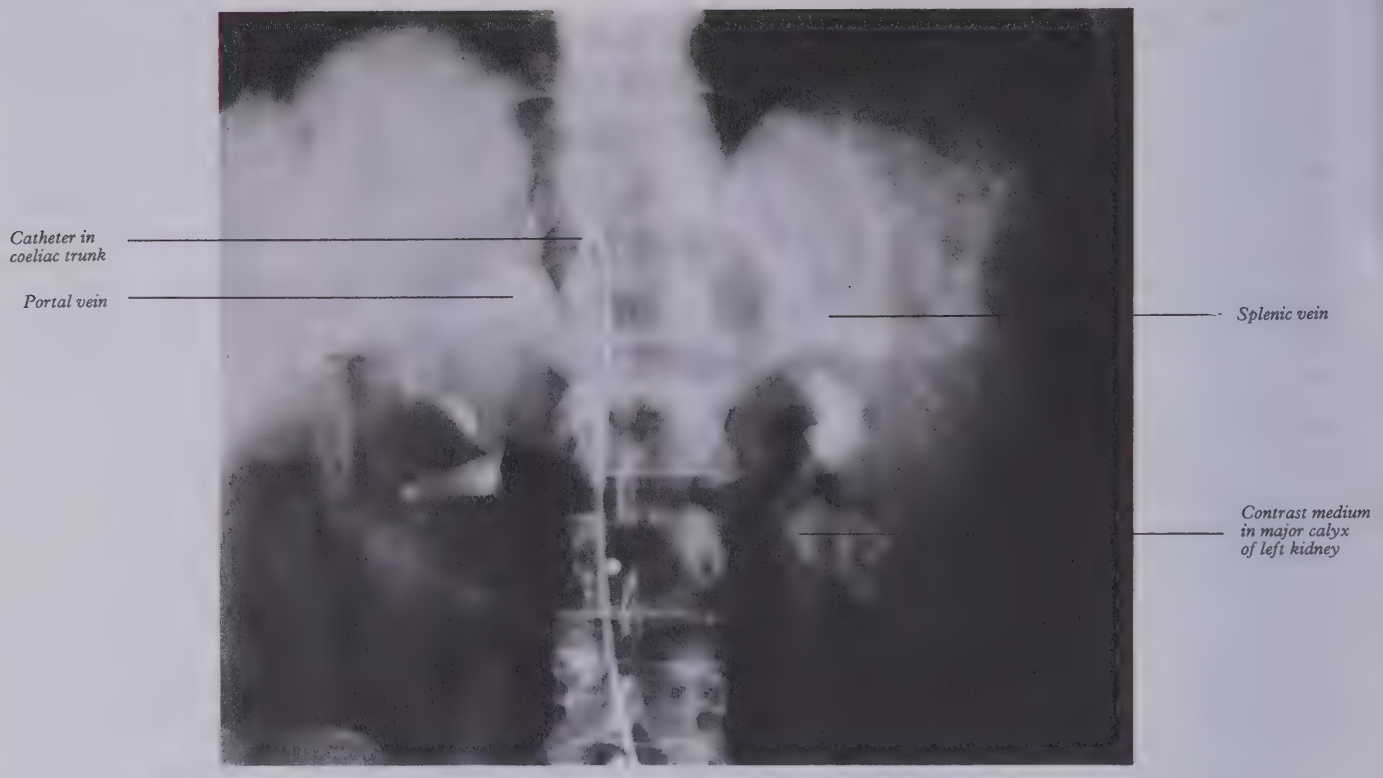
The portal system (**6**.173,174) includes all the veins draining the abdominal part of the digestive tube (*except* the lower anal canal but *including* the preterminal oesophagus) and spleen, pancreas and gallbladder. From these viscera blood is conveyed by the *portal vein* to the liver, where it ramifies like an artery, ending in the sinusoids, from which blood again converges to reach the inferior vena cava via the hepatic veins. The blood therefore passes through *two* sets of 'exchange' vessels: (1) capillaries of the digestive tube, spleen, pancreas and gallbladder; (2) the hepatic sinusoids. In adults, the portal vein and its tributaries have no valves; in fetal life and for a short postnatal period valves are demonstrable in its tributaries; usually they atrophy but some may persist in degenerate form.

The portal vein (**6**.111,173,174), about 8 cm long, begins at the second lumbar vertebral level as the junction of the superior mesenteric and splenic veins, *anterior* to the inferior vena cava, *posterior* to the neck of the pancreas. It inclines slightly right as it ascends behind the superior part of the duodenum, bile duct and gastroduodenal artery and is here directly anterior to the inferior vena cava; however, it enters the right border of the lesser omentum, ascending anterior to the epiploic foramen to the right end of the porta hepatis, dividing into right and left stems, which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum it is posterior to both bile duct and hepatic artery, the former being to the right; it is surrounded by the hepatic nerve plexus and accompanied by many lymph vessels

6.173 The portal vein and its tributaries (semi-diagrammatic). Portions of the stomach, pancreas and left lobe of the liver and the transverse colon have been removed.

and some lymph nodes. The *right branch* enters the right hepatic lobe but usually first receives the cystic vein. The *left branch*, longer but of smaller calibre, branches into caudate, quadrate and left lobes. (See critique on hepatic lobation and lobulation pp. 1385, 1387.) As it enters the left lobe it is joined by para-umbilical veins (p. 820) and the *ligamentum teres*, a remnant of the obliterated left umbilical vein. It is connected to the inferior vena cava by the *ligamentum venosum*, a vestige of an obliterated ductus venosus, ascending in a fissure on the liver's posterior aspect (p. 723). The small extrahepatic section of the left branch, from which veins to the quadrate and left lobes arise, is a persistent part of the left umbilical vein. Tributaries of the portal vein are: splenic, superior mesenteric, left gastric, right gastric, para-umbilical and cystic veins.

The splenic vein (**6**.173,174), large and *not* tortuous, is formed by five or six tributaries from the spleen. It traverses the lienorenal ligament with the splenic artery and tail of the pancreas, and descends to the right, across the posterior abdominal wall inferior to its artery and posterior to the body of the pancreas (which it grooves), receiving numerous short rami from the gland. It crosses anterior to the left kidney and its hilar structures (or lower pole of the left suprarenal gland), separated from the left sympathetic trunk and crus by the left renal vessels and from the abdominal aorta by the superior mesenteric artery and left renal vein. It ends behind (lodged in) the neck of pancreas, where it joins the superior mesenteric vein at a right angle to form the portal vein.



Tributaries: short gastric, left gastro-epiploic, pancreatic and inferior mesenteric veins.

Short gastric veins, four or five, drain the gastric fundus and the left part of its greater curvature, traversing the gastrosplenic ligament to reach the splenic vein or one of its large tributaries.

The left gastro-epiploic vein drains both gastric surfaces and the adjacent greater omentum; it runs from right to left along the greater curvature, between the anterior two omental layers, ending in or near the beginning of the splenic vein.

Pancreatic veins drain the body and tail of the pancreas. They may be small and many or large and few. The former empty more or less directly into the splenic vein; in the latter case, superior and inferior arcades receive these larger veins, their ultimate drainage being into the splenic (Sow et al 1976, and p. 1385).

The inferior mesenteric vein (**6**.173) drains the rectum, and sigmoid and descending parts of the colon. It begins as the *superior rectal vein*, from the rectal plexus (p. 816), through which it connects with middle and inferior rectal veins. The superior rectal vein leaves the pelvis and crosses the left common iliac vessels medial to the left ureter with the superior rectal artery, continuing up as the inferior mesenteric vein. This is left of its artery, ascending behind the peritoneum anterior to the left psoas major; it may cross the testicular or ovarian vessels or be medial to them and then passes above, or behind, the duodenojejunal flexure, opening into the splenic vein posterior to the body of the pancreas; sometimes it ends at the union of the splenic and superior mesenteric veins. If a duodenal or paraduodenal fossa exists, the vein is

6.174 Venous phase showing the splenic and portal veins after injection of contrast medium into the coeliac trunk.

usually in its anterior wall (p. 1345). Its *tributaries* are *sigmoid veins* from the sigmoid colon and the *left colic vein* from the descending colon and the left colic flexure.

The superior mesenteric vein (**6**.173) drains the small intestine, caecum and ascending and transverse parts of the colon. Beginning in the right iliac fossa by the union of tributaries from the terminal ileum, caecum and vermiform appendix, it ascends in the mesentery on the right of the superior mesenteric artery, passing anterior to the right ureter, inferior vena cava, the horizontal part of the duodenum and uncinate process of the pancreas, joining the splenic vein behind its neck to form the portal vein (**6**.173,174). Its *tributaries* are: jejunal, ileal, ileocolic, right and middle colic, right gastro-epiploic and pancreaticoduodenal veins.

The right gastro-epiploic vein drains the greater omentum and distal part of stomach, passing right on the gastric greater curvature between the anterior layers of the greater omentum to join the superior mesenteric vein below the neck of the pancreas.

The pancreaticoduodenal veins accompany their corresponding arteries: the *inferior* often joins the right gastro-epiploic vein; the *superior* usually ascends to the left behind the bile duct to end in the portal vein. Sow et al (1975) have observed anterior intraglandular and *posterior venous arcades* between the superior and inferior pancreaticoduodenal veins in about 70% of 157 pancreatic corrosion preparations.

The left gastric vein drains both gastric surfaces, ascending the lesser curvature to the left in the lesser omentum, to the oesophageal opening, where it receives the oesophageal veins. It then curves back down and to the right *behind* the omental bursa to end in the portal vein at the upper border of the superior part of the duodenum.

The right gastric vein is small and runs to the right along the pyloric section of the lesser curvature in the lesser omentum, ending in the portal vein. It is joined by a *prepyloric vein* ascending anterior to the pylorus (a surgical guide to the pyloric opening).

Para-umbilical veins connect veins of the anterior abdominal wall and portal vein, extending along the ligamentum teres and median umbilical ligament (p. 1417). Best developed is one beginning at the umbilicus and running in or on (the hepatic) ligamentum teres in the falciform fold to end in the left branch of the portal branch.

Cystic veins draining the gallbladder vary. Those from its superior surface are in areolar tissue between the gallbladder and liver, usually entering the liver through the vesical fossa to join the hepatic veins. The remainder form one or two cystic veins which commonly also enter the liver either directly or after joining the veins draining the hepatic ducts and upper bile duct. Only rarely does a single or double cystic vein drain into the right portal branch.

Applied Anatomy. Portal obstruction may cause ascites, whether obstruction is intra- or extrahepatic. In cirrhosis, radicles of the portal vein are compressed by contraction of the fibrous tissue in their portal canals. In valvular cardiac disease, back-pressure on the hepatic veins, and thus on the whole hepatic circulation, has similar effects. The portal vein may be compressed by hepatic tumours, enlarged lymph nodes in the lesser omentum or carcinoma of the pancreatic head. Portal thrombosis may complicate various conditions. In portal obstruction *anastomoses between portal and systemic circulations*, which may offer effective collateral circulation, are as follows: (1) On the abdominal oesophagus tributaries of the left gastric vein (portal) connect with oesophageal tributaries of the azygos and accessory hemiazygos veins (systemic). Enlargement of these may result in varicosity (oesophageal varices) and even fatal haematemesis. (2) In the anal wall opening up of connections between the inferior and middle rectal (systemic) and superior rectal (portal) veins may result in varicosity. (3) At the umbilicus, veins running on the ligamentum teres to the left portal branch (p. 819) connect with the epigastric veins (systemic); enlargement of these connections may produce varicosities of veins radiating from the umbilicus, the *caput Medusae*. (4) Retroperitoneal veins communicate directly with venous radicles of the colon and bare area of the liver. (5) Very rarely a patent ductus venosus connects the left branch of the portal vein to the inferior vena cava.

Some success has been achieved in treating portal obstruction by anastomosis of the portal vein to the inferior vena cava, or of the splenic to the left renal vein after splenectomy.

THE LYMPHATIC SYSTEM

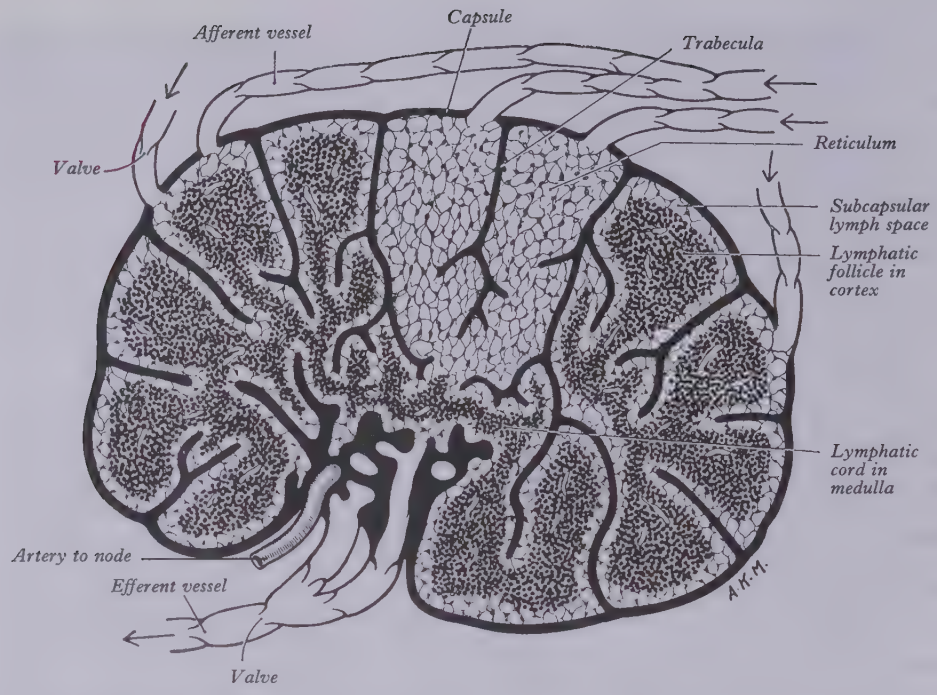
Introduction

Dispersed widely in the body are the tissues, fluids and cells concerned in a variety of interrelated functions, including the circulation and modification of tissue fluid formed in the capillary beds, the removal by mononuclear phagocytes of cell debris and foreign matter (p. 668) and the long-term specific immune responses of the lymphocytes (p. 667) and other cells. These activities overlap and have a common cellular base with those of the blood vascular system, but it is important to distinguish between *lymphatic vessels* or '*lymphatics*' which are endothelial tubes, lined externally in the case of larger conduits with connective tissue, and *lymphoid tissue*, consisting of aggregates of lymphocytes and associated cells. These cells are in many instances intimately connected with the lymphatic channels, and process or add to their fluid and cellular contents, e.g. in lymph nodes and lymphoid nodules. In other cases, lymphoid *tissue* may be quite separate from lymphatics, e.g. the spleen, which is concerned with modifying the blood, and the bone marrow and thymus, which produce lymphocytes and other cells to populate the lymphoid tissue elsewhere, with immunologically active cells of different classes.

As stated elsewhere, most tissue fluid formed at the arterial ends of capillaries returns to the circulation via their venous ends but 10-20% of such fluid passes into blind ending lymphatic capillaries, then traverses one or more lymph nodes before returning to the venous system and thus the haemal circulation. Before considering the detailed topography of lymphatic channels and lymph nodes, we will consider the general structure of lymphatic vessels, lymph nodes, lymphatic nodules, the spleen and the thymus.

Lymphatic Vessels

Lymphatic capillaries form plexuses in tissue spaces which have much wider meshes than those of the adjacent blood capillaries. They often begin as dilated lymphatics with closed ends; the calibres are larger and cross-sectional appearances are less regular than those of blood capillaries, and they lack a basal lamina, though they have numerous vesicles within their cytoplasm, a typical endothelial feature. (See Leak 1984 for a review of lymphatic microstructive and physiology.) Their endothelium is generally quite permeable to much larger molecules (Allen 1967) and, unlike most haemal capillaries, are readily permeable to colloidal materal and larger particles such as cell debris and micro-organisms from tissue spaces, and to cells. When lymph vessels are obstructed, the surrounding tissues become oedematous, i.e. distended with fluid containing much protein. Experiments suggest that the observed absorption of macromolecules and particles is via gaps between endothelial cells or by micropinocytosis through them. Lymph from most tissues is clear and colourless but from the small intestine it is milky, due to the absorption of fat globules (chylomicrons), and is called *chyle*, the terminal vessels in the small intestine being *lacteals*. Lymphatic capillaries, though present in many tissues, are absent from avascular structures (epidermis, hair, nails, cornea, articular and some other cartilages), and from central nervous tissue and bone marrow. They are very few in the endomysium of skeletal muscle.



Lymphatic capillaries join into larger vessels which pass to local or sometimes more remote lymph nodes. These are arranged largely in *regional groups*, sufficiently regular in position to be named. Each has its region of drainage but a local group is often bypassed. Nodes within a group are often interconnected (Kubik 1974). In general, lymph traverses a series of nodes before reaching the major collecting ducts. There are exceptions to this: lymph vessels of the thyroid gland and oesophagus and of the coronary and triangular ligaments of the liver drain directly to the thoracic duct without passing through lymph nodes (Rusznyak et al 1960). The superficial lymphatics of skin adjoin the deep fascia and accompany superficial veins, but some run independently; they have few connections with deep lymphatics. Deep lymphatic trunks usually accompany the arteries or veins, almost all reaching either the *thoracic duct* or the *right lymphatic duct* (p. 841), which join the left and right brachiocephalic veins respectively with the veins at the root of the neck. Some observers have also reported additional entry points into the venous system through the inferior vena cava and the renal, suprarenal, azygos and iliac veins. As the lymphatic vessels are closely associated with veins in their development (p. 226), such additional connections would not be surprising, although they are likely to be variable. Most lymphatic vessels anastomose freely and *across the midline*; larger ones have their own plexiform vasa vasorum. If their walls are acutely infected (lymphangitis) this plexus is congested, marking the paths of superficial vessels by red lines, visible through the skin and tender to the touch. Nerve fibres, in and near the walls of larger vessels have been described.

Lymphatic vessels repair easily and new vessels readily form after damage; these are at first solid cellular sprouts from the endothelial cells of persisting vessels, which later canalize.

The microscopic structure of lymphatic vessels. The wall of lymphatic capillaries consists of a single layer of endothelium, as in haemal capillaries. A basal lamina is often lacking and specialized intercellular attachments are few. Fenestrae have been demonstrated in subserous lymphatics, though they are absent in well-fixed subcutaneous lymphatic vessels, except after trauma. Filopodia are frequent on their luminal surfaces and in lacteals similar projections may exist on their external surface. Pericytes are absent (Fraley & Weiss 1961). As in haemal capillaries, there are structural variations between lymphatic capillaries in different tissues (Allen 1967, Leak & Bruke 1968). As they unite into larger vessels, a thin external connective tissue coat supports the endothelium. Larger collecting trunks have three layers, similar to those of small veins. The tunica intima is composed of endothelium with a thin subendothelial layer of fibrous tissue. The tunica media contains some myocytes, mostly circumferential; the tunica adventitia is mainly fibrous tissue with a slight admixture of muscle. Boggon & Palfrey (1973) confirmed this trilaminar structure but did not observe muscle fibres in the adventitia, even with electron microscopy. Elastic fibres are sparse in the tunica intima, but sufficient to form an external elastic lamina in the tunica adventitia. Lymphatics differ from small veins in having many more valves, which are semilunar, generally paired and each composed of an extension of the intima. Their edges point in the direction of the current and the vessel wall downstream of their attached edges is expanded into a sinus, giving the distended vessels a beaded appearance. Valves are important in preventing the backflow of lymph. The thoracic duct is like a medium-sized vein in structure but the non-striated muscle in its tunica media is more prominent and pulsatile movements of its walls have been described (vide infra and pp. 822, 841).

Satiukova & Rassokhina-Volkova (1972) have studied regeneration of lymphatic capillaries in dogs after auto-transplantations of hind legs and lungs; they observed early formation of buds from severed lymphatics in junctional scar tissue, concluding that lymph flow was largely restored.

Movement of lymph. Several factors aid the propulsion of lymph from tissue spaces to lymph nodes and the venous bloodstream: (1) 'Filtration pressure' in tissue spaces, generated by filtration of fluid under pressure from haemal capillaries. (2) Contraction of neighbouring muscles compresses lymph vessels, moving lymph in the directions determined by their valves; extremely little lymph flows in an immobilized limb, whereas flow is increased by either active or passive movements. This fact has been used clinically to diminish dissemination of toxins from infected tissues by immobilization of the relevant regions. Conversely, massage aids the flow of lymph from oedematous regions. (3) The pulsation of neighbouring arteries probably compresses adjacent lymphatic vessels, assisting flow in them. (4) Respiratory movements and the negative blood pressure in the brachiocephalic veins also promote flow of lymph. (5) Non-striated muscle in the walls of the lymphatic trunks is most marked proximal to their

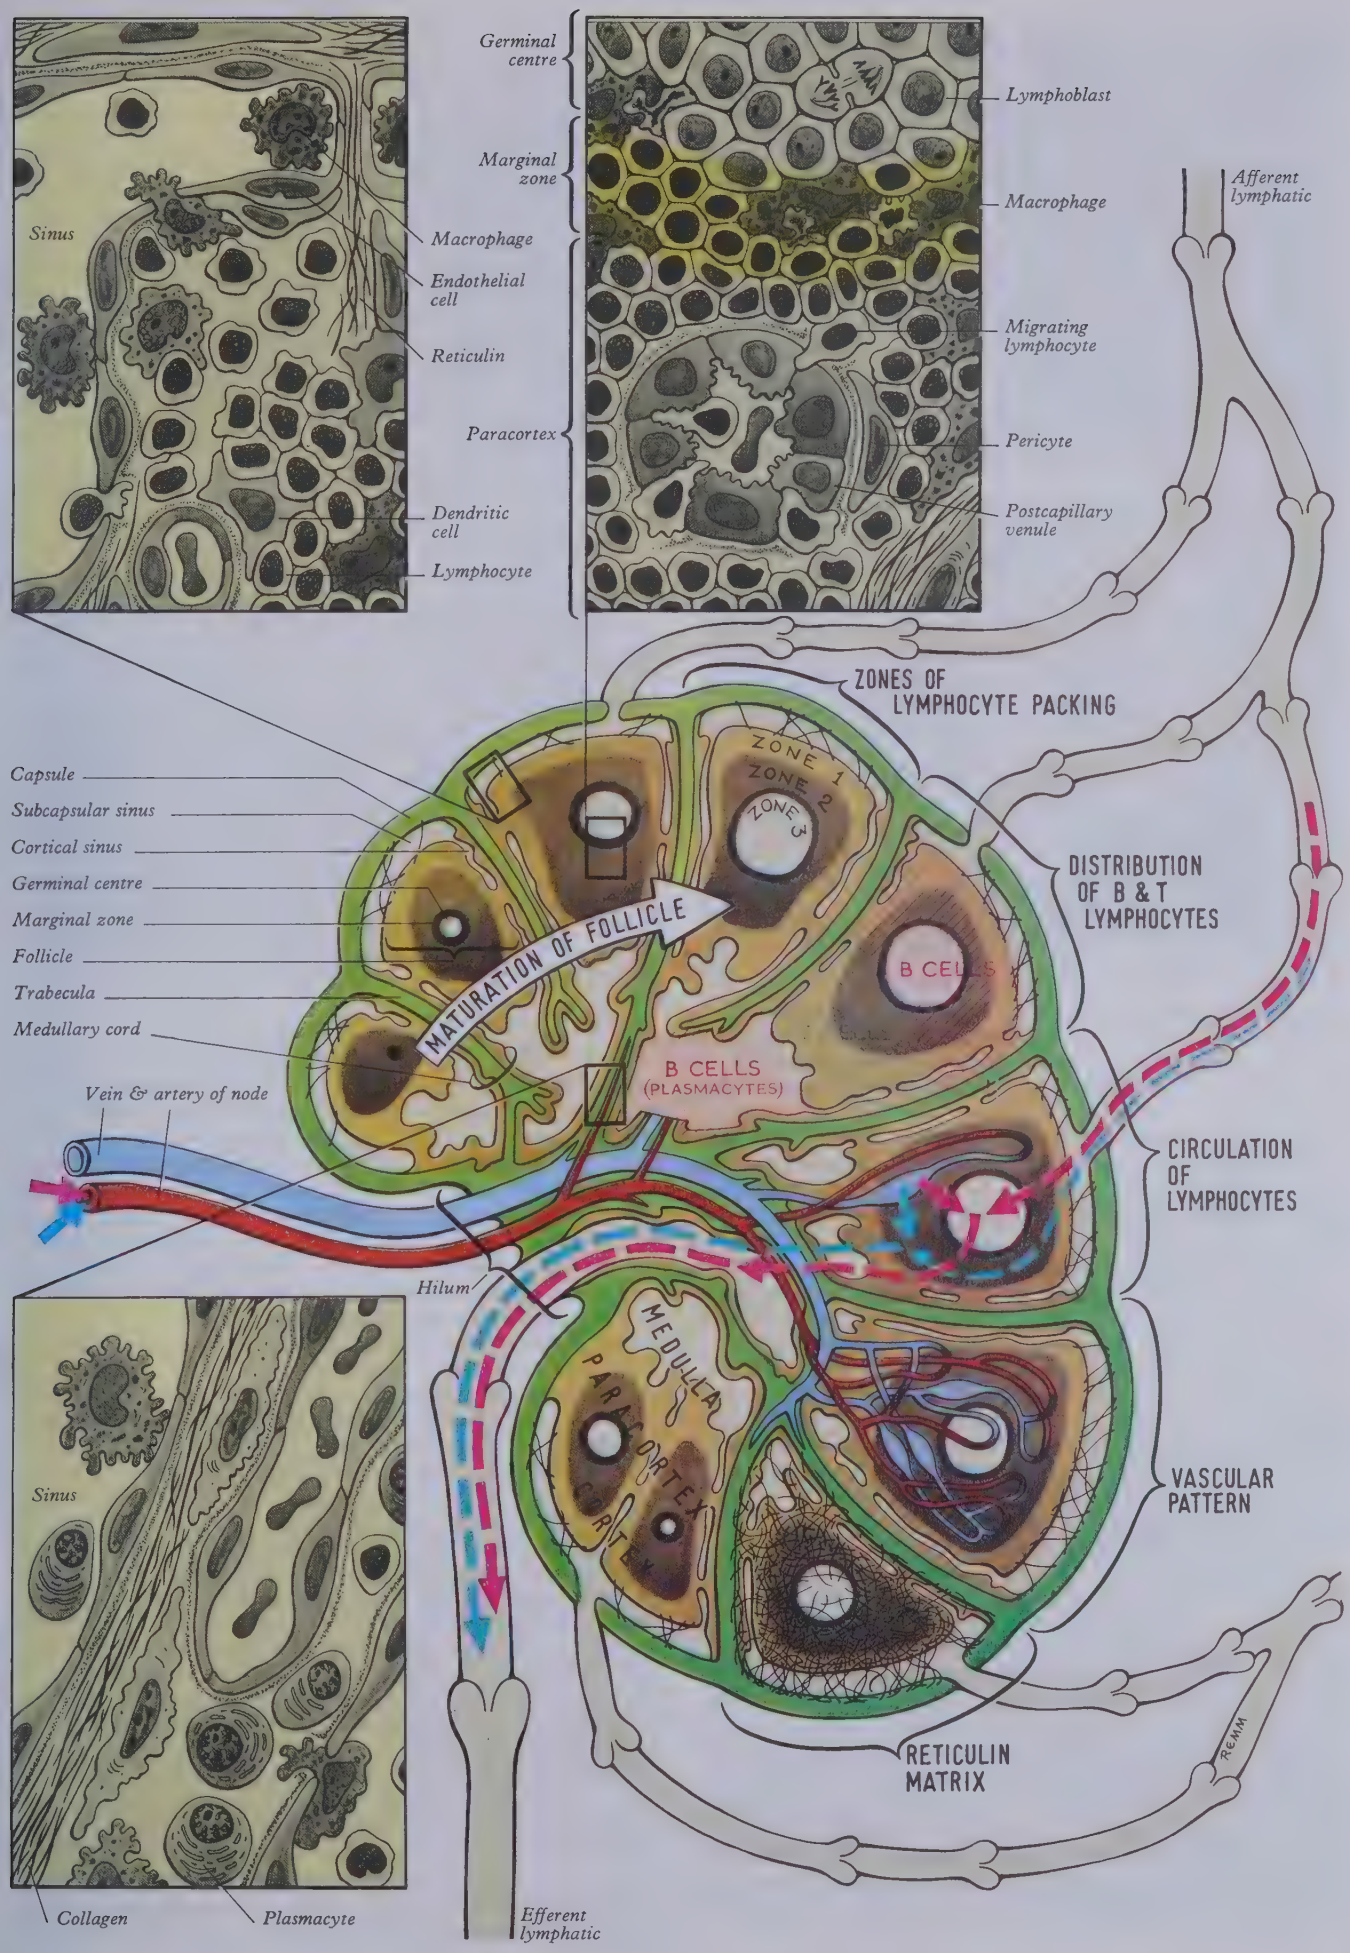
6.175 Diagram of a lymph node (modified from Maximow & Bloom). In part of the diagram, lymphocytes have been omitted to show the reticulum. This diagram from an earlier source has been retained for historical interest; greater detail and more modern concepts are displayed in **6.176**.

valves and stimulation of sympathetic nerves accompanying them results in their contraction. Pulsatile contractions in the thoracic duct also occur (Kinmonth 1982) and, because of the numerous valves along this structure, lymph is forced undirectionally by this muscular action. However, although valves determine the direction of flow, in markedly dilated vessels they may become incompetent, allowing retrograde flow, perhaps explaining the observed retrograde spread of some malignant tumours.

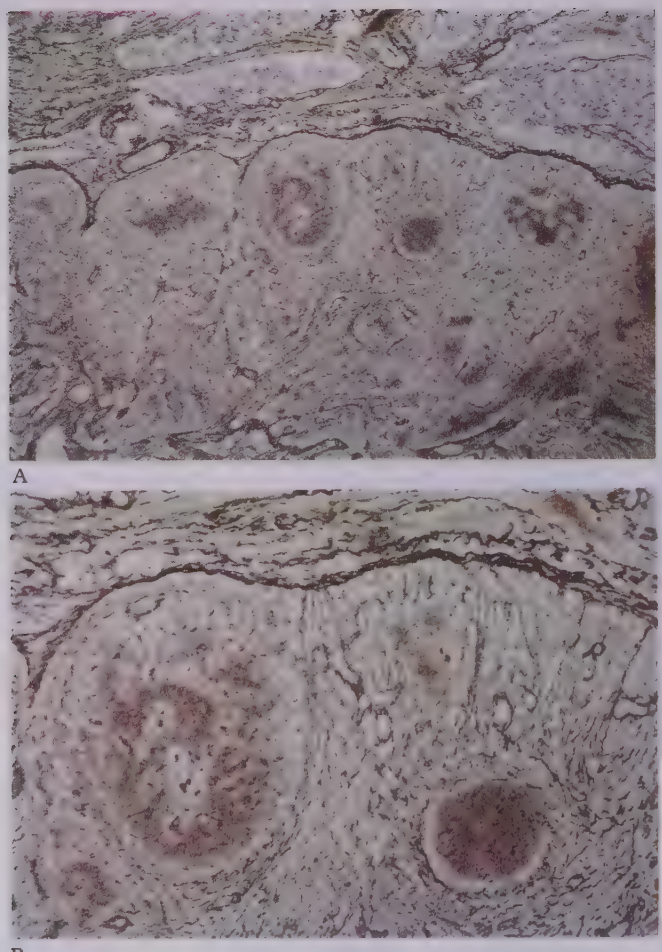
Methods of study. Infective material and neoplastic cells often spread from an affected site along lymphatics, and so the details of their pathways from different regions and organs are clinically important. Dissection is not a suitable method for the tracing of these routes because lymphatic vessels are slender and difficult to see. More reliable information has been obtained as follows: (1) *Experimental injection* of substances into organs or tissues of living or dead animals, including man. These enter the lymphatics draining the site of injection and render them and their related lymph nodes visible. The materials most commonly used for this purpose are suspensions of India ink, Neoprene latex or Prussian blue, the latter employed by Jamieson & Dobson (1907–20) in extensive studies of human pathways. In living animals methylene blue and radio-opaque substances, such as lipiodol, have been injected, the latter requiring radiography. Lymphangiography in human subjects, following the injection of lipiodol into the appropriate peripheral lymphatic channels has much increased our knowledge of their routes and is much used diagnostically (Kinmonth 1964, Kinmonth & Taylor 1964). (2) *Clinical observation* of lymph nodes involved in the spread of known inflammatory or malignant disease. However, it must be cautioned that retrograde spread of tumour cells after blockage of a channel limits the reliability of such observations by altering the normal directions of flow.

Lymph Nodes

Lymph nodes are small, oval or reniform bodies, 0.1–2.5 cm long, lying in the course of the lymphatic vessels. Each usually has a slight indentation on one side, the *hilum*, through which *blood* vessels enter and leave; an *efferent lymphatic* vessel also emerges. Several *afferent lymphatic vessels* enter peripherally. Lymph nodes have a highly cellular *cortex* and a *medulla* containing numerous, poorly demarcated cavities. The cortex is deficient at the hilum, where the medulla reaches the surface; thus the efferent vessel emerges from the medulla, while afferent vessels empty into the cortex. Lymph nodes are particularly numerous in: the neck, mediastinum, posterior abdominal wall, abdominal mesenteries, pelvis and proximal regions of the limbs. By far the greatest number of these lie close to the viscera, especially in the mesenteries.



THE MICROSCOPIC STRUCTURE OF LYMPH NODES



A lymph node is essentially a continuous framework consisting of the capsule, trabeculae, and the reticulum, with cells enmeshed in it (**6**.177,179).

The **capsule and trabeculae**. The capsule is composed mainly of collagen fibres, a few fibroblasts and elastin fibres, the latter being more numerous in the deeper layers. In some animals non-striated myocytes occur but these are few in human nodes. From the capsule, trabeculae of dense connective tissue extend radially into the node's interior, continuous with the network of fine collagen (reticulin) fibres, the *reticulum* which supports the lymphoid tissue. At the hilum, dense fibrous tissue may extend into the medulla, with an efferent lymphatic vessel embedded in it.

The reticulum. This network of fine reticulin fibres and associated cells permeates the spaces enclosed in the capsule and trabeculae (**6**.177) and supports the cell masses within them. Microscopically, the fibres are identifiable with reticulin stains (**6**.178), which show how their bundles branch and interconnect, forming a very dense network in the cortex, although the germinal centres have fewer fibres. Bundles of these fibres, covered by endotheliocytes, criss-cross the sinuses, providing attachment for various cells, mostly macrophages and lymphocytes. Reticulin fibres with an associated proteoglycan matrix are apparently formed by cells indistinguishable from the fibroblasts, though various names (e.g. 'reticular cells') have been applied in the past.

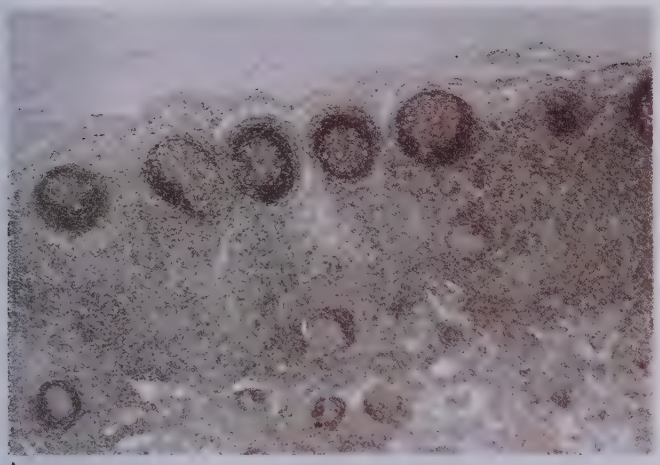
Lymphatic channels. Lymph nodes are permeated by channels through which lymph percolates after its entry from the afferent vessels; because macrophages line channels or are entangled amongst the fibres crossing them, lymph is exposed to the action of these phagocytic cells, as well as to the activities of B- and T-lymphocytes adhering to endothelia.

Afferent vessels enter at many points on the periphery, branching to form a dense intracapsular plexus and then opening into the *subcapsular sinus*, a cavity peripheral to the whole cortex except at the hilum (**6**.176). From this sinus numerous radial *cortical sinuses* lead to the medulla, coalescing as larger *medullary sinuses*, which are in turn confluent at the hilum with the efferent vessel draining the node. All these spaces are lined by an endothelium which is continuous despite the constant passage of lymphocytes, macrophages and other cells through the walls of sinuses in both directions. Numerous trabeculae cross them, making their lumina almost labyrinthine and providing large areas for the attachment of various cell types in the spaces (Nopajaroonsri et al 1971, Luk et al 1973).

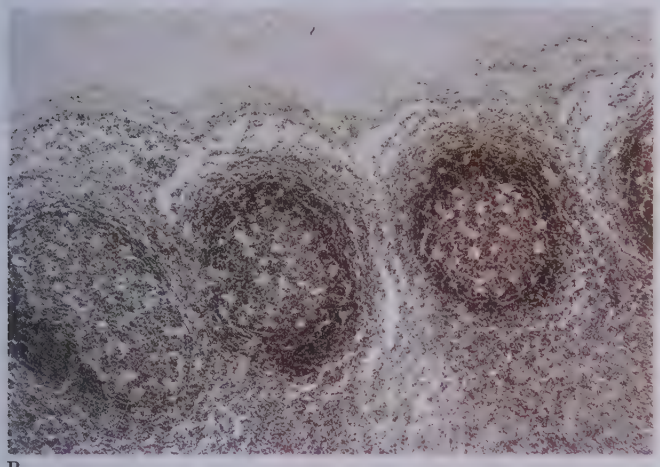
Lymphatic vasculature. Arteries and veins serving lymph nodes pass through the hilum, giving off straight branches which traverse the medulla and issue minor branches en route. On reaching the cortex, arteries form dense arcades of arterioles and capillaries in numerous anastomosing loops, eventually returning to highly branched venules and veins. Capillaries are specially profuse around the follicles, with fewer vessels within these structures (Herman et al 1973, Blau 1976); postcapillary venules are abundant in the paracortical zones, forming an important site of lymphocytic migration (vide infra). The pattern of vascularization is altered when lymphocytes multiply in response to antigenic stimulation, and then the density of the capillary beds increases greatly (Herman et al 1972).

The structure of these blood vessels is normal except for the *postcapillary venules*, which are lined by tall cuboidal endothelial cells, between which colloids pass readily to perivascular spaces (Mikata & Niki 1970); they also allow extensive movement of lymphocytes from the bloodstream into the paracortex and probably also the reverse (Marchesi & Gowans 1964, Gowans & Knight 1964). The route of migration appears to be through tight junctions which part to allow the passage of cells (Schoefl 1972). Some veins may leave a node through its principal trabeculae and capsule, supplying these and the surrounding connective tissue.



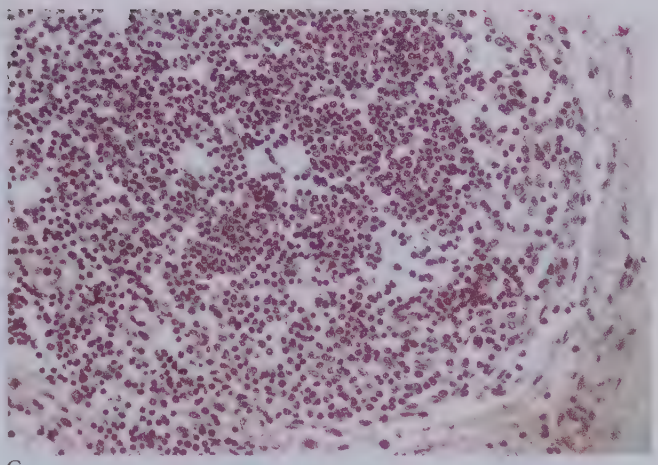
The cells. Most of the cells in the reticulum are *B-* and *T-lymphocytes* but *macrophages* also occur, especially along the walls of sinuses and within germinal centres (vide infra). The distribution of lymphocytes varies in different regions. In the sinuses are some cells which are swept into lymph as it circulates through the node; in the cortex, cells are densely packed and may form isolated *lymphatic follicles* (nodules) (**6**.176–180). The number and isolation of follicles vary according to the prevailing antigenic stimulation. The follicular centre is composed of cells which are larger, less deeply staining and more rapidly dividing than those at its periphery. These areas are *germinal centres*, their cells being mainly *lymphoblasts* which, by prolific mitotic divisions, produce small lymphocytes accumulating at first in the *marginal zones* around germinal centres. The cells pass from follicles into sinuses, which convey them across the medulla to the hilar efferent vessel.

In the medulla, lymphocytes are much less densely packed, forming irregular branching *medullary cords* between which the reticulum is easily seen. Entangled cells include some macrophages, more numerous in the medulla, plasma cells, and a few granulocytes. Under antigenic stimulation, e.g. when the node drains a site of infection or an immunization, the whole node *reacts* by an increase in size and vascularity. The number and size of germinal centres also increases, as lymphocytes and macrophages proliferate, and differentiation of numerous plasma cells occurs in the sinuses. For further details of lymphocyte biology, see pp. 670–675.



CELL ZONES IN LYMPH NODES

As stated above, the cells of lymph nodes are arranged in regions of different packing densities and of distinct cell types. (Nopajaroonsri et al (1971) have suggested the division of the cortex into three zones indicating the packing density of its cells (**6**.176). *Zone 1* is a region of loosely packed cells, predominantly small lymphocytes, macrophages and occasional plasma cells around the extreme periphery of follicles and extending centrally into the medullary cords. *Zone 2* is a denser region internal to zone 1, limited to cortical and paracortical areas and composed mainly of small lymphocytes and macrophages. *Zone 3* comprises the germinal centres of follicles, which are particularly prominent in antigenically stimulated lymph nodes; its cells include large lymphoblasts, some in mitosis, dendritic cells and macrophages. Fibroblasts, reticulin fibres and other cells, mentioned below, appear in all zones. These zones may form a maturational sequence, lymphocytes arising by division in germinal centres (zone 3), passing to the dense zone 2, becoming smaller and finally migrating to zone 1, from which they may traverse the endothelium into the sinuses. But the sequence is complicated by immigration of other cells from lymphatic and haemal sources, and the precise relation between overall cellular architecture and maturation is not clear. In any case, though helpful for descriptive purposes, purely structural schemes also have to note the different functional subclasses of lymphocytes in such zones.



It is also possible to map the distribution of B- and T-lymphocytes within nodes by their immunohistological reactions to monoclonal antibodies (**6**.179). Immunofluorescent staining shows that they occupy distinct territories. Immature B cells occur in the more peripheral parts of follicles, whereas T cells lie mainly between the germinal centres and the medulla, i.e. in the *paracortex* or *thymus-dependent zone*. Mature B cells (plasma cells) exist mainly in medullary cords and sinuses, while some are also peripheral to the cortical follicles. The distribution of T-lymphocytes is clear in animals with a congenital absence of the

thymus (e.g. '*nude*' mice), which fail to develop a paracortex. Whether germinal centres contain T or B cells or both is debatable; possibly also cytological markers for their detection are only effective after the lymphocytes have left the germinal centres.

Other Types of Cell in Lymph Nodes

The different types of 'non-lymphocytic' cells have been considerably clarified by recent studies although certain details are as yet unclear. Following Steinman et al (1974) and other authors, we can distinguish the following: endothelial cells, fibroblasts, typical macrophages, follicular dendritic cells and paracortical dendritic cells ('interdigitating cells of the paracortex'); cells lining blood vessel walls (non-striated myocytes, pericytes) also occur, as do the terminals of non-myelinated nerve fibres. Endothelial cells lining the nodal sinuses appear typical in structure and, contrary to earlier views, do not show the phagocytic ability

which had attracted terms such as 'endothelial macrophages', reticulo-endothelial cells', 'reticular cells' or 'littoral cells' (Nopajaroonsri et al 1971), although true macrophages do occur along the walls of sinuses. The endothelial walls appear to be of the discontinuous type, allowing the free passage of lymphocytes and macrophages. Fibroblasts ('reticular cells' of some authors) produce collagen including reticulin to form the nodal framework, i.e. the capsule, trabeculae and reticulum. Highly phagocytic macrophages (see p. 668) are identifiable in the cortex within and between the follicles and elsewhere.

FUNCTIONS OF LYMPH NODES

Lymphatic capillaries and larger lymphatic vessels returning excess tissue fluid to the venous system carry particulate materials of various kinds to the lymph nodes scattered along their course. The nature of these materials will vary with the region drained; areas rich in microbial flora, e.g. the alimentary tract, are a major potential route of entry of pathogenic organisms and debris into the circulation and of course any area of the body may supply microbes and debris of various kinds, particularly after damage or local infections. In the respiratory tract there is the additional problem of the removal of inhaled particles from the alveoli, which is carried out in part by macrophages re-entering the tissues and passing into the lymphatic pathways. Lymph nodes form a major protection against such materials and organisms, removing them by phagocytic activity and exposing them to a wide variety of powerful defensive actions carried out by lymphocytes resident within them or added to the population of defensive cells circulating in the lymph and blood. Lymph nodes respond dynamically to the presence of such materials and can modulate their activities and structure according to the demands put upon them.

The essential roles of lymph nodes include: (1) The provision of a labyrinth of channels, of large volume and surface area, through which lymph slowly percolates. (2) The exposure of foreign material in the lymph to macrophages in nodal sinuses. (3) The trapping of antigens by different mononuclear phagocytes

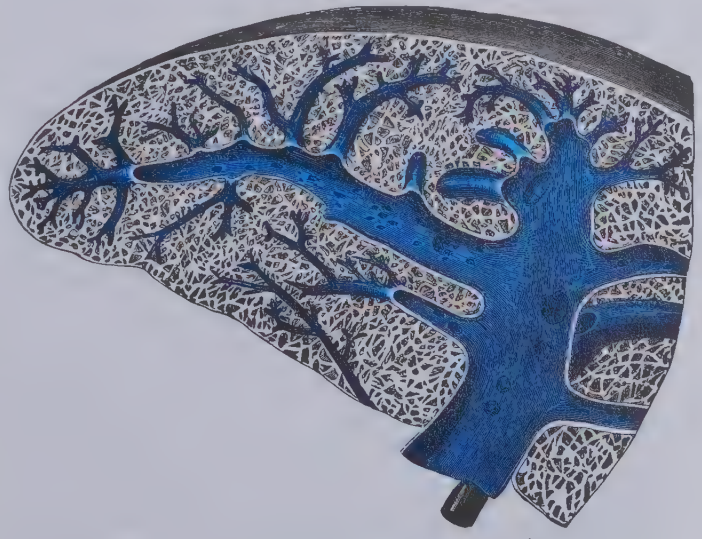
including dendritic types. (4) Production of lymphocytes and a pool of stem cells able to become antibody-producing B-lymphocytes and mature T-lymphocytes. (5) Interaction between antigen-bearing mononuclear phagocytes and lymphocytes to produce an immune response, both cell-mediated and humoral. (6) Re-entry of blood-borne lymphocytes into lymphatic channels and thence to the haemal circulation. (7) Humoral antibody production and addition to lymph and, via that route, to blood.

Haemal nodes

In human lymph nodes, erythrocytes may sometimes be found within sinuses. In some animals, small encapsulated lymphoid bodies occur in relation to the abdominal and thoracic viscera, where the sinuses are typically filled with blood, giving the whole structure a red colour; these are termed *haemal nodes* and appear to be more closely related to the blood-vascular than to the lymphatic system, since they lack afferent lymphatics (although they have a single efferent lymphatic vessel). Their structure has been described in detail by Turner (1969), Nopajaroonsri et al (1974) and Hogg et al (1982).

Fast and slow routes of blood circulation have been reported, the former through arterioles, capillaries and venules, the latter through a tortuous sinusoidal system. Specialized post-capillary venules with a high endothelium occur as in ordinary nodes. It is possible that haemal nodes are intermediate between lymph nodes and spleen, and perhaps a basis from which both have evolved. Their human incidence remains uncertain. In some animals, *haemolymph nodes* have been described, with a structure intermediate between that of the lymphatic and haemal nodes and with both lymphatic *and* vascular connections. Some consider them stages in the transformation of lymph into haemal nodes; others deny the existence of such intermediary structures.

Applied Anatomy. Lymphatic vessels and nodes draining infected areas are liable to inflammation, resulting in acute or chronic lymphangitis and lymphadenitis. Chronic lymphangitis, with blocking of vessels by the escaped ova of a minute parasitic worm, *Wuchereria bancrofti*, is the cause of elephantiasis (filariasis), typified by enormous thickening and reduplication of skin, frequently in the lower limbs and scrotum. Blockage of lymphatic vessels may also result from the spread of neoplasms or widespread surgical removal of nodes. Neoplastic cells may spread by minute emboli or may grow along lymphatic vessels in solid masses. Removals of tumours are therefore planned to take away *in one mass* the tumour, the intervening vessels and local nodes. It is important to note that lymphatic vessels from a region may not drain to the local lymph nodes, but to those more remote, often making operative removal difficult if not impractical.



6.182 The visceral surface of the spleen.

The Spleen

The spleen (6.182–188) lies mainly in the left hypochondriac region of the abdomen, its posterior edge extending into the epigastric region. It is situated between the gastric fundus and diaphragm. In shape it varies from a slightly curved wedge (if the colic impression is small) to a tetrahedron (if the impression is large). Its long axis lies in the plane of the tenth rib, its posterior border being about 3.5–4.0 cm from the mid-dorsal line at the level of the tenth thoracic spine and its anterior border reaching the mid-axillary line. It is soft, friable, highly vascular and of a dark purple colour.

Relations. The spleen has diaphragmatic and visceral surfaces, superior and anterior borders and inferior and posterior extremities. The *diaphragmatic surface*, convex and smooth, faces posterosuperiorly and to the left, except at its posterior edge which faces slightly medial. It is related to the abdominal surface of the diaphragm which separates it from the lowest part of the left lung and pleura and the ninth to eleventh left ribs. The pleural costodiaphragmatic recess extends down as far as its inferior border. *The visceral surface* (6.182), facing the abdominal cavity, presents gastric, renal, pancreatic and colic impressions. The *gastric impression*, directed anteromedially and upwards, is broad and concave where the spleen abuts on to the posterior aspect of the stomach, from which it is separated by a recess of the greater sac. Near the inferior limit of the spleen is the *hilum*, a long fissure pierced by several irregular apertures through which vessels and nerves of the spleen pass. The *renal impression*, slightly concave, is located on the lowest part of the visceral surface and is separated from the gastric impression above by a raised margin. It faces inferomedially and slightly backwards, being related to the upper and lateral area of the anterior surface of the left kidney and sometimes to the superior pole of the left suprarenal gland. The *colic impression*, at the extreme lateral end of the spleen, is usually flat and is related to the left colic flexure and phrenicocolic ligament (8.125). The *pancreatic impression*, small when present, is situated between the colic impression and the lateral part of the hilum; it is related to the tail of the pancreas which lies in the lienorenal ligament (8.114A).

The *superior border*, separating the diaphragmatic surface from the gastric impression, is usually convex and, near its lateral end, has one or two notches indicating the lobulated form of the spleen in early fetal life (p. 238). The *inferior border* separates the renal impression from the diaphragmatic surface and lies between the

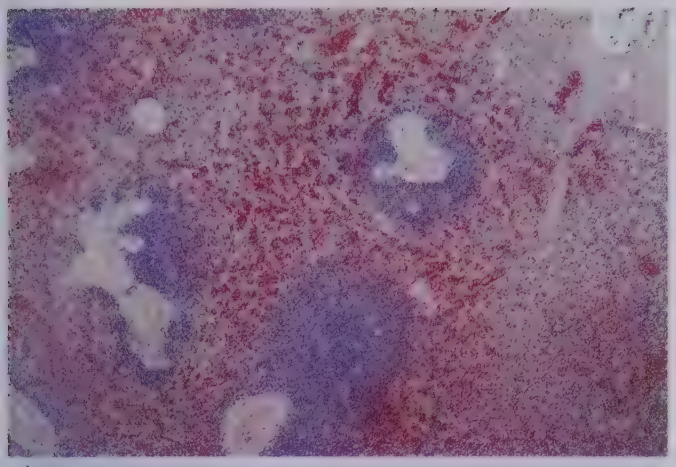
6.184 The main features of splenic structure; the various elements are not drawn to scale, to enable representation on a single diagram. Note the capsule, trabeculae, reticular fibres and cells, the perivascular lymphatic aggregation (white pulp), and the ellipsoids, cell cords and venous sinusoids of the red pulp. The 'open' and 'closed' theories of splenic circulation are illustrated. The venous sinusoids are shown in two states: (1) with their lining of 'stave' cells (bright blue) in close apposition, (2) with intercellular gaps (these have been over-emphasized for clarity). Consult text for further details.

diaphragm and the upper part of the left kidney's lateral border. More blunt and rounded than the superior border, it corresponds in position to the eleventh rib's lower margin.

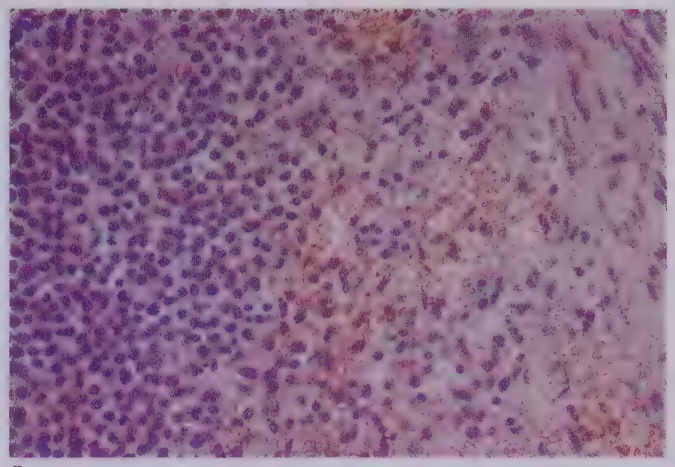
The *posterior extremity* usually faces the rounded vertebral column. The *anterior extremity* is more expanded and commonly forms a margin connecting the lateral ends of the upper and lower borders. It is related to the left colic flexure and to the phrenicocolic ligament.

The spleen is almost entirely covered by peritoneum, which adheres firmly to its capsule. Recesses of the greater sac separate it from the stomach and left kidney. It develops in the upper dorsal mesogastrium (**2**.106), remaining connected to the posterior abdominal wall and stomach by two folds of peritoneum, respectively the *lienorenal ligament* and the *gastrosplenic ligament*. *The lienorenal ligament* is derived from peritoneum where the wall of the general peritoneal cavity meets the omental bursa between the left kidney and spleen; the splenic vessels lie between its layers (**8**.114A). The *gastrosplenic ligament* also has two layers, formed by the meeting of the walls of the greater sac and the omental bursa between spleen and stomach (**8**.114B); the short gastric and left gastro-epiploic branches of the splenic artery pass between its layers. Most laterally the spleen is in contact with the phrenicocolic ligament.



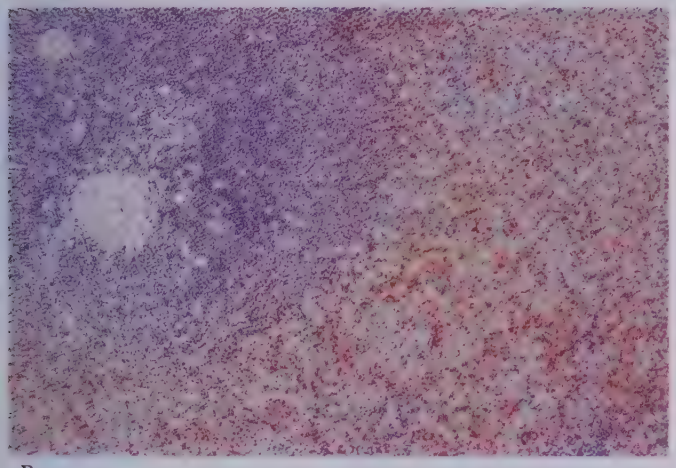
The size and weight of the spleen vary at different ages, in different individuals and in the same individual under different conditions. *In the adult* it is usually about 12 cm in length, 7 cm in breadth and 3–4 cm in thickness but tends to diminish in size and weight with age. Its average adult weight is about 150 g, ranging between 80–300 g, largely according to its content of blood. It slowly enlarges during alimentary digestion and varies in size with state of nutrition, being large in well-fed animals and small in starved ones.

Near the spleen, especially within the gastrosplenic ligament and greater omentum, small encapsulated nodules of splenic tissue may occur, isolated or connected to the spleen by thin bands of splenic tissue. Such *accessory spleens* or *spleniculi* may be numerous and widely scattered in the abdomen. The spleen may retain its fetal lobulated form or show deep notches on its diaphragmatic surface and inferior border in addition to those usually present on its superior border.



Surface Anatomy. The position of the spleen in the living can be assessed by percussion; the dull area extends over the ninth to eleventh ribs in vertical extent and should not go forward beyond the mid-axillary line. The normal spleen is not palpable.

THE MICROSCOPIC STRUCTURE OF THE SPLEEN (**6**.186–187)



The spleen is enclosed in two coats: an outer serous layer (the peritoneum) and an internal fibrous *capsule*. The serous layer

covers the entire organ except at its hilum and along the lines of reflexion of the lienorenal and gastrosplenic ligaments. The *capsule* or *fibro-elastic layer* sends *trabeculae* into the substance of the spleen, branching within it to form a supportive framework (**6**.184). The largest trabeculae enter at the hilum and ensheathe the splenic vessels, dividing into branches in the splenic pulp (**6**.184–6). The capsule and trabeculae are composed of dense irregular connective fibres, rich in collagen and elastin, the latter more numerous in the trabeculae. In many mammals both capsule and trabeculae contain many non-striated myocytes, the rhythmical contraction of the spleen being attributed to these. In man there are few myocytes and contraction and distension of the spleen are attributed to the effects of the constriction or relaxation of blood vessels altering the volume of blood in the organ. An increase of intrasplenic blood pressure distends the spleen and stretches the elastic fibres and contraction is due to their recoil.

Within the spleen, branching trabeculae are continuous with a network of fine collagen (reticulin) fibres pervading this organ. Electron microscopy shows this reticulum to be a dense amorphous matrix, probably mainly proteoglycan, with a few fine collagen fibres. Associated with it are fibroblasts ('reticular cells') into which strands of matrix may be invaginated, and macrophages. The reticular spaces are occupied by *red* and *white splenic pulp*. The reticulum is especially dense around the borders of white pulp where they form the framework of the *marginal zone*.

Circulation of blood inside the spleen; white and red pulp (Knisely 1936, MacKenzie et al 1941, Snook 1950, Peck & Hoerr 1951, Lewis 1957, Wennberg & Weiss 1969, & Li-Tsun Chen & Weiss 1972, 1973) The large, tortuous splenic artery, before reaching the spleen, divides in the lienorenal ligament into five or more rami entering the hilum to ramify in the trabeculae throughout the organ. Likewise, the splenic vein forms in the ligament from five or more tributaries emerging from the hilum. Within the spleen, the finest arteriolar branches pass out of the trabeculae, their adventitia being replaced by a *periarteriolar sheath* of lymphoid tissue accompanying these vessels and their branches (**6**.184). These sheaths constitute the *white pulp* of the spleen, in places being enlarged as *splenic lymphatic follicles* (Malpighian bodies), from 0.25 mm–1 mm across and visible to the naked eye on the freshly cut surface of the spleen as white semi-opaque dots, which contrast with the surrounding *red pulp*. Both periarteriolar sheaths and lymphoid follicles are centres of lymphocytic proliferation. When antigenically stimulated, the follicles develop germinal centres as in the lymph nodes, and these become smaller when the infection subsides. Follicles also atrophy with increasing age and may be absent in the very old. Arterioles usually lie to one side of such germinal centres but supply slender branches to follicles. Before arterioles finally lose their sheaths of lymphoid tissue to enter the surrounding red pulp they divide into a series of straight vessels termed *penicilli* (penicillar arterioles). After a course of about 0.5 mm, these pass into or through the *marginal zones* around the white pulp, each penicillus developing slight thickening of its sheath known as an *ellipsoid (sheath of Schweigger-Seidel)*, formed by an aggregation of macrophages and fibroblasts; here the lumen of the vessel is much narrowed. Ellipsoids are well developed in some mammals, e.g. pig, cat and dog, but not in humans. Beyond the ellipsoids,

each vessel continues as a fine arteriole or may divide into two; thereafter the course of the blood is uncertain but, whatever its detailed route, it eventually passes into the red pulp and thence via the sinusoids, venules and small veins (the latter entering the trabeculae) into larger veins which pass out of the spleen at the hilum. Human red pulp consists of numerous *venous sinusoids*, large complex cavities containing blood, embedded in tissue rich in macrophages attached to the splenic reticulum, forming the *splenic cords* (cords of Bilroth).

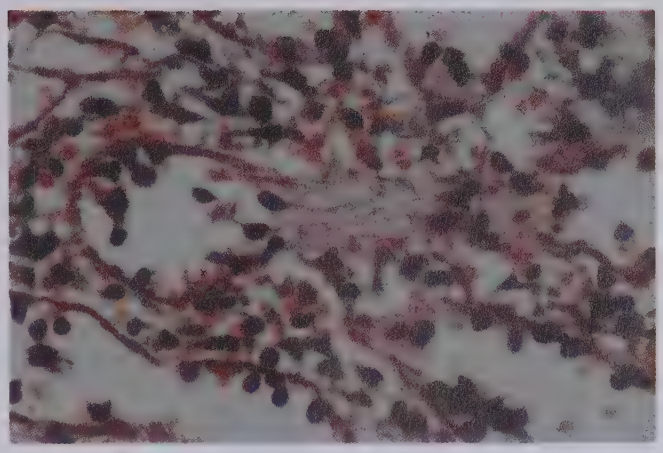
Splenic venous sinusoids are lined by flat, much elongated fusiform endotheliocytes (*stave cells*, reminiscent of planks in a barrel, **6**.187, 188); when sinusoids are inflated by a rise in blood pressure, numerous gaps appear between these cells allowing blood to pass in and out of the tissue of the surrounding splenic cords. The sinusoids are supported externally by circumferential and longitudinal reticulin fibres, which are connected to the fibrous reticulum of the splenic cordal tissue around them.

Ultrastructurally, the endothelial cells of venous sinusoids have some special structural features. Besides possessing numerous endocytic/exocytic vesicles and numerous filopodia on luminal and extraluminal surfaces, they have a complex cytoskeleton which probably determines their elongated shape and may modulate the form of the cell to alter the sizes of the slits in the sinusoid walls, thus regulating the passage of blood through the intercellular gaps (see Chen & Weiss 1972, 1973). The endothelial cells are mildly phagocytic (as are others of this type elsewhere in the body) but do not appear to contribute strongly to the uptake of particles in the spleen.

6.187 Scanning electron micrograph of a splenic sinusoid (monkey) to show endothelial cells and associated tissue. Magnification × 1000.

Splenic cords consist of all the tissue in the red pulp lying outside the venous sinusoids; the term 'cord' is really a misnomer, as it only describes their appearance in histological sections cut parallel to the long axes of the sinusoids. In three dimensions, this tissue forms a continuous network, penetrated by the vascular channels of the sinusoids and other vessels. Splenic cords contain a network of reticulin fibres and fibroblasts which synthesize them; the elaborate meshes of this network form attachment sites for numerous highly phagocytic *splenic macrophages* and permitting the passage of lymphocytes from the white pulp to the sinusoids and of blood cells as they flow to or from the sinusoid lumen through the gaps in their walls. In some animals sinusoids appear absent and most red pulp is formed by splenic cordal tissue.

The route of the blood from the penicillar arterioles to the sinusoids is controversial, perhaps due to variations in the techniques and species of animals studied. According to the 'open circulation' theory, blood passes directly from arterioles into the splenic cordal tissue, collecting in the venous sinusoids to enter the venous circulation. In the 'closed' theory, blood is envisaged as passing from arterioles directly into venous sinusoids, entering the extravascular cordal tissue only later, in a tidal flow between the sinusoids' endothelial cells. In the spleens of some species of animals, blood appears to flow directly from arteries into sinusoids, escaping through their walls into the surrounding cordal tissue, where it can certainly be demonstrated by electron microscopy. It is probable that blood flow along these routes depends on local control by the intermittent opening and closing of blood vessels at both ends by perivascular myocytic contraction, allowing a tidal flow between the sinusoids and spaces outside them; but this has not yet been demonstrated. However, in animals apparently lacking sinusoids there must be some other type of circulation, presumably of 'open' type.



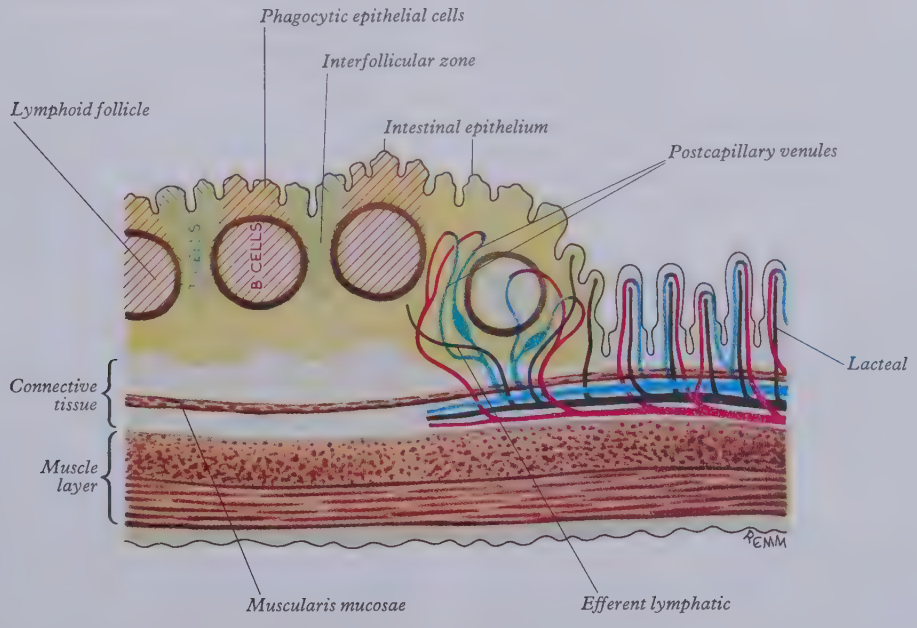
FUNCTIONS OF THE SPLEEN

The spleen is essentially concerned in phagocytosis, immune responses cytopoiesis and erythrocyte storage. In the fetus it is also an important site of haemopoiesis. However, although of great importance to the defence of the body, it is not absolutely

essential, since many of its functions can be assumed by the liver and by other lymphoid tissues if the spleen is removed (see p. 832).

Phagocytosis. Splenic macrophages form a large part of the mononuclear phagocytic system of the body (p. 668). They comprise highly phagocytic cells distributed mainly in the marginal zones of the white pulp and in the ellipsoids and splenic cords. Particulate matter such as carbon is also taken up in small amounts by the fusiform endotheliocytes of venous sinusoids. Beside the removal of microbes, tissue debris and other particulate matter, splenic macrophages remove effete erythrocytes, leucocytes and platelets from circulating blood. The processing of ageing or damaged red cells is especially important. Within splenic macrophages, all stages of erythrophagocytosis, from disintegrating erythrocytes to granules of haemosiderin, can be discerned (Chen & Weiss 1972). Bilirubin, an end-product of haemoglobin catabolism, is conveyed in the bloodstream to the liver for excretion and the iron is largely re-used by bone marrow. Amino acids from the hydrolysis of globin are returned to the amino acid pool of the body. Splenic macrophages are also important in removing microbes and cellular debris from the circulation and their lysosomes possess many powerful enzymes which can hydrolyze these bodies, particularly when activated by lymphokines during immune responses (p. 672). Like other lymphoid organs, the spleen is also involved in phagocytosis of circulating antigens for the initiation of humoral and cellular immune responses (see also p. 673). In addition to such overt phagocytosis, there are numerous dendritic mononuclear phagocytes in the white pulp, particularly in the marginal zones around the perimeters of its lymphoid tissue. Like others of this type, these cells are only moderately phagocytic and are engaged in presenting alien antigens which they have taken up, to lymphocytes, in combination with their Class II MHC surface molecules, to activate both T and B cells (see p. 673).

Immune responses due to lymphocytes. T- and B-lymphocytes occur in different parts of the white pulp, the periarteriolar layers of cells being mainly T-lymphocytes; follicles with germinal centres are largely B-lymphocytes. Cells may migrate from these into splenic cordal tissue and other areas, to perform their specific functions. Some B-lymphocytes mature into plasma cells particularly in the marginal zones, secreting antibodies into the circulating blood when stimulated. T-lymphocytes carry out a wide range of defensive activities, described elsewhere in details (p. 672). Lymphocytes are also added to the general defence of the body by passing into the haemal circulation via venous sinusoids



6.188 A splenic sinusoid sectioned tangentially to show parallel strap-like endotheliocytes and surrounding tissue. Gomori's method. Magnification × 600.

and thus the spleen is an important source of these cells. When antigenically stimulated, the white pulp increases in size as lymphocytes proliferate; the (primary) follicles become intensely active in B-cell proliferation, and gain the typical appearance of secondary follicles, as in lymph nodes (p. 822). The presentation of antibody-antigen complexes by dendritic cells of the follicles and marginal zones are involved in these processes and in the generation of 'memory' lymphocytes for future immune responses.

Cytopoiesis. In human fetuses, from the fourth month onwards, the spleen is *haemopoietic*, red pulp containing groups of myelocytes, erythroblasts and megakaryocytes. In some anaemias and myeloid leukaemia, stem cells persisting in red pulp may revert to haemopoiesis. In the mature spleen lymphopoiesis in the white pulp contributes to a circulating reserve of immunologically competent T- and B-lymphocytes and also mononuclear phagocytes to the blood and connective tissues (see p. 670).

Immune responses. With adequate antigenic stimulation, particularly under the action of T-cell derived lymphokines, splenic macrophages proliferate and become highly active; T- and B-cell lymphopoiesis, growth and differentiation increase. In individuals suffering chronic infection of the blood cells, e.g. in

malaria, the splenic tissues may be permanently hypertrophied and the spleen greatly enlarged *(splenomegaly)*.

Because of the large volume of blood within the spleen, it can be regarded as a store of this fluid, which can under certain conditions be discharged into the circulation. According to the 'closed' theory of splenic circulation, this occurs in the venous sinusoids, the filling and emptying of which are controlled by sphincters at each end; according to the 'open' theory storage is amongst the reticular meshes of the splenic cords. In states of emergency, especially anoxia, blood is discharged into the circulation. In most mammals, this discharge is due to the contraction of capsular and trabecular muscle, excited by sympathetic innervation and adrenalin; in the human spleen recoil of stretched elastic fibres causes emptying of blood into the circulation, although storage and discharge are not nearly so marked in humans as in other species.

SPLENIC VASCULAR SEGMENTATION

There is evidence (Dreyer & Budtz-Olson 1952) that human spleens, like those in other species, consist of separate 'segments' or 'compartments', each served by a hilar branch of the main splenic artery and splenic vein (Braithwaite & Adams 1957). Adjacent compartments, it is claimed, are connected by intersegmental veins; a congested compartment can thus pass excess blood to those adjacent (vide infra) but, when blood flow is not excessive, splenic segments may act as separate units. (For a review of splenic vascular segmentation since first proposed by Kyber 1870, consult Gupta et al 1976.) Gupta et al studied corrosion casts of 50 adult human spleens. In 42 of these (84%) only two segments existed (superior and inferior); in 8 (16%) three segments (superior, intermediate and inferior) were demonstrated. There was no clear anastomosis between segments. A comparable segmental arrangement of splenic veins was described by Fuld & Irwin (1954). The occurrence of only two or three segments (arterial or venous) was supported by many investigators quoted by Gupta et al; but this does not accord with the usual description of splenic arteries dividing into five or more major branches in the lienorenal ligament before even entering the hilum: no explanation of this discrepancy is advanced by these authors. Braithwaite & Adams described 5–7 vascular splenic segments in rats. Clearly, further investigation is necessary.

Effects of splenectomy. Partial splenectomy is followed by rapid regeneration of lost tissue but even total splenectomy has few obvious effects, its functions being largely assumed by the liver. But especially in the early years of life, splenectomy may entail a general reduction in the rapidity of immune responses and in a consequent increased susceptibility to infection. Splenectomy in later life is followed by leucocytosis with increased lymphocytic, neutrophil, eosinophil and platelet counts in peripheral blood, interpreted as due to removal of humoral factors produced in the spleen which oppose the formation and release of cells from haemopoietic tissues. These effects fade and disappear within a few weeks.

The lymphatic vessels of the spleen, once considered insignificant and merely the drainage of the capsule and largest trabeculae, has been shown (in some species) to occur in *all* parts of the organ. Extensive blind-ended efferent lymphatic vessels occur in the white pulp, running tortuously with arterioles and arteries and emerging at the hilum, the flow of lymph being counter to that of arterial blood. No afferent lymphatic vessels have been identified. This lymphatic pathway drains tissue fluid infiltrating the white pulp and is also a major route for lymphocytes from the spleen into the general circulation, as is the case in lymph nodes (Weiss 1979).

Splenic nerves arise from the coeliac plexus, chiefly non-myelinated. In humans, their distribution is said to be confined mainly to the branches of splenic arteries; in other mammals they also supply non-striated muscle in the capsule and trabeculae.

Applied Anatomy. Splenomegaly may accompany several conditions, e.g. increased phagocytosis in some generalized infections, bacterial or viral, and in conditions of increased erythrocyte breakdown, such as malaria infections and other haemolytic diseases and in various lipoidoses. Any massive immune response may be accompanied by splenic enlargement, also occurring in many reticuloses. In splenomegaly, the anterior border, anterior diaphragmatic surface and notched superior border become palpable below the left costal margin; the marginal notches are exaggerated and easily palpable. The transverse colon and left colic flexure are displaced downward, no area of colonic resonance remaining over the enlarged spleen, in contrast to a retroperitoneal tumour (e.g. renal), which does not displace the gut and therefore leaves an area of colonic resonance. There is no anastomosis between the smaller splenic arteries, so that their obstruction leads to infarction. During splenectomy the tail of the pancreas is in danger.

Epithelio-lymphoid or 'Mucosa-associated' Lymphoid Tissue

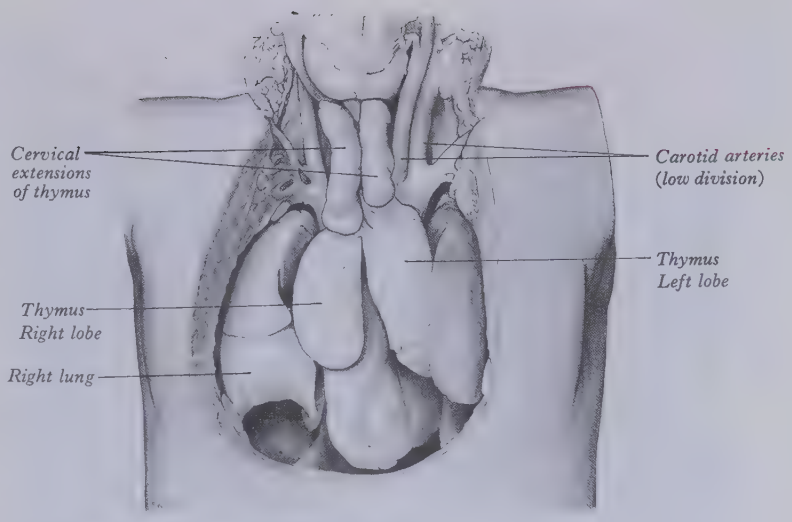
In addition to the encapsulated peripheral lymphoid organs, lymphatic nodes and spleen, large amounts of unencapsulated lymphoid tissue exist as *lymphoid nodules* in the walls of the alimentary respiratory tracts, termed collectively *epithelio-lymphoid* or so-called *mucosa-associated lymphoid tissue (MALT)*. These nodules are located chiefly in the lamina propria subjacent to the epithelium but may when active extend into deeper layers, e.g. the intestinal submucosa; their cells may also migrate widely into neighbouring tissues. Such nodules are often grouped into those associated with the alimentary tract, collectively termed *gut-associated lymphoid tissue (GALT)*: pharyngeal, tubal, palatine and lingual tonsils, oesophageal nodules, aggregated lymphatic nodules in the small intestine (e.g. Peyer's patches) and the vermiform appendix, and smaller nodules in the colon and rectum. Bronchial-associated lymphoid tissue (BALT) is the equivalent lymphoid nodular tissue of the lower respiratory tract.

The form of lymphoid nodules depends on their location but in all sites numerous round follicles similar to those in lymph nodes can be distinguished; they develop germinal centres when antigenically stimulated (Anderson 1977). Between follicles (**6**.189) are cuneiform masses of less closely packed (parafollicular) lymphocytes. The whole mass with numerous macrophages is supported by a fine network of reticulin fibres and associated fibroblasts, with coarser trabeculae in the larger nodules, such as those in the pharyngeal tonsil. Adjacent alimentary epithelium covers the luminal surfaces of nodules, usually producing glandular or other diverticula which penetrate the lymphocytic masses. In some sites (e.g. palatine tonsils, p. 1324) such *crypts* may be loci of infection, leading to general inflammatory response in the whole area. In many sites domes of specialized, thinner epithelium cover the lymphoid nodules (vide infra). Blood vessels branch from the surrounding connective tissue to supply the follicles with a capillary plexus draining to post-capillary venules, which have cuboidal endothelial cells like those of lymph nodes, allowing the migration of lymphocytes between blood and nodule. The lymphatic vessels of nodules are all efferent, draining into the lymphatic channels of the organ in which they are sited.

Immunofluorescence technique has shown that B- and T-lymphocytes of lymphoid nodules are segregated, again resembling lymph nodes, the follicles containing B-lymphocytes and the parafollicular zones, T-lymphocytes. All of these cells can migrate into the lymphatic drainage to rejoin the bloodstream, or into adjacent tissues including the intercellular spaces of neighbouring epithelia. As a rule most of them appear to pass into the circulation before finally migrating into their sites of effective action. In simple epithelia they may eventually enter the alimentary or respiratory lumen. B-lymphocytes which have migrated into the neighbouring lamina propria often mature into plasma cells. In addition, mononuclear phagocytes are present, both as active highly phagocytic macrophages and dendritic, antigen-presenting cells which are Class II MHC positive. These are mainly interdigitating cells similar to those of lymph nodes (p. 825).

FUNCTIONS OF LYMPHOID NODULES

The precise role of lymphoid nodules in lymphocyte biology has evoked much speculation, stemming in part from the avian condition in which B-lymphocytes become committed to their distinctive lineage in lymphoid tissue in a proctodael (hindgut) diverticulum (*bursa of Fabricius*), suggesting that alimentary lymphoid tissues in mammals may have a similar function. However, experiments have failed to support this idea and it seems that lymphoid nodules are regions in which B- and T-lymphocytes can proliferate in association with antigen-presenting mononuclear phagocytes and are thus producers of activated, antigen-specific defensive cells passing to the tissues of the structures they are grouped around.



B-lymphocytes are mainly involved in the synthesis of secretory antibodies of the IgA class occurring in alimentary secretions and in IgE (homocytotropic antibody related to mast cell activities, see p. 672). These are secreted first by plasma cells in the lamina propria and intercellular spaces of simple epithelia and in sub-epithelial glands, the latter being of special significance where epithelium is of the stratified squamous type. Antibodies appear to be absorbed by certain glandular cells (although not goblet cells, at least in the gut) and are modified by the addition of carbohydrate to form secretory IgA (sometimes termed sIgA) which is then passed into the intestinal or bronchial lumen. These antibodies are vital in eliminating pathogenic organisms, although other types of antibody (IgM and IgG), secreted by plasma cells of the lamina propria, are also essential to the destruction of any pathogens which breach the epithelium and infect the adjacent tissues.

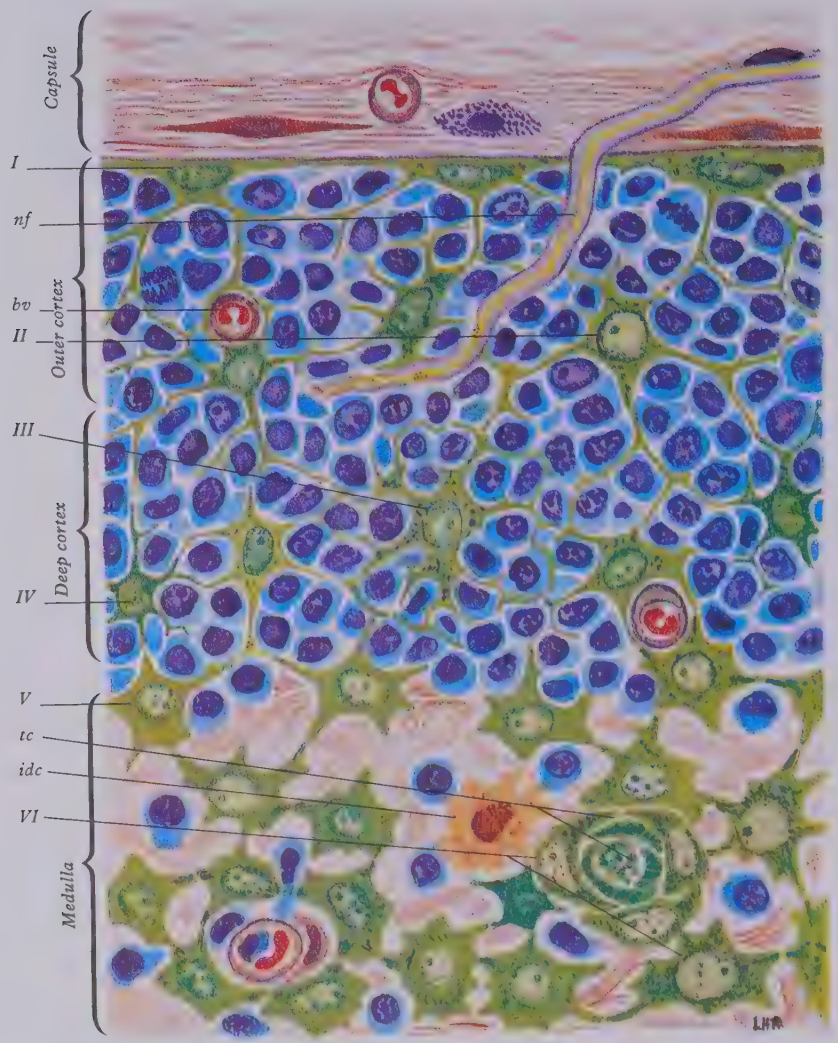
If this system is to operate efficiently lymphocytes must be able to detect antigens present on the luminal side of epithelium covering them. Special, probably phagocytic, cells (*follicle associated epithelial cells, FAE, or microfold, M cells*) have been demonstrated in the epithelium covering lymphoid follicles, which may be capable of transferring particulate material to the subjacent lymphoid tissue, thus carrying antigens to the immune system (Bockman & Cooper 1973, Chamberlain et al 1973, Owen & Jones 1974, Smith & Peacock 1980). These cells are columnar in form and bear long, irregular microvilli, numerous apical invaginations and vesicles and an irregular basally-situated nucleus. The lateral borders are deeply indented by small lymphocytes lying within the epithelium.

The Thymus

The thymus (**6**.190–1956) is one of the two central organs of the lymphoid system, the other being the bone marrow, and is responsible for the provision of thymus-processed lymphocytes (T-lymphocytes) to the whole body. It also has certain humoral secretory functions and so may be regarded as an endocrine gland. It varies considerably in size and activity, depending on age, disease and the physiological state of the body, but remains active even into old age. Its significance was long obscure; but experimentation has revealed the thymus as a primary *central lymphoid organ*. At birth it weighs 10 to 15 g, growing until puberty, when it weighs 30-40 g. Thereafter it gradually diminishes and is progressively infiltrated and replaced by adipose tissue; after middle age it may weigh only 10 g, but in some cases may remain large, weighing 28 and 50 g (Young & Turnbull 1931, Keynes 1954, Kendall et al 1980). Certain diseases greatly accelerate its involution, perhaps accounting in part for this variation.

In early life it is pinkish grey, soft and finely lobulated, consisting of two unequal, pyramidal lobes connected by loose connective tissue. Although it is often described as a single median organ, each lobe develops from the third pharyngeal pouch of the same side (p. 229), so that strictly there are right and left thymic bodies. The thymus lies in the superior and anterior inferior mediastina, extending inferiorly to the fourth costal cartilages, its upper parts tapering into the neck and sometimes reaching the inferior poles of the thyroid gland or even higher. Its shape is largely due to the adjacent structures, to which it is moulded. *Anterior* are the sternum, adjacent parts of the upper four costal cartilages and the sternohyoid and sternothyroid muscles. *Posterior* are the pericardium and the aortic arch with its branches, the left brachiocephalic vein and the front and sides of the trachea. After middle age the thymus becomes yellowish due to its gradual replacement by adipose tissue. Small accessory nodules may occur in the neck, representing portions of the thymic diverticula which have become detached during their early descent (p. 229); or the thymus may be found even more superiorly as thin strands along this path, reaching the thyroid cartilage or above. Sometimes its cervical part is represented by strands of connective tissue connecting the thymus to the inferior parathyroid glands. These strands may also approach the superior parathyroids, those related to the superior (parathyroids IV) being developed from the fourth pharyngeal pouches, those to the inferior parathyroids (parathyroids III) from the third pair.

6.190 Dissection to display the neonatal thymus.



MICROSCOPIC STRUCTURE OF THE THYMUS

Each lobe (**6**.190) has a loose fibrous capsule, from which septa penetrate to the junction of cortex and medulla, to partially separate the irregular lobules, each 0.5–2.0 mm in diameter. Lobules consist of an external, dark staining, dense, highly cellular *cortex* and an internal, light staining, less dense *medulla*. Lobules are not completely separated and their medullary parts are continuous through a central parenchymatous cord, derived from the embryonic thymic diverticulum. Lobules are connected to this cord by prolongations of the medullary substance; if interlobular connective tissue is removed (in the young), lobules present an irregular 'necklace' appearance. The fibrous capsule is quite thin and contains numerous mast cells.

Both the cortex and medulla have two principal cellular components, differing quantitatively in the two regions. These are: (1) a framework of irregular, interconnected epithelial ('reticular') cells, quite distinct from those in other lymphoid tissues; and (2) lymphoblasts, lymphocytes, macrophages and a few other cells enmeshed in the epithelial framework. Other cells also occur in small numbers including *myoid cells* resembling striated muscle fibres, epithelial cysts and goblet cells. These may represent 'accidents' of embryological development.

The epithelial framework

Unlike other lymphoid structures, where the supportive framework is composed chiefly of collagenous reticular tissue, the thymus is permeated by a network of interconnected epithelial cells (thymic epitheliocytes); there is only a little reticulin and few fibroblasts. Epitheliocytes vary in size and shape in the different regions of the thymus. Typically they have pale, oval nuclei, a rather eosinophilic cytoplasm and desmosomal attachments between cells. Intermediate (keratin) filament bundles lie within the

6.191 Cellular organization of the thymus showing thymocytes (blue) and epitheliocyte framework (green) of types I-VI cells. nf = nerve fibre; tc = thymic corpuscle; idc = interdigitating cell; bv = blood vessel.

cytoplasm. These cells form a continuous external lining to the thymus beneath its fibrous capsule, following its lobulated profile and investing the vessels which pass into it. Other cortical cells are branched, with large spaces between them, while the epithelial cells of the medulla tend to form more solid cords as well as the characteristic whorls of (often) partially keratinized stratified epithelium (thymic or Hassal's corpuscles). Lymphocytes lie within the meshes and cords formed by these various cells. There is much evidence that many distinctive functional roles are subserved by the epithelial cells (Ritter et al 1985), some of them related to the differentiation of T-lymphocytes, others with the production of soluble thymic factors or hormones or with barrier and mechanically supportive functions (see Wijngaert et al 1984). At least some possess Class II MHC molecules at the surfaces, indicating an important role in the generation of immune responses.

Type I epitheliocytes (subcapsular- perivascular) create the continuous monolayer around the perimeter of the thymus, extending along the septa to the cortico-medullary boundary; they rest on an (external) basal lamina and send long processes into the cortex to contact other (type 2) epitheliocytes. In rodents these cells form basket-like structures which separate an outer, *subcapsular* cortex from the deeper regions. Pale and darkly-staining varieties of these cells are visible by electron microscopy; in small children they may contain numerous small vesicles. *Type 2 cells*, found in the outer cortex, are stellate and in internal structure are similar to type 1 epitheliocytes; they have a large, pale nucleus. Their cytoplasm shows some granular endoplasmic reticulum, occasional dense bodies and bundles of microtubules. *Type 3 cells*, occurring deeper in the cortex, have distended cisternae of granular endoplasmic reticulum and cytoplasmic vacuoles; while *type 4 cells*, in the deepest cortex and occasionally the medulla, stain densely, have abnormally swollen mitochondria and electron-lucent granular endoplasmic reticulum. It has been proposed that these cells form a graded series whose precise form and function varies according to position in the thymus.

Type 5 cells ('undifferentiated' epitheliocytes) occur in groups in the medulla and show no particularly prominent features; *type 6 (large medullary) epitheliocytes* are usually associated with thymic (Hassal's) corpuscles in the medulla and contain tortuous bundles of microtubules and numerous intermediate (keratin) filaments. The thymic corpuscles themselves are distinctive in their staining and immunochemical properties, although the outermost cells are similar to type 6 cells.

Many investigators have supported the view that the type 1 cells form a partial haemothymic barrier which limits access of certain extrathymic materials including circulating antigens into the tissue spaces of the thymus. However, recent work has shown that particulate tracers and monoclonal antibodies directed against thymic cells can, after intraperitoneal injection, penetrate the thymus through its capsule (Eggli et al 1986, Stet 1987). Stem cells and prothymocytes also gain access to the thymus through this route, especially in the fetus. (See the further discussion of the thymic barrier, p. 229.)

Embryonic origins of epitheliocytes. Most embryological evidence at present favours the view that the thymic epithelium is derived from both the ectoderm and the endoderm of the third and often the fourth branchial grooves and pharyngeal pouches, with the associated mesenchyme playing an inductive role in the production of the necessary soluble factors (see e.g. Norris 1938, Auerbach 1961, Cordier & Haumont 1980). In the mutant mouse *nude*, where the ectodermal anlage for the thymus is deficient, the thymus is abnormal, cystic and does not support lymphopoiesis, although lymphocytes are still produced in the bone marrow (Pritchard & Micklem 1973). It is not yet known if the epithelial cells are of ectodermal or endodermal origin or both, although ectoderm appears to be necessary for its functional development.

Developing thymocytes

In the *cortex*, massive numbers of densely packed small lymphocytes predominate, occupying the interstices of the epithelial reticulum, which in histological sections they largely obscure, and forming about 90% of the total weight of the thymus. A distinct subcapsular zone is present, housing the thymic stem cells, prothymocytes and lymphoblasts undergoing mitotic division. The first stem cells to enter the thymus in the embryo come from the yolk sac and liver during their haemopoietic phases, possibly, as in birds, being attracted by thymic chemotactic substances. 94During later periods it is probable that all thymic lymphocytes originate in the bone marrow, or at least have sojourned there, before passing in the bloodstream to the thymus.

The cortex has two rather ill-defined zones: an outer cortex with a framework of types 1–3 epitheliocytes and a deep cortex where type 4 cells occur. Thymocytes undergo mitosis in all cortical zones as the clones of differentiating T cells mature, gradually moving deeper in the cortex. In rodents, cell cycling times of eight hours have been recorded in the outer cortex, but no estimates exist for the human thymus. The appropriate conditions for the proliferation and differentiation of thymocytes appear to be produced by their close proximity to neighbouring epitheliocytes (see Janossy et al 1986). Although the nature of these interactions is not clear, it may involve the release from the epitheliocytes of soluble mitogenic and differentiation factors as well as induction of changes through intercellular contact. During this process, not only are thymocytes switched to become T cells but their potential to form different T-cell subclasses is determined. The differentiating thymocytes are pushed towards the medulla by the intense proliferation of cells in the subcapsular cortex, leaving the thymus at the cortico-medullary junction or deeper in the medulla through blood vessels and lymphatics; such cells (*post-thymic thymocytes*) are not yet immunocompetent and in general

6.192 A scheme of thymic structure; the various elements are not drawn to scale to enable representation in a single diagram. Note the lobular outlines, capsule, delicate interlobular septa, cortical lymphocytes, the epithelial 'reticular' cells and their junctions and the medullary corpuscles of Hassall showing a graded series of increasing maturity; also the transcortical circulation. See text for further discussion.

attain maturity only after leaving the cortex and probably only when they leave the thymus altogether and reach their peripheral destinations.

It has been estimated that 99% of thymocytes never leave the thymus (Scollay et al 1980) although this figure is often regarded as far too high (vide infra). However, during their maturation, thymocytes become able to recognize the HLA (MHC) markers expressed by the unique genome of the individual they belong to, i.e. 'self-antigens', so that when they migrate to the peripheral lymphoid organs and other tissue sites, they and the clone of cells they give rise to can detect alien antigens when these are present in association with 'self'-MHC determinants (see pp. 674, 675) to mount an appropriate immune attack. It has been proposed that the thymocyte's correctness of response to self-MHC antigens is in some way tested by the thymic epitheliocytes before release and that, if they do not interact properly with these cells, the thymocytes do not survive. In this way are selected only T cells which can recognize alien antigens in combination with self-MHC molecules (i.e. they become MHC-restricted, see p. 675). Mechanisms of death of 'inappropriate' thymocytes may involve the loss of control of enzyme systems associated with purine metabolism which, unless corrected by successful interaction with the epitheliocytes, leads to lethal levels of certain metabolites within the cell. However, there is little histological evidence of high levels of cell death and mitotic figures are more common in sections than pyknotic cells; where pyknosis occurs, the cells involved are both epitheliocytes and thymocytes. Nevertheless it is possible that the unwanted thymocytes die rapidly and their remnants are quickly disposed of by phagocytes, limiting the number of observable moribund cells to a minimum.

Mononuclear phagocytes of various types occur in the thymus. Those of the subcapsular cortex may contain phagocytosed nuclei and cell debris and appear to be highly phagocytic macrophages engaged in removing dead thymocytes. Those deeper in the thymus at the cortico-medullary junction and in the medulla are more numerous but only rarely contain phagocytosed particles; some of these are dendritic *interdigitating* cells (p. 825) as they contain characteristic 'Birbeck' granules and bear the Class II MHC antigens typical of such dendritic cells at their surfaces. These latter cells are weakly phagocytic and are presumably concerned with the presentation of antigens to lymphocytes. However, there is much evidence that the thymocytes differentiate in the thymic cortex in an environment free of alien antigens and so it is probable that the antigen-presenting dendritic cells are part of the *medullary compartment* of the thymus into which the more mature thymocytes move after their crucial early development is over. The occurrence of occasional mature B-lymphocytes (plasmocytes) and germinal centres in the medulla (Middleton 1967) also supports the conclusion that at least part of the medulla is more like a secondary ('peripheral') as opposed to a primary ('central') lymphoid tissue, receiving differentiated lymphocytes capable of immune interactions. However, there may be important interactions between the antigen-presenting cells and immature, deep cortical thymocytes, as the thymus

may also be involved in the generation of 'self'-tolerance, and is perhaps an observed case of acquired tolerance of persistent 'alien' antigens.

Haemopoietic cells are present in fetal life, when the thymus makes an important contribution to the formation of erythrocytes and leucocytes. Later haemopoietic cells are often present, possibly as a result of the reactivation of persistent fetal stem cells. Normoblasts have been found in the thymuses of many adult open heart surgery patients and immature eosinophils, neutrophils and mast cells have also been observed. Where present in adults, the erythropoietic foci are mainly in the subcapsular and outer cortex.

The concentric thymic corpuscles (of Hassall) first appear in fetal life and then form continuously throughout life. A medullary epitheliocyte enlarges, develops intense eosinophilia and follows a train of degenerative changes. Progressive cytoplasmic vacuolation and nuclear fragmentation are followed by ingestion of nuclear debris by vacuoles which become confluent. More epitheliocytes enlarge, approach the degenerating central cell and form a series of eosinophilic concentric lamellae around the central hyalinizing mass. As the corpuscle grows, further degenerate epitheliocytes join the mass with, it is said, effete macrophages carrying products of lympholysis, which pass between the lamellae to reach the centre and become hyalinized or soluble. Corpuscles vary from 30–100 μm in diameter, increasing in size and number during periods of intense lympholysis and thymic involution.

Thymic involution. The thymus–body ratio is greatest perinatally (**6**.190) but the organ continues to increase in absolute size until about puberty, after which it tends to gradually decline, although a great range of sizes has been recorded throughout post-pubertal life (Kendall et al 1980). Early work from autopsies, often related to patients dying after chronic, debilitating illness, suggested an age-dependent decline in thymic weight, but Steinmann et al (1986) found no evidence of this in autopsies conducted within 24 hours of sudden death. However, such measurements are difficult to assess in functional terms because fatty infiltration occurs progressively from the neonatal period onwards. This process begins in the septa around the lobules and then adipocytes enter the cortex and gradually replace its cells, such infiltration advancing from the capsule towards the medulla. This fatty infiltration often makes the distinction between the thymus and surrounding mediastinal adipose tissue difficult at post-mortem, but careful dissection reveals that encapsulated tissue is always present, albeit fatty.

Because of these changes, the numbers of thymocytes present must be greatly reduced in old age, as was also found in cultured tissue. However, thymocyte production and differentation persist throughout life, and T cells from this source continue to populate the peripheral lymphoid tissue, blood and lymph (see Steinmann & Muller Heremlink 1984). The activity of the thymus appears to be related to the levels of thymic hormones in the organ; with ageing the functional capacity of the thymus may be reduced, suppressed or not effectively stimulated but is not completely lost.

Vessels and nerves. The arteries are derived mainly from internal thoracic and inferior thyroid artery branches which also supply the surrounding mediastinal connective tissue. There is no main hilum but arterial branches pass either directly through the capsule or, more often, into the depths of the interlobar septa before entering the thymus at the junction of the cortex and medulla. Within the septa the vessels are quite large and are separated from the main substance of the thymus by a continuous sheath of Type 1 thymic epitheliocytes (vide supra) and a perivascular space containing pericytes and other connective tissue elements. After entering the thymus proper, these vessels course along the cortico-medullary junction giving off irregular branches to the medulla and small radially-arranged arterioles and capillary loops to the cortex. Epitheliocyte sheaths and perivascular spaces around arteries and arterioles persist into the medulla and cortex for some distance. The endothelium of vessels in the cortex is generally of the complete type, although medullary and intraseptal vessels may show fenestrations.

Post-capillary venules of the cortico-medullary junction have a thickened endothelium as in lymph nodes (p. 824) permitting the migration of lymphocytes. Venules retrace the arteriolar paths, converging to principal veins in the interlobular septa; from there the venous return is partly via a capsular plexus and hence circulation from arteriole to radial capillary continues as a *transcortical centrifugal route* through the venules to the small veins, finally joining with the capsular veins (**6**.192). These contrasting microvascular routes may be significant in movements of thymic cells (Blau 1976). *Thymic veins* drain to the left brachiocephalic, internal thoracic and inferior thyroid veins; one or more veins often emerge medially from each lobe of the thymus to form a common trunk opening into the left brachiocephalic vein.

The blood–thymus barrier. When colloidal substances are injected intravascularly they fail to penetrate the extravascular spaces in the thymic cortex, where lymphocytes are proliferating, suggesting that the walls of thymic blood vessels may bar antigens and other substances from passing into the thymic tissue. This tissue would thus be an *immunologically sequestered site* for the differentiation of lymphocytes (vide infra). Raviola & Karnovsky (1972) found that, in rodents, electron-opaque tracers traversed the intercellular junctions of medullary endotheliocytes, particularly in post-capillary venules, diffusing extensively into the medullary tissue. However, the endothelium of cortical capillaries forms a more effective barrier and the small amounts of tracer passed by endothelial vesicular transport were immediately phagocytosed by perivascular macrophages. Presumably macrophagic action also prevents diffusion of particulate substances from medulla to cortex.

Afferent lymphatics are absent from the thymus but **efferent lymphatics** arising from the medulla and cortico-medullary junction drain through the extravascular spaces in company with the arteries and veins entering and leaving the thymus. In rodents, large lymphatic vessels draining to perithymic lymph nodes are often found within the subcapsular cortex but these also receive lymph from other areas of the body; these lymph nodes drain in turn to neighbouring regional nodes (Goldstein & Mackay 1969). Whether there is a similar perithymic lymphatic drainage in humans remains unknown.

Thymic innervation is derived from the sympathetic chain via the cervicothoracic (stellate) ganglion (or ansa subclavia) and the vagus. Branches from the phrenic nerve and descendens cervicalis are distributed mainly to the capsule of the thymus. During development (Hammar 1935), vagal innervation of the thymus commences in the neck before its descent into the thorax. The two lobes are innervated separately through their dorsal, lateral and medial aspects and rich neural plexuses are formed in the medulla. After its descent, the thymus receives the sympathetic nerves along vascular routes, their terminals branching radially and forming with the vagal fibres a plexus at the cortico-medullary junction. Innervation is complete by the onset of thymic function.

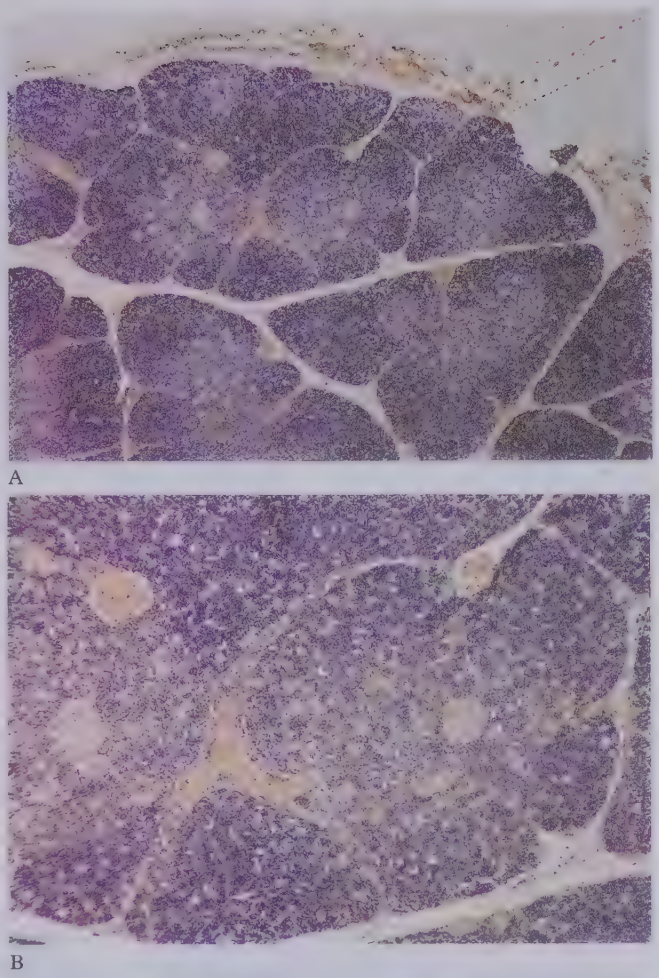
While many of the autonomic nerves are doubtless vasomotor, many terminal branches also (at least in rodents) leave their perivascular pathways and pass among the cells of the thymus, particularly the medulla, suggesting that they may have other roles. The medulla also contains a variety of non-lymphoid cells, including cells positive for vasoactive intestinal polypeptide (VIP), acetylcholinesterase (large, non-myoid cells), oxytocin, vasopressin and neurophysin cells and with possible neural crest origin. Clearly, the roles of the nervous system and other neuroendocrine elements in the overall biology of the thymus are far from being understood and suggest many intriguing possibilities.

FUNCTIONS OF THE THYMUS

Thymic functions are not yet completely clarified although in recent years dramatic advances have been made. The evidence comes from a variety of experimental approaches, including studies of the effects of thymectomy or thymic destruction by radiation in neonatal and mature animals and the study of mutant murine strains, e.g. '*nude*', in which the thymus is vestigial or absent in homozygous individuals. Attempts have been made experimentally in animals to compensate for thymectomy by the injection of cell suspensions from various lymphoid tissues or the bone marrow, by normal or irradiated thymic tissue, either as free grafts or surrounded by barriers impermeable to cells and by cell-free thymic extracts.

The nature and origins of stem cells capable of re-populating cell-depleted lymphoid tissues or thymic grafts have also been investigated by chromosomal marker or autoradiographic techniques. The restoration of immune competence in animals made immunologically tolerant to certain antigens, by prolonged exposure to small quantities, has been studied in early neonatal animals. It is possible only to summarize the concepts emerging from this busy field of experimentation. These experimental approaches are now being supplemented and greatly clarified by the use of monoclonal antibodies either to characterize different cell types or to demonstrate the presence of particular functional markers in cell interactions.

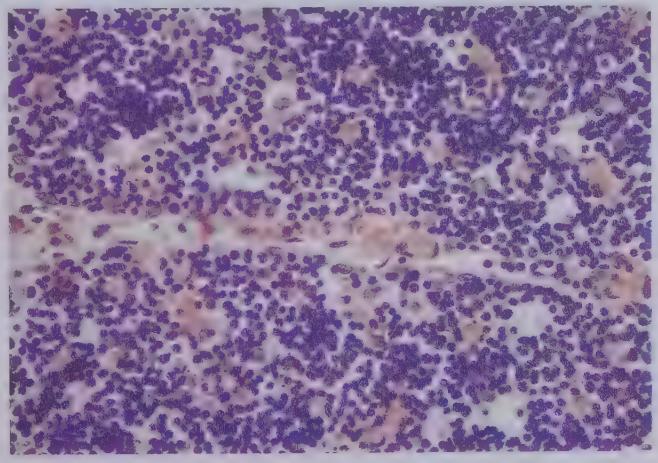
The major functions of the thymus are to achieve the differentiation of lymphocytes into the different classes of T cells (thymocytes) and to maintain a sufficient supply of them in the general circulation and peripheral lymphoid organs to react to whatever antigenic stimuli may be presented to the body, as described elsewhere (p. 672). During neonatal and early postnatal life, the thymus is essential to the normal development of lymphoid tissues. Thymectomy at this stage leads to a progressively fatal condition, with hypoplasia of the peripheral lymphoid organs, wasting and an inability to mount an effective immune response. By puberty, when the main lymphoid tissues are fully developed, thymectomy is less debilitating, but a reduction in effective responses to novel antigens ultimately ensues.



Secretory activities of the thymus

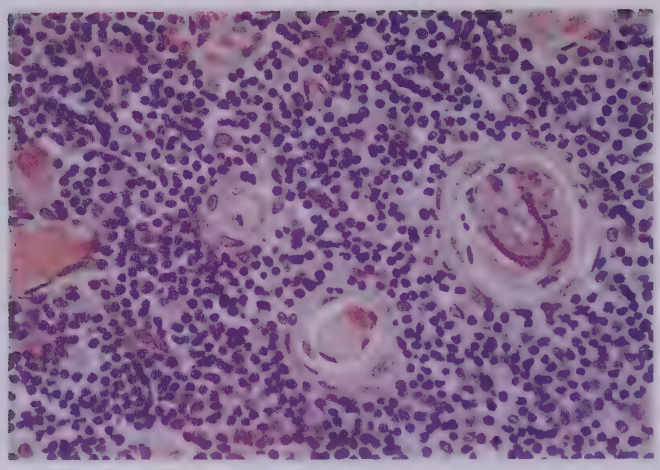
A second major function of the thymus is the production of various factors and hormones which regulate lymphocyte production, differentiation and activities within the thymus, in peripheral lymphoid tissue and elsewhere. These substances include four major, chemically well-defined polypeptides: thymulin, thymopoietin, thymosin alpha 1 and thymosin beta 4 (Hadden 1987). The first two of these fulfil the strict criteria defining them as hormones, whereas the other two are more problematical (vide infra). Thymic humoral factor is also probably of thymic origin and various other substances involved in the later stages of T-cell and mononuclear phagocyte function, also found in other lymphoid tissue, are also produced by the thymus, e.g. interleukins I and II (pp. 669, 673). *Thymulin* appears to be produced exclusively within the thymus; it is a nonapeptide hormone needing the presence of zinc for functional activity. It acts exclusively on T cells, binding to T-cell receptors with high affinity and enhancing the performance of various T-cell subsets, especially (at high doses) T-cell suppressor cells. It can be detected and measured in circulating blood by the appropriate methods of bioassay or radio-immunoassay. *Thymopoietin* is, in vitro, an inducer of the final differentiation of T cells into distinct subclasses and in vivo enhances several T-cell functions, e.g. the generation of cytotoxic T cells. Both thymulin and thymopoietin act systemically to give a finely tuned immunoregulation of T cells, helping to maintain a balance between the activities of their different subsets.

The nature and biological activities of the other factors produced by the thymus are less clear. *Thymosin alpha 1* stimulates (in mice) lymphocyte proliferation and antibody production, enhances the action of macrophage migration inhibition factor and affects DNA metabolism in thymocytes. It has been localized within epitheliocytes of the thymic medulla but may be synthesized elsewhere, possibly in the central nervous system where it has also been localized in regions related to autonomic and neuro-endocrine control. However, there is some evidence that thymosin alpha 1 may be a degradation product of a precursor present in other tissues, too. *Thymosin beta 4* is a product of mononuclear phagocytes (monocytes) and is therefore not unique to the thymus. *Thymic humoral factor* regulates the proliferation and maturation of T-helper and T-suppressor cells, but its chemical structure has not yet been described; various other factors may be produced by the thymus but their specificity to this organ and their chemical status also have yet to be clarified.



Summary of the origins and fates of lymphocytes in the thymus

The thymus develops before other lymphoid organs as an epithelial structure that begins to receive lymphoid precursor cells at 9–11 weeks in utero; by 15 weeks, differentiation into cortex and medulla has occurred and the epitheliocytes now express the typical immunochemical markers of the adult thymus.



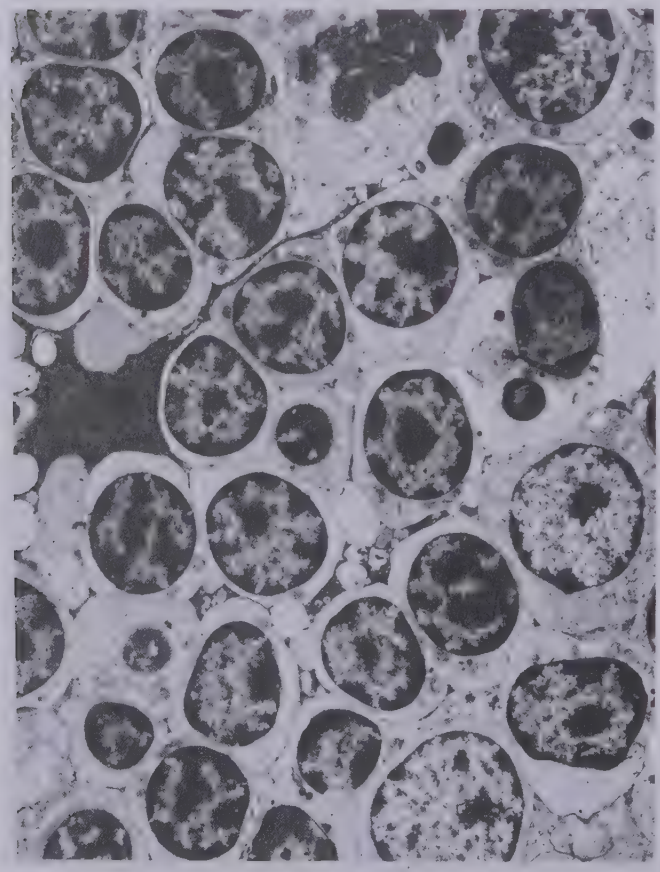
6.193 Survey photographs of a neonatal human thymus stained with haematoxylin and eosin. The general lobular architecture is seen; each lobule contains a relatively pale medullary core surrounded by a densely cellular, dark, heavily stained cortex. From a specimen prepared and provided by R O Weller, Department of Pathology, Guy's Hospital Medical School.

Thymocytes arise from stem cells of the bone marrow and, in earlier fetal life, the spleen; they migrate via the bloodstream to the thymus, entering its tissues chiefly through the post-capillary venules. They become pro-thymocytic lymphoblasts in the outer

6.194 Neonatal thymus. A cortical field showing a delicate interlobular connective tissue septum, densely packed cortical lymphocytes and scattered profiles of larger, pale, eosinophilic, epithelial, reticular cells.

6.195 Neonatal thymus. A medullary field showing three concentric corpuscles of Hassall of varying degrees of maturity, surrounded by many closely packed lymphocytes and a number of reticular cells.

cortex, proliferating extensively and differentiating into different subsets but about 90% of their progeny die in the thymus within a few days; the remainder go on to become fully immunocompetent T-lymphocytes after returning to the circulation to join the reserve pool of T-lymphocytes and to populate the thymus-dependent regions of lymph nodes and other peripheral lymphoid organs where final maturation takes place.



Interactions between the thymus and other endocrine organs

Interestingly, the neonatal thymus appears to have other, non-immunological powers, since neonatal thymectomy (or the congenital athymic condition) in rodents is associated with degranulation of cells in the adenohypophysis (probably somatotrophs or prolactin-secreting cells). The levels of circulating luteinizing hormone (LH) and Follicle Stimulating Hormone (FSH) are also reduced but can be corrected by transplantation of a new thymus at birth. Likewise, in girls the development of the ovary is affected in cases of thymic dysfunction, e.g. in ataxia telangiectasia and the Di George and Cri-du-chat syndromes where the thymus fails to develop. Thymectomy in mice later than seven days after birth no longer affects ovarian development; removal of the thymus earlier than this leads to death from wasting disease. There is evidence that thymulin and a thymosin-related factor are involved in these effects.

Interactions with other endocrine glands appear to be widespread (see Michael 1983, Kendall 1988). The activity of the thymus is affected by Adrenocorticotrophic Hormone (ACTH), LH, FSH, prolactin, thyrotrophic hormone (TSH) and somatrophic hormone (STH). ACTH acts indirectly by stimulating the release of glucocorticoid hormones, principally cortisol, from the adrenal cortex; these substances are potent inhibitors of thymic function and cause its involution (human thymocytes bear up to 3000 cortisol receptors per cell and thymic epitheliocytes have 10 times this number). Glucocorticoids induce thymocytes to synthesize endonucleases which damage their own DNA and cause their death. Conversely, adrenalectomy causes thymic enlargement, while neonatal thymectomy (in rodents) stimulates the adrenal glands. The sex hormones also have important effects on the thymus, some of them inhibitory; others have different actions depending on the physiological state, particularly age. In animals, gonadectomy of both sexes leads to an increase in thymic size, while in pregnancy it involutes but is restored during lactation, possibly under the action of prolactin.

STH, which is similar in structure to prolactin and possibly also binds to its receptors on thymic cells, has a similar stimulatory role. Various other hormones (e.g. insulin, insulin-like growth factor, etc.) also affect the production of lymphocytes by the thymus. Like many other aspects of hormonal regulation, the significance of these diverse findings is difficult to assess in the context of the overall strategy of the immune system at different times of life and under various conditions of normal health and disease, but they indicate that the immune and neuro-endocrine system are heavily interdependent and that agents which affect either, including different forms of physiological, neurological and immune stress, are likely to cause complex changes in the operation of both systems.

Applied Anatomy. Castration or adrenalectomy delays thymic involution; hypertrophy of the suprarenal cortex, injection of cortisone or of androgenic hormones all cause atrophy. In young children a large thymus may press on the trachea, causing attacks of respiratory stridor. Thymic tumours may also compress the trachea, oesophagus and large veins in the neck, causing hoarseness, cough, dysphagia and cyanosis. Myasthenia gravis, a chronic auto-immune disease of adults (Castleman 1966), is a diminution in power of certain voluntary muscles for repetitive contraction. Muscles commonly involved are levator palpebrae superioris (leading to ptosis) and extra-ocular muscles (leading to diplopia). Others in the face, jaws, neck and limbs may be involved and in severe cases the respiratory muscles. In many patients thymic abnormalities have been observed, such as hyperplasia or thymoma, a tumour of epithelial cells derived from the reticulum or possibly the lymphocytes. In some cases transient or more lasting improvement may follow thymectomy. Although there may be more than one condition with these signs, myasthenia gravis is now considered an auto-immune disease, in which acetylcholine receptor proteins of neuromuscular junctions are attacked by internal antibodies; the coincidence of the disease with thymic disorders may reflect the role of the thymus in modulating the immune responses of the whole body.

Topography of the Lymph Nodes and Vessels

The detailed architecture of lymph nodes and lymphatic vessels of varying calibre has been given in the preceding pages and brief

allusion has also been made to some *major lymph trunks* and the common aggregation of nodes into *regional groups*. The latter have, in most cases, fairly well defined topographical sites, specifically named (but varying criteria have been used), each with its variably well established area of drainage, interconnections with other nodes or groups and the predominant destination of its efferent vessels. A more detailed consideration of these matters is the concern of the remainder of this chapter; this must be prefaced by a summary, or sometimes a reiteration, of a few general principles. The reasons for this cannot be overemphasized. Lymphatic anatomy often appears an almost impossible plethora of topographical names for trunks, groups and subgroups of nodes and their connections. However, an elemental knowledge of general anatomy and a recognition of which of the limited number of general principles apply to the major organ systems make many of the difficulties evaporate. It is particularly useful to appreciate the *overall pattern* present in a particular organ, whole organ system or whole body segment. (Good examples are: the whole subdiaphragmatic alimentary tract, the foregut, the stomach, the tracheobronchopulmonary system, the similarities and contrasting features of the arm and leg and the head and neck as a whole.) These encompass all the main patterns and principles, include all the main *terminal lymph trunks* whereby lymph is returned to the venous system and indicate how helpful reference to main embryological events may be. The *principal groups* of lymph nodes towards which lymph converges from wide tissue areas (often through one or more *subgroups*) and knowledge of which, for many, is mandatory, is clarified. Thereafter, many (but not all) the lesser subgroups, in relation to their formal topographical names, assume a diminished importance in terms of mental retention; nevertheless, their *distribution* can in the majority of instances be *predicted* with confidence. The various criteria for the *topographical naming* of nodes will be mentioned below. Certain *general names* applied to nodes, although not universally used, often prove useful. Lymph circulating in lymphatic capillaries may be returned to the venous system (ignoring intralymphoidal venular events on a microscopic scale, p. 824) almost exclusively at *bilateral sites* at or near the junctions between internal jugular and subclavian veins forming right and left brachiocephalic veins; however their routes vary enormously in *length* and *complexity*. In certain exceptional sites (thyroid, oesophagus, dorsal hepatic 'bare areas', p. 1388) the capillaries drain via a radicle of the thoracic duct with no intervening lymph node (an *anodal* route). In some, a single node provides *uninodal* routes; the majority of routes are *multinodal* with a number of, sometimes many, nodes forming irregular cross-connected *chains*. In such a chain the node or group nearest the tissue drained is variously termed *primary (outlying*, or *peripheral*) in different circumstances. The last group of the chain, whose efferents form a final uninterrupted principal lymph trunk, is termed *terminal*. Between its primary peripheral and its terminal groups intervening nodes are often segregated into *intermediary* groups; some use the collective term *regional lymph nodes* to include all three groups; others, peripheral and intermediary only. The significance of multinodal pathways is by no means clear; it should be noted that classifications such as the above may impose an artificial simplicity on a potentially highly complex monitoring and reacting system.

Thus briefly a particular node is not one element in a simple chain but, receiving multiple afferent vessels, may be e.g. the primary node for various loci, number three in the chain for other loci, number five for others and so forth. Such considerations, of course, apply to other members of the chain and, summating for the whole chain, there emerges the notion of a system of lymphatic channels and lymphoid stations of great three-dimensional complexity. Differential lymphangiography amply confirms this complexity. This prompts the question: are lymph nodes in general roughly *equivalent* in their ranges of receptivity (monitoring) and reactivity or do they vary? If *variation* exists, to what degree? An extreme (and fanciful) extension of this is the possibility of individual nodes, or even sectors of nodes, being *unique* in their properties, as they unquestionably are in their locations and connections. (The writer emphasizes that these ideas are entirely speculative but hopes that they are sufficiently provocative to merit consideration.)

Topographical naming of lymph nodes has not followed a single rigid classification; four main frames of reference have been found convenient, and quite lucid. These are (1) superficial/deep position, (2) related vasculature, (3) related organ's name and architecture, and (4) general topographical location.

Superficial and deep refer, as with a number of other structures, to their location with respect to the deep fascia. As noted below, many superficial nodes are closely applied to prominent superficial veins. An interesting but unexplained fact is that the upper limb has few superficial nodes and its *superficial* lymphatic drainage mostly passes directly to *deep* axillary nodes; in contrast, in the leg the *superficial* lymphatic drainage passes, almost exclusively, to the large *superficial* inguinal nodes before continuing to the external iliac nodes.

Relation to Vasculature. The majority of nodes and node groups are clustered around or abut a prominent blood vessel or one of its branches; from this (with many notable exceptions) the name of the group is derived. The association assists in recalling the location of the group and in many instances is a strong pointer to the main region of lymph drainage. Examples of exceptional superficial nodes associated with veins are: buccal nodes (facial vein), superficial cervical nodes (external jugular vein), anterior cervical nodes (anterior jugular veins), infraclavicular nodes (cephalic vein), supratrochlear nodes (basilic vein), superficial inguinal nodes (great saphenous vein). Deep nodes associated with vessels are so numerous that only a few illustrative examples can be given. The abdominal aorta and common, internal and external iliac arteries are encrusted with nodes. The whole consists of massive chains of nodes, interconnected by lymphatic channels, predominantly vertically but also obliquely and transversely. Thus, the main groups are named with their vessels: *external, internal* and *common iliac* and *circumaortic*. The latter (often grouped with neighbouring nodes particularly scattered over the inferior vena cava as *lumbar nodes*) are divided, on sound developmental and lymphodynamic grounds, into a large median *ventral aortic group*, prominent right and left *lateral aortic groups* and a sparse *retro-aortic group*. Details are furnished in subsequent pages but a *few examples* with comments and one possible synthetic approach to study may be appropriately outlined here. The ventral aortic group aggregates around the three large subdiaphragmatic ventral splanchnic arteries (p. 766) as *coeliac, superior mesenteric* and *inferior mesenteric* groups of nodes, which drain the subdiaphragmatic foregut, midgut and hindgut (and their derivatives), respectively. The foregut provides an excellent framework with respect to its extent and parts (terminal oesophagus, stomach, proximal duodenum); its derivatives (liver, gallbladder and biliary ducts, pancreas and the closely associated spleen); and the mutual disposition of the foregoing and their peritoneal reflexions, omenta and the lesser sac. To this is added the position of the upper abdominal aorta, the coeliac artery, its trifurcation into common hepatic, left gastric and splenic arteries and the courses and main branches of these. Groups of nodes named in relation to these are, e.g. left gastric, right gastro-epiploic, hepatic and pancreaticosplenic; other groups related to these have visceral names, e.g. paracardial and pyloric (stomach), cystic (gallbladder), 'anterior border of epiploic foramen' (bile duct). The general (interconnected) areas of drainage of these groups are evident and their efferents discharge into the coeliac nodes. The latter also receive the efferents of the superior and inferior mesenteric groups, each of which has received the efferents from systematically named groups, aggregated along their branches, or are scattered in the mesentéries; again their areas of drainage are obvious. The *coeliac nodes* are thus the *terminal group* for the whole subdiaphragmatic gut down to mid-rectal level and for most of the liver, the gallbladder and biliary ducts, pancreas and spleen. Their efferents join to form wide right and left *intestinal lymph trunks*; these coalesce and also join the right and left *lumbar lymph trunks* (vide infra) to form the morphologically variable **abdominal confluence of lymph trunks**, the cranial end of which is the entry to the thoracic duct. (Its variability—saccular in a minority of instances only—is mentioned below.) Briefly (details p. 854) the *lateral aortic groups* drain the tissues supplied by the lateral splanchnic and dorsolateral somatic intersegmental aortic branches; caudally they receive the profuse efferents from the common iliac

groups which in turn receive the efferents from the internal and external iliac groups, each with their extensive areas of drainage and further associated outlying groups of nodes. These will not be repeated here, as they are given in subsequent pages. The cranial members of the lateral aortic groups are the *terminal nodes* for all these tissues; their efferents converge to form the bilateral lumbar lymph trunks which are the other main avenues forming the abdominal confluence of lymph trunks and thence the initial (caudal) end of the thoracic duct. Mention may be made of the nodes associated with drainage of the leg, often misrepresented. Some drainage first involves a limited outlying group of popliteal nodes (near their vessels), then traverses the superficial or deep inguinal nodes which are *intermediary (not* terminal) groups at the limb's root; thereafter the lymph ascends the chains just described, i.e. via the external and common iliac, the lateral aortic to its upper terminal nodes, then the lumbar lymph trunk, confluence and thoracic duct. (Some deep gluteal lymph follows the internal iliac path to the same destination.) Prominent nodes in the thorax named in relation to vessels are the brachiocephalic group.

Relation to Viscera. These names are self-evident. Examples already mentioned are the paracardial and pyloric, gastric groups; others are the superficial and deep parotid, submandibular and paracolic. The best examples are concerned with, primarily, the drainage of the lower respiratory tract. Passing from the periphery these are named: *pulmonary* (at major bronchial divisions within the lung), *bronchopulmonary* (or simply 'hilar'), *inferior* and *superior tracheobronchial* (p. 857) and *paratracheal*. Their ascending efferents are joined by some from the ipsilateral *parasternal, brachiocephalic* and *posterior mediastinal nodes* forming the *right* and *left bronchomediastinal lymph trunks*; these incline over the trachea, then to the ventral aspect of their jugulo-subclavian venous junctions. At or in either great vein, near the junction, the trunks usually open independently, but in about one-fifth of individuals the right trunk may join a **right lymphatic duct**; the left may join the **thoracic duct** or both may occur.

Names related to general topography. The groups of nodes most easily accessible to clinical palpation have widely used general positional names, which vary considerably in their precision. The relation of many (but not all) their subgroups to prominent blood vessels and their branches is close and this provides a more accurate reference system; in some notable sites this is seldom adopted. *Leg*: outlying *popliteal nodes*—here the name is used indiscriminately with respect to the vessels or the fossa; their *palpation* is by finger tips probing the fossa along the line of the popliteal vessels with the passively supported limb gradually moved from extension to semiflexion. *Inguinal nodes*, superficial and deep—here, inguinal simply implies the rather imprecise 'related to the groin'. The deep nodes are few and applied to the medial aspect of the femoral vein; the superficial nodes comprise a lower vertical group clothing the upper great saphenous vein; an upper group parallel to, but *below* the inguinal ligament (related to the superficial circumflex iliac and superficial external pudendal vessels). *Palpation*—with the supported limb slightly flexed, abducted and laterally rotated, along a strip 1 cm below the inguinal ligament and a strip 1 cm medial to the central apicobasal line of the femoral triangle.

Arm: outlying *supratrochlear nodes* (more aptly supra-epicondylar) are adjacent to the basilic vein. *Palpation*—along the line of the vein a few centimetres above the elbow joint; many approaches are satisfactory; facing the subject, an elegant approach is to cup the back of the supracubital arm with the appropriate palm, the semiflexed fingers encircle the medial aspect and their aligned tips effortlessly probe along the vein. The *axillary nodes* have subgroups with alternative names; one system applies to their topographical positioning with respect to the 'walls' of the axilla, the second system applies to their disposition close to the axillary vessels and their branches (especially the *veins*). These are detailed on p. 845 and will not be pursued here. *Palpation*—these must be approached systematically, exploring each wall of the axilla and any attendant vessels and nodes as separate manoeuvres. The supported arm is slightly abducted, the examiner facing the lateral aspect of the shoulder; each fold of the axilla is examined with the appropriate hand, semiflexed fingertips invaginating the axillary floor while the thumb grips the fold externally. The fingertips of one or both hands next probe deeply, then down and *laterally* along the axillary vessels. Finally, the fingers of the pronated hand, inserted deeply, are drawn down the medial wall, i.e. the resistant thoracic wall and serratus anterior.

It should be noted that most of the axillary groups are intermediary with their wide areas of drainage and the central group is preterminal; only the *apical group* is *terminal*. The latter's efferents form the *subclavian lymph trunk* which approaches and, with variable final morphology, opens at or near its jugulo-subclavian junction. The trunk and its opening are on the anterior aspect of the venous walls.

Head and Neck: apart from a few retrovisceral nodes and some deep to the sternocleidomastoid, members of all the nodal groups in the head and neck are clinically palpable when enlarged and all receive regional topographical names. Many of the latter are appropriate and helpful; in the *neck*, however, the major groups have only the most generalized names, despite their principal relationship to large vessels. (Alternative names based on this merit consideration.) The various groups are detailed elsewhere (p. 843); thus a simplified overall plan for the head and neck will be mentioned and some group names added to a suggested approach to their clinical examination. The relationship of craniocervical nodes to the deep fascia (superficial or deep) is discussed subsequently but in some important cases is implied in their names. At and near the junction of the head with the neck an encircling band extends bilaterally from the chin to the external occipital protuberance, the *pericraniocervical ring* (often loosely shortened to *'pericervical ring'*). Throughout this encompasses topographically named regional groups with outlying nodes in the face; sequentially the groups are: *submental, submandibular* (with outlying *buccal* nodes), *retromandibular* (outlying *parotid, retro-auricular* (or *mastoid*) and *occipital*. As noted, verbal descriptions of their sites and areas of drainage are given (p. 843) but in general are obvious from their names. *Palpation*—carried out from behind the seated subject, using both hands simultaneously, their fingers semiflexed and adducted and thumbs in partial opposition; the fingers explore systematically: the submental triangle, the submandibular glands and triangles (thumbs probing over buccinators), the retromandibular depressions (thumbs over parotids), the upper attachment of sternocleidomastoid and the occipital attachment of trapezius. Palpation now continues along the approximately *vertical* chains of cervical nodes, superficial and deep. The superficial chains of relatively few, small nodes are associated with the external jugular and anterior jugular veins, the *superficial cervical* and *anterior cervical* groups respectively; both drain finally into deep nodes. (These, and unqualified 'deep cervical' are indifferent, non-specific, unhelpful names; the relative precision of vascular or visceral names are preferable.) The main chain of *deep cervical nodes* is ranged along and embedded in, or in areolar tissue near, the carotid sheath but particularly those aspects surrounding the *internal jugular vein*. Customarily divided into upper and lower groups, they receive, in addition to their direct areas of drainage, all the efferents from the pericraniocervical ring, efferents from the superficial cervcial nodes and efferents from other paravisceral deep nodes (e.g. *retropharyngeal, infrahyoid, prelaryngeal, pretracheal*, paratracheal and subclavian). *All* the lymph from the head and neck finally traverses its ipsilateral *lower deep cervcial group*, which is the *terminal group*. Efferents from the latter converge, forming (right and left) jugular lymph trunks; each descends on its vein to its termination at or near the jugulosubclavian venous junction.

Lymph Node Numbers: Regional Distribution. Accurate, large statistical surveys are not available; the following are pooled data from many limited sources, nevertheless the overall approximations allow interesting speculation. A normal young adult body contains some 400–450 lymph nodes. Of these the limbs and associated superficial body wall are least well served. The arm and superficial thoraco-abdominal wall (down to the umbilicus) contain about 30 nodes, the leg and superficial buttock, infraumbilical abdominal wall and perineum only about 20 nodes. (Note this does not include the iliac and lateral aortic groups which have numerous additional intra-abdominal afferents.) The head and neck carry some 60–70 nodes. The

remainder (about 330) is divided between the thorax (deep walls and contents, some 100 nodes or less), and the abdomen and pelvis (deep walls and contents, some 230 nodes or more). Most richly served by nodes is the gastrointestinal tract; also profusely served is the tracheobronchopulmonary tract.

CERVICAL LYMPHOVENOUS PORTALS

Lymph is returned to the venous blood circulation via the right and left lymphovenous portals which are sited at, or near, the junctions of the large internal jugular and subclavian veins forming the even larger right and left brachiocephalic veins. On the right *three* main lymph trunks converge towards their venous junction; on the left *four* main trunks (three corresponding to the right-sided trunks, but additionally the largest trunk, *the thoracic duct*). The morphology of the venous termination of these trunks is subject to much variation and the account frequently given in textbooks is a fairly uncommon occurrence, hence the introduction of the generalized term lymphovenous portal.

On the right the three trunks converging are: (1) The *right jugular trunk* which extends along the ventrolateral aspect of the internal jugular vein from the terminal lower deep cervical nodes and conveys all the lymph from the right half of the head and neck.

(2) The *right subclavian trunk* from the terminal apical axillary group extending along the axillary and subclavian veins and conveying lymph from the right upper limb and superficial tissues of the right half of the thoraco-abdominal wall down to the umbilicus anteriorly and iliac crest posteriorly (and including much of the mammary gland).

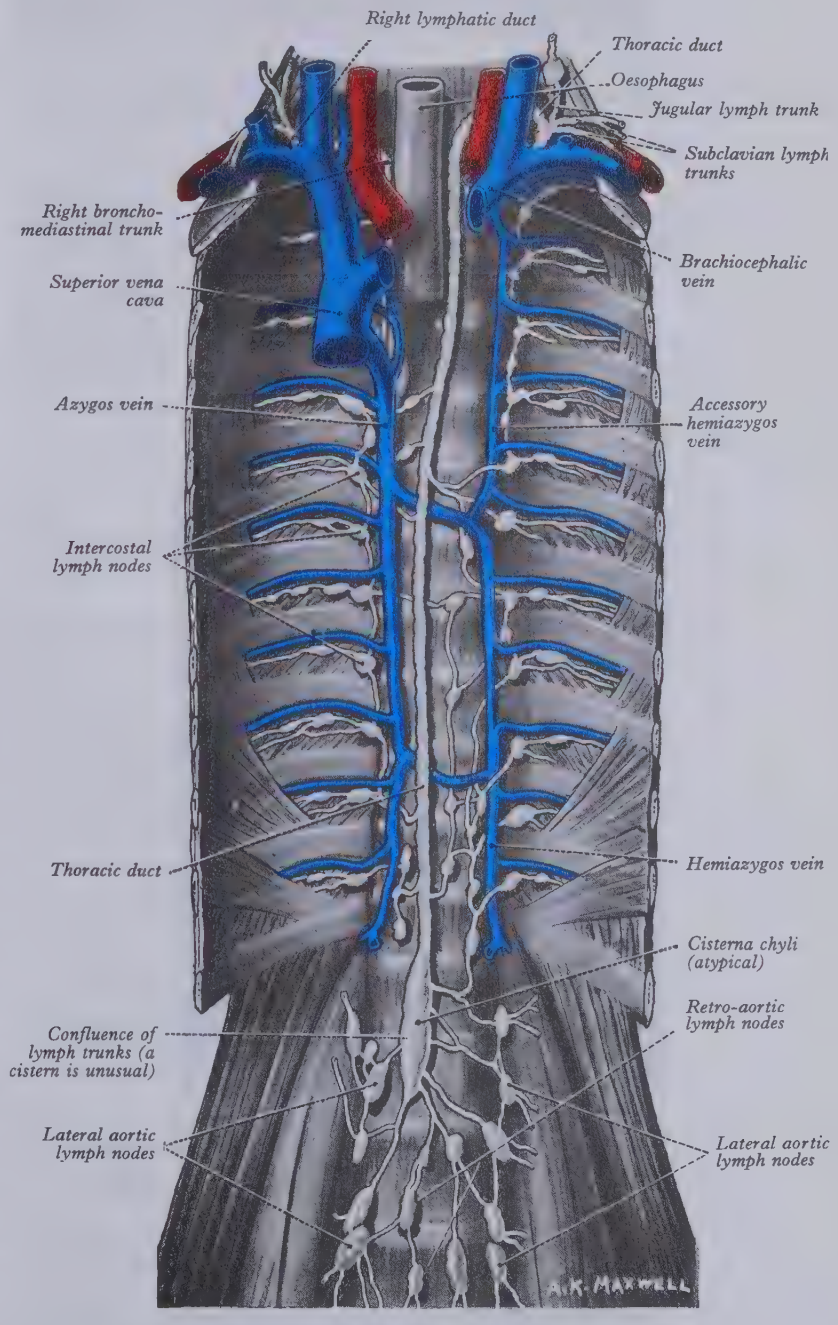
(3) The *right bronchomediastinal trunk* (p. 857), which ascends over the trachea towards the portal and conveys lymph from the deeper thoracic parietes, the right cupola of the diaphragm and subjacent liver, the right lung, bronchi and trachea, the greater part of the 'right heart' (of clinical parlance, *not* the geometric right half, see p. 857) and a proportionately small drainage from the thoracic oesophagus.

The right venous termination of the three lymphatic trunks is subject to great variation. In the great majority of subjects (80%) they open *independently*, their orifices clustered on the ventral aspect of the jugulo-subclavian junction or in the nearby wall of either of the great veins. In a proportion of these one or more of the trunks may bifurcate (or even trifurcate) preterminally and then have multiple orifices. In one-fifth of subjects only, the three trunks fuse to form a short (1 cm) single **right lymphatic duct** that inclines across the medial border of scalenus anterior to the ventral aspect of the venous junction, where its orifice is preceded by a bicuspid semilunar valve. An **incomplete right lymphatic duct** may be present following fusion of, usually, the subclavian and jugular trunks, or any combination of their terminals when divided. In such cases the bronchomediastinal trunk almost invariably opens separately.

Summary. The **right** lymphovenous portal, whatever the final morphology of its trunks, receives lymph from: the *right half* of the head and neck, the thorax and its contents and superficial tissues of the abdomen and trunk down to the umbilicus and iliac crest, *part* of the right cupola of the diaphragm and convex surface (only) of the underlying liver and the *whole* of the right arm. The **left** portal receives much the greater volume of lymph from all the remainder of the body.

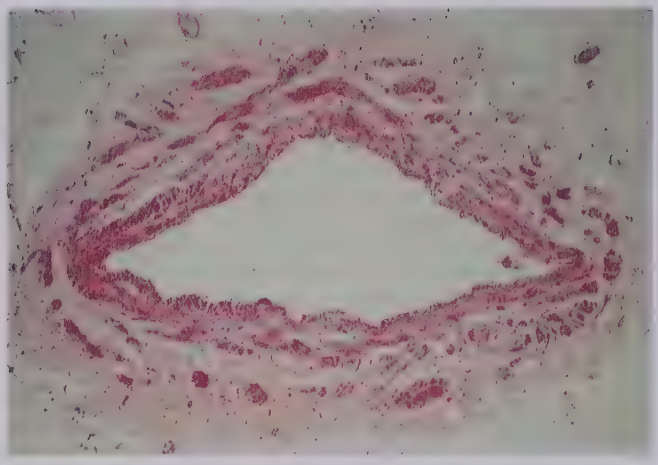
On the left the four trunks converging on the lymphovenous portal are:

(1) the *left jugular trunk*, mirroring its right fellow;



(2) the *left subclavian trunk*, also with a disposition corresponding to its contralateral fellow;

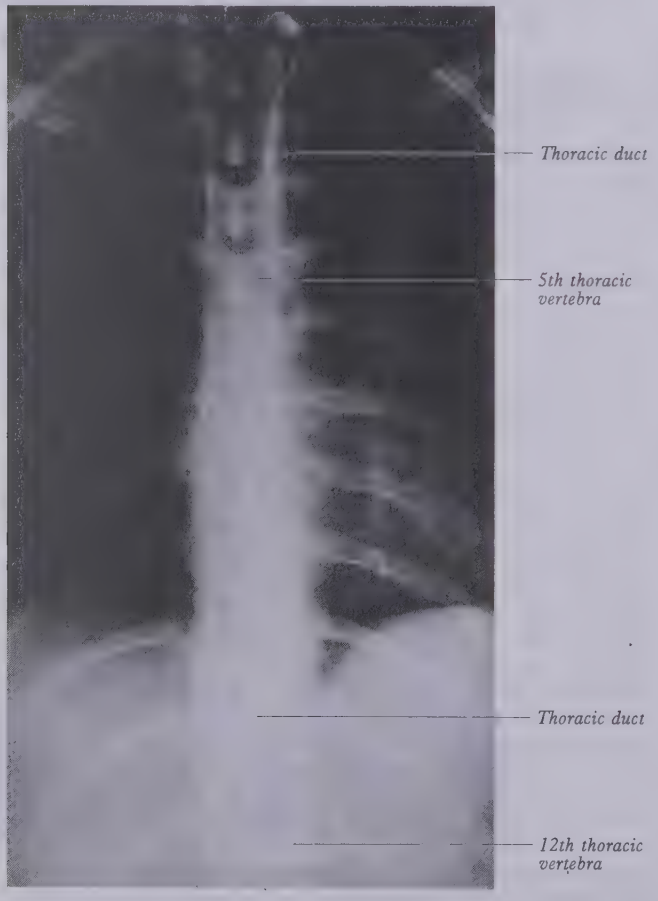
(3) the *left bronchomediastinal trunk*, similar to the right trunk, but draining more of the heart (the 'left' and part of the 'right hearts' of clinical parlance, p. 698) and more of the oesophagus;



(4) the *thoracic duct*, which drains all the extensive remaining regions of the body. At its caudal origin as a continuation of the abdominal confluence of lymphatic trunks (vide infra), throughout its course and at its cervical venous termination it is subject to considerable variation.

THE THORACIC DUCT (6.197,198,199)

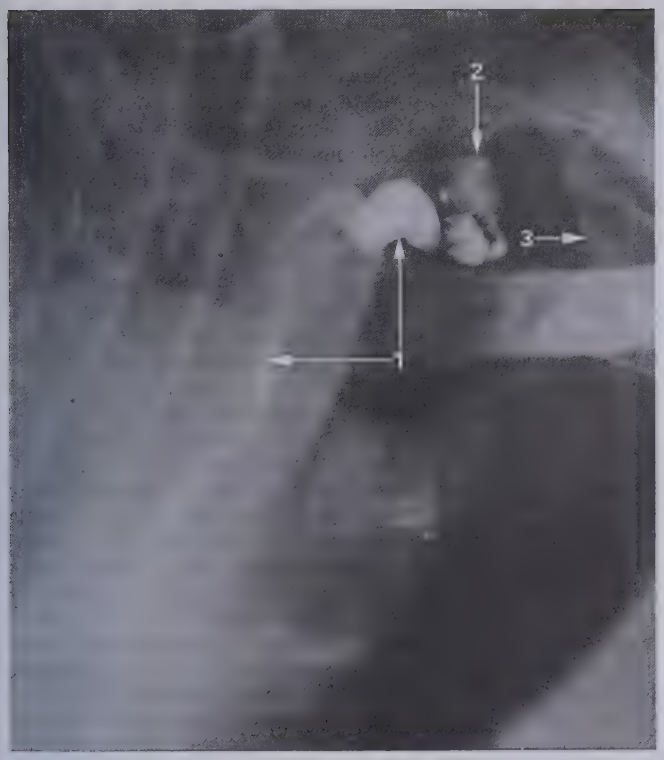
In adults the thoracic duct *including* the confluence of lymph trunks (or the cisterna chyli in the small proportion in whom the latter is saccular) is 38–45 cm in length, extending from the second lumbar vertebra to the root of the neck. Starting from the superior pole of the confluence near the lower border of the twelfth thoracic vertebra, it traverses the diaphragm's aortic aperture, then ascends the *posterior mediastinum*, right of the midline, between the descending thoracic aorta (on its left) and the azygos vein (on its right). *Posterior* to it is the vertebral column (vertebral bodies, symphyses, anterior longitudinal ligament), the right aortic intercostal arteries and terminal segments of the hemiazygos and accessory hemiazygos veins. *Anterior* to it are the diaphragm and



6.197 The thoracic and right lymphatic ducts. The accessory hemiazygos vein is crossing the median plane lower and the hemiazygos higher than usual. Note also the comments concerning the more common course of the azygos vein made in illustration **6.162B** and on p. 810. Two features are also uncommon: a single right lymphatic duct (usually two or more trunks open independently); a simple cisterna chyli is infrequent (it is usually a confluence of lymph trunks of varying morphology, p. 842).

6.198 Transverse section of the thoracic duct showing the fibro-muscular coat (see text). Stained with haematoxylin and eosin. Preparation by Millie Harrison, Department of Anatomy, UMDS, Guy's Campus, London. Magnification × 80.

oesophagus; a recess of the right pleural cavity may separate the duct and oesophagus. Reaching the level of the fifth thoracic vertebral body it gradually inclines to the left, enters the *superior mediastinum* and then ascends to the thoracic inlet along the left border of the oesophagus. In this part of its course the duct is first crossed anteriorly by the aortic arch and it then runs posterior to the left subclavian artery's initial segment, in close contact with the left mediastinal pleura. Passing into the *neck* it arches laterally at the level of the seventh cervical vertebral transverse process. Its *arch* rises 3 or 4 cm above the clavicle and curves *anterior* to the vertebral artery and vein, the left sympathetic trunk, thyrocervical artery or its branches and the left phrenic nerve and medial border of scalenus anterior (but is separated from the nerve and muscle by the prevertebral fascia). The arch passes *posterior* to: the left common carotid artery, vagus nerve and internal jugular vein. Finally, the duct descends anterior to the arched cervical 'first part' of the left subclavian artery and ends by opening into the junction of the left subclavian and internal jugular veins. However, the duct may open into either of the great veins, near the junction, or it may divide into a number of smaller vessels before terminating (vide infra).



6.199 Lymphangiogram showing the entire length of the thoracic duct, approximately 24 hours after injection of lipiodol into a lymphatic vessel on the dorsum of each foot; the cisterna chyli is not evident. Supplied by G I Verney, Addenbrooke's Hospital, Cambridge; photography by Sarah Smith, Department of Anatomy, UMDS, Guy's Campus, London.

At its abdominal commencement the thoracic duct is about 5 mm in diameter but diminishes in calibre at mid-thoracic levels, then in about 50% of subjects is again slightly dilated before its termination. It is slightly sinuous, constricted at intervals and appears varicose. It may divide in its mid-course into two unequal vessels which soon re-unite, or into several small branches which form a plexus before continuing as a single duct. At a higher level it occasionally bifurcates, the left branch ending as usual, the right branch diverging to join one of the right lymph trunks or, when present, a right lymphatic duct; the combined vessel usually opens into the right subclavian vein. The thoracic duct has several valves corresponding to sites exposed to pressure. At its termination a bicuspid valve faces into the vein to prevent or reduce reflux of blood. (After death blood regurgitates freely into the duct, which then looks like a vein.)

Termination. Kinnaert (1973) has collected accounts of 529 dissections (49 his own) of the thoracic duct's termination. In 0–4.5% no thoracic duct appeared on the left. Multiple terminal openings were frequent (10–40%, according to different observers). In Kinnaert's series the preterminal duct was multiple in 66%, but in only 21% were actual terminal openings multiple. Patterns varied greatly in different studies but, in the two largest by Jdanov (1959) and Kinnaert (1973), *sites* of termination were respectively 48% and 36% internal jugular vein, 9% and 17% subclavian vein, 35% and 34% jugulo-subclavian junction. Termination in the left brachiocephalic (innominate) vein occurred in 8% of Jdanov's series, but none of Kinnaert's.

Origin and tributaries. The abdominal origin of the thoracic duct proper is, as stated, situated to the right of the midline at the level of the lower border of the twelfth thoracic vertebral body or the thoracolumbar intervertebral disc. It is the recipient of all the lymph delivered by the four main abdominal lymph trunks which converge to an elongated arrangement of channels of *variable morphology* and hence is given here the generalized name, **abdominal confluence of lymph trunks**. This may be a simple duct-like extension or be duplicated, triplicated or plexiform; when it is wider than the thoracic duct its interior is sometimes irregular and bilocular or trilocular and may surround intercalated lymph nodes. Only in a small proportion of instances is it a simple, fusiform, saccular dilatation, and the widely-used name **cisterna chyli** should be reserved for these. A published thorough statistical study of the origin of the thoracic duct in mankind appears lacking. Anson (1963) depicted variations: in many a cisterna was absent; when present it was usually multilocular or plexiform; no statistics of incidence were given. Kubik (personal communication 1978) observed a 'cisterna' in 14 of 70 dissections. In only six was it single; it was double in five specimens and trilocular in three. In 56 dissections no cisterna was observed; in half of these collecting trunks formed a direct extension of the thoracic duct; in the other half intercalated nodes (also depicted by Anson 1963) simulated the profiles of cisternae.

The abdominal confluence extends from the caudal beginning of the thoracic duct, vertically, for 5–7 cm anterolateral to the right, of the first and second lumbar vertebral bodies (and their intervening disc), immediately to the right of the abdominal aorta. (Thus its site is overlapped by territories containing upper right lateral aortic lymph nodes and right-sided members of the coeliac and superior mesenteric pre-aortic groups.) The upper two right lumbar arteries and the right lumbar azygos vein (p. 808) are between the confluence and the vertebral column. Anterior to it is

6.200 Lymphangiogram showing the upper part of the thoracic duct. There has been some filling of a cervical lymph node. 1. Thoracic duct. 2. Lower deep cervical lymph node. 3. First rib. Supplied by J B Kinmonth.

the medial edge of the right diaphragmatic crus. As mentioned, the confluence (and thence the thoracic duct) receives the right and left lumbar and intestinal lymph trunks. In summary:

(1) The *lumbar trunks* are formed by efferents from lateral aortic lymph nodes. Thus, either directly or after traversing intermediary groups, they carry lymph from: the lower limbs, the full thickness of the pelvic, perineal and infra-umbilical abdominal walls, the deep tissues of most of the supra-umbilical abdominal walls, the pelvic viscera, testes or ovaries, kidneys and suprarenals.

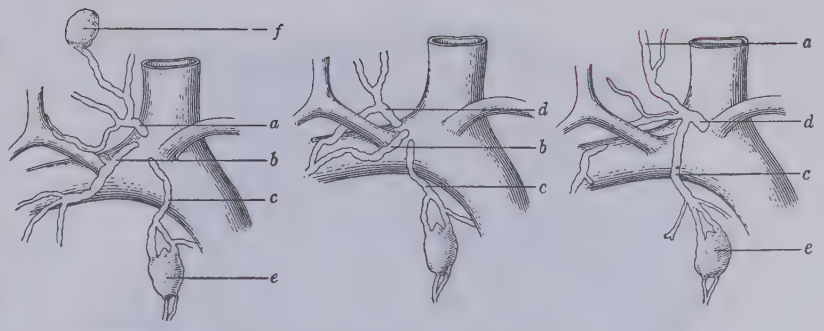
(2) The *intestinal lymph trunks* receive efferents from the coeliac nodes (terminal ventral aortic group) which, after traversing intermediary groups, drain the stomach, intestines (to mid-rectal levels), pancreas, spleen and the (greater) antero-inferior part of the liver.

Tributaries of the thoracic duct proper (in summary):

The *confluence of lymph trunks*, just described, the whole outflow of which enters the origin of the thoracic duct;

The bilateral *descending thoracic lymph trunks* from intercostal lymph nodes of the lower six or seven intercostal spaces of both sides which traverse the aortic orifice and join the lateral aspects of the thoracic duct in the abdomen immediately after its origin;

The bilateral *ascending lumbar lymph trunks* from the upper lateral aortic nodes which ascend and pierce their corresponding diaphragmatic crus, then join the thoracic duct at a variable level within the thorax;



The *upper intercostal trunks* draining the intercostal nodes in the upper five or six *left* intercostal spaces;

The *mediastinal trunks* draining various nodal groups noted below and providing (amongst other tissues) paths to the thoracic duct from the convex diaphragmatic aspect of the liver, the diaphragm, the pericardium, heart and oesophagus;

The *left subclavian trunk* which usually joins the thoracic duct, but may open independently into the left subclavian vein;

The *left jugular trunk* which usually joins the thoracic duct, but may open independently into the left internal jugular vein;

The *left bronchomediastinal trunk* which occasionally joins the thoracic duct, *usually* having an independent venous opening.

6.201 Variations in the terminal lymph trunks of the right side (after Poirier & Charpy). a. Jugular trunk. b. Subclavian trunk. c. Bronchomediastinal trunk. d. Right lymphatic duct. e. Lymph node of parasternal chain. f. Lymph node of deep cervical chain.

Many of the trunks listed above are described as possessing terminal bicuspid valves which possibly prevent reflux of lymph. However, Sapin & Boryiak (1974) studied the behaviour of radio-opaque masses in thoracic ducts of 180 *cadavers*; they found that reflux into several groups of mediastinal and paravertebral groups was usual (under these conditions!).

Lymphatic Drainage of the Head and Neck

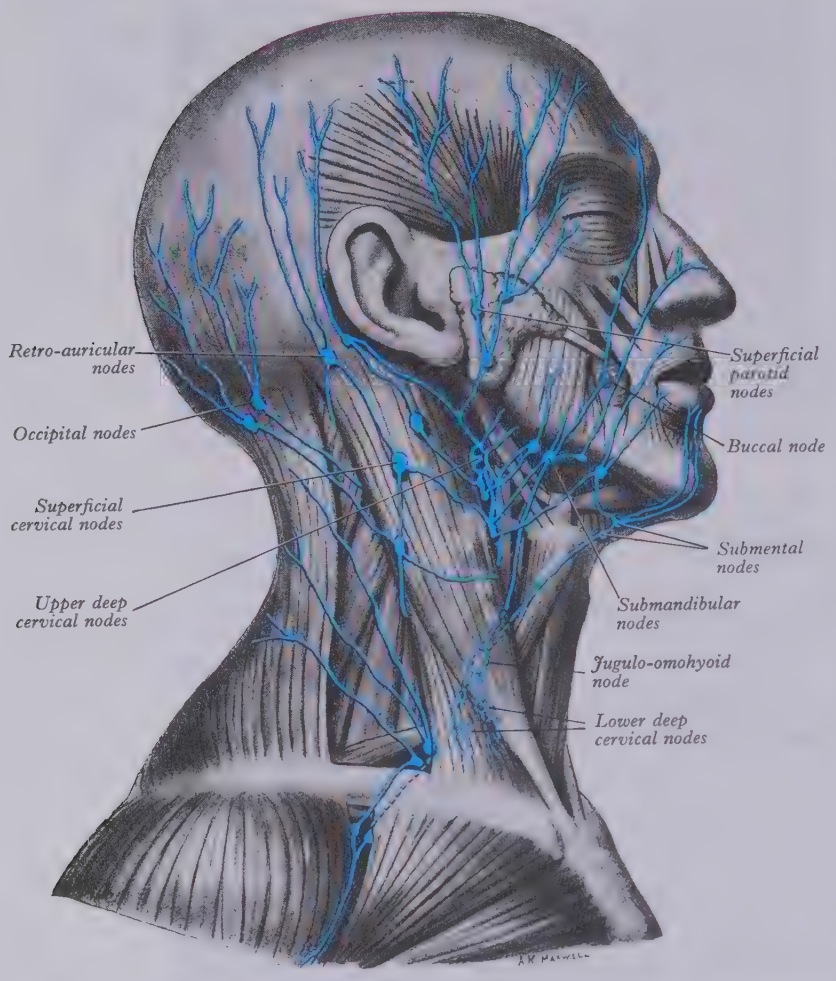
Nodes in the head and neck comprise a terminal (collecting) group and intermediary, outlying groups. The terminal group is related to the carotid sheath and is named *deep cervical*. All lymph vessels of the head and neck drain into this, directly from tissues or indirectly through nodes in outlying groups. Efferents of the deep cervical nodes form the *jugular trunk*, which on the right may end in the jugulo-subclavian junction or right lymphatic duct; on the left it usually enters the thoracic duct but may join the internal jugular or subclavian vein.

Deep Cervical Lymphatic Nodes

These nodes are alongside the carotid sheath; they form superior and inferior groups.

Superior deep cervical nodes (**6**.202) adjoin the upper internal jugular vein. Most are deep to the sternocleidomastoid; a few extend beyond it. One subgroup, of one large and several small nodes, is in a triangular region bounded by the posterior belly of the digastric and the facial and internal jugular veins; this *jugulodigastric group* is concerned specially with lingual drainage. *Efferents* from the upper deep cervical nodes drain to the lower group or direct to the jugular trunk.

Inferior deep cervical nodes are partly deep to the sternocleidomastoid, particularly related to the lower internal jugular vein but some, extending also into the subclavian triangle, are closely related to the brachial plexus and subclavian vessels. One node is on or just above the intermediate tendon of omohyoid, the *jugulo-omohyoid node*, and is concerned especially with the tongue (p. 845). Efferents from this lower group join the jugular lymph trunk.



In lymphatic drainage the tissues of the head and neck, like other regions, can conveniently be considered as (1) superficial and (2) deep. (See also the generalized arrangement of a *pericraniocervical ring* and *vertical cervical chains*, p. 840.)

Lymphatic Drainage of the Superficial Tissues of the Head and Neck (**6**.202)

Most superficial tissues in the region drain by vessels afferent to local groups of nodes, efferents from these draining to the deep cervical nodes; but some structures drain directly to deep nodes. Groups concerned in superficial drainage are:

(*a*) *In the head*: occipital, retro-auricular (mastoid), parotid, buccal (facial);

(*b*) *in the neck*: submandibular, submental, anterior cervical, superficial cervical.

6.202 The superficial lymph nodes and lymph vessels of the head and neck.

Lymphatic drainage of the scalp and ear. Vessels from the frontal region above the root of the nose drain to the submandibular nodes (6.202) and are considered with the face. Vessels from the rest of the forehead, temporal region, upper half of the lateral auricular aspect and anterior wall of the external acoustic meatus drain to the *superficial parotid nodes*, just anterior to the tragus, on or deep to the parotid fascia. These also drain lateral vessels from the eyelids and skin of the zygomatic region. Their efferent vessels pass to the upper deep cervical nodes. A strip of scalp above the auricle, the upper half of the auricle's cranial aspect and margin and the posterior wall of the external acoustic meatus all drain to the upper deep cervical and retro-auricular nodes.

The *retro-auricular nodes* (6.202), superficial to the mastoid attachment of sternocleidomastoid and deep to auricularis posterior, drain to the upper deep cervical nodes. The auricular lobule, floor of the meatus and skin over the mandibular angle and lower parotid region are drained to the superficial cervical or upper deep cervical nodes. *Superficial cervical nodes* spread along the external jugular vein superficial to sternocleidomastoid, some efferents passing round the anterior border of sternocleidomastoid to the upper deep cervical nodes; others follow the external jugular vein to the lower deep cervical nodes in the subclavian triangle.

The occipital scalp is drained partly to the occipital nodes, partly by a vessel along the posterior border of sternocleidomastoid to the lower deep cervical nodes. *Occipital nodes* are occasionally in the superior angle of the posterior triangle but commonly superficial to the upper attachment of trapezius.

Lymphatic drainage of the face. Lymph vessels draining the eyelids and conjunctiva commence in a subcutaneous plexus and a deep plexus around the tarsal plates; these communicate and medial and lateral vessels drain from them. Lateral vessels drain the whole thickness of both lids, except their medial parts and *all* the conjunctiva. They pass from the lateral commissure to the superficial parotid nodes and *deep nodes* embedded in the parotid gland, also receiving lymph from the middle ear (vide infra). The medial palpebral vessels drain the whole thickness of the medial parts of the lids and caruncula lacrimalis. Following the facial vein, they end in submandibular nodes.

Submandibular nodes (6.202, 203), internal to the deep cervical fascia in the submandibular triangle, are usually three: one at the anterior pole of the submandibular gland, two flanking the facial artery as it reaches the mandible. Other nodes are often embedded in the gland or deep to it. Submandibular nodes drain a wide area, including vessels from the submental, buccal and lingual groups of nodes; their efferents pass to the upper and lower deep cervical nodes. The external nose, cheeks, upper lip and lateral parts of the lower lip drain directly to the submandibular nodes; the afferent vessels may have a few *buccal nodes* along their course and near the facial vein. The mucous membrane of lips and cheeks also drains to the submandibular nodes. The lateral part of the cheek drains to the parotid nodes, the skin over the nasal radix and central forehead drains partly to the parotid nodes, partly to the submandibular.

The central part of the lower lip, buccal floor and lingual apex drain to the *submental nodes*, which are on the mylohyoid between the anterior bellies of the digastric muscles (6.203). They receive afferents from *both* sides, some decussating across the chin; their efferents pass to the submandibular and jugulo-omohyoid nodes.

Lymphatic drainage of the neck. Many vessels draining the superficial cervical tissues skirt the borders of sternocleidomastoid to the superior or inferior deep cervical nodes; but some pass over sternocleidomastoid and the posterior triangle to the superficial cervical and occipital nodes. Lymph from the superior region of the anterior triangle drains to the submandibular and submental nodes; vessels from the anterior cervical skin inferior to the hyoid bone pass to the *anterior cervical lymph nodes* near the anterior jugular veins; their efferents go to the deep cervical nodes of both sides, including the *infrahyoid, prelaryngeal* and *pretracheal* groups (vide infra). An anterior cervical node often occupies the suprasternal space (p. 582).

Lymphatic Drainage of the Deep Tissues of the Head and Neck

Tissues of the head and neck internal to the deep fascia drain to the deep cervical nodes directly or through outlying groups which include, in addition to those named above: the retropharyngeal, paratracheal, lingual, infrahyoid, prelaryngeal and pretracheal groups.

Retropharyngeal nodes comprise a median and two lateral groups, the latter anterior to the lateral atlantal masses along the lateral borders of the longi capitis. All lie between the pharyngeal and prevertebral fasciae, receiving afferents from the nasopharynx, pharyngotympanic tube and atlanto-occipital and atlanto-axial joints. They drain to the upper deep cervical nodes.

Paratracheal nodes flank both trachea and oesophagus along the recurrent laryngeal nerves. Efferents pass to the corresponding deep cervical nodes.

Infrahyoid, prelaryngeal and pretracheal nodes, beneath the deep cervical fascia, drain afferents from the anterior cervical nodes, their efferents joining the deep cervical nodes. The infrahyoid nodes are anterior to the thyrohyoid membrane, prelaryngeal on the conus elasticus and cricovocal membrane, pretracheal anterior to the trachea near the inferior thyroid veins.

Lingual nodes are small and inconstant, situated on the external surface of hyoglossus and also between the genioglossi. They drain to the upper deep cervical nodes.

Lymphatic drainage of the nasal cavity, nasopharynx and middle ear. Lymphatics of the nasal cavity can be injected from the subarachnoid space, via communications along the olfactory nerves. Lymph vessels from its anterior region pass superficially to join those of the external nasal skin, ending in the submandibular nodes. The rest of the cavity, paranasal sinuses, nasopharynx, and pharyngeal end of the pharyngotympanic tube drain to the upper deep cervical nodes, directly or through the

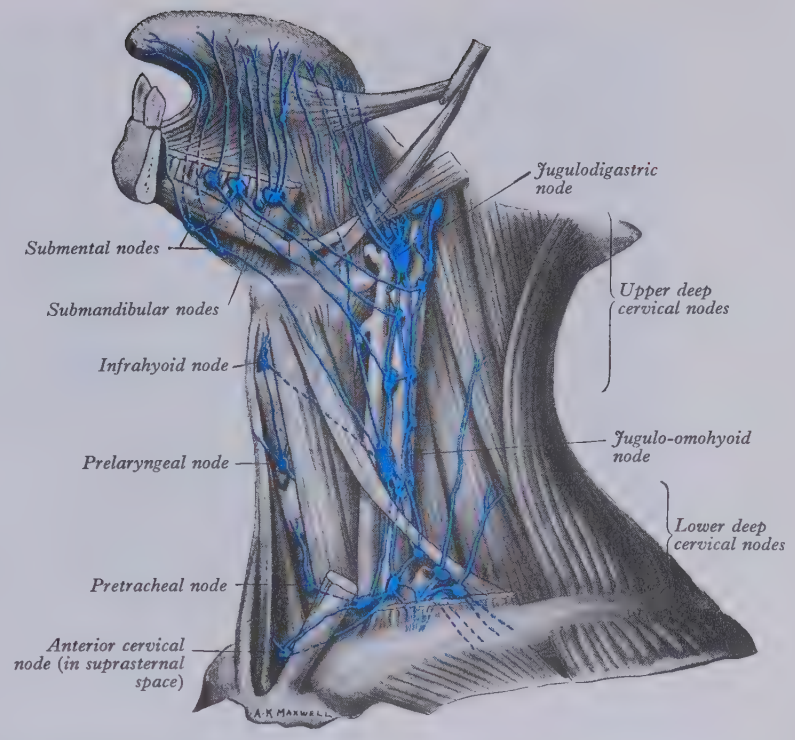
retropharyngeal nodes. The posterior nasal floor probably drains to the parotid nodes.

Lymphatic vessels of the tympanic and antral mucosae drain to the parotid or upper deep cervical lymph nodes; vessels of the tympanic end of the pharyngotympanic tube probably end in the deep cervical nodes; its vessels have been identified in the submucosa by injection and electron microscopy (Pulec et al 1975).

Lymphatic drainage of the larynx, trachea and thyroid gland. Laryngeal lymphatic vessels form superior and inferior groups; on the lateral wall they are distinct, their division being at the level of the vocal fold; the two sets anastomose on the posterior wall. Superior vessels pierce the thyrohyoid membrane to accompany the superior laryngeal vessels, ending in the superior deep cervical nodes; inferior vessels pass between the cricoid cartilage and the first tracheal ring to the inferior deep cervical lymph nodes, or pierce the cricovocal membrane to reach the pretracheal and prelaryngeal nodes.

A dense network of lymph vessels exists in the tracheal wall; its cervical part drains to the pretracheal and paratracheal nodes, or directly to the inferior deep cervical nodes.

Thyroid lymphatic vessels communicate with the tracheal plexus, passing to the prelaryngeal nodes just above the thyroid isthmus and to the pretracheal and paratracheal nodes; some may drain into the brachiocephalic nodes, related to the thymus in the superior mediastinum. Laterally, the gland is drained by vessels along the superior thyroid veins to the deep cervical nodes. Some thyroid lymphatics may drain *directly*, with no intervening node, to the thoracic duct (p. 842).



Lymphatic drainage of the mouth, teeth, tonsil and tongue. *Mouth.* Gingival vessels drain to the submandibular nodes; those of the hard palate continue anteriorly into the superior gingival channels but also run back to pierce the superior constrictor, ending in the superior deep cervical and retropharyngeal nodes; from the soft palate they pass posterolaterally partly to the retropharyngeal, partly to the superior deep cervical nodes. The anterior part of the floor of the mouth drains to the lower nodes of the upper deep cervical group, either directly or via the submental nodes; vessels from the remainder of the floor drain to the submandibular and superior deep cervical nodes. *Teeth.* Dental lymphatics pass to the submandibular and deep cervical nodes.

Tonsil. Vessels from the tonsil pierce the buccopharyngeal fascia and superior constrictor to pass between the stylohyoid muscle and the internal jugular vein to the superior deep cervical nodes. Most end in the jugulodigastric nodes; occasionally one or two vessels run to the small nodes on the lateral aspect of the internal jugular vein, deep or medial to sternocleidomastoid.

Tongue (**6**.203). A lymphatic plexus in the lingual mucosa is continuous with an intramuscular plexus. The anterior lingual region drains into the marginal and central vessels and behind the vallate papillae into the dorsal lymph vessels.

(1) *Marginal vessels* from the lingual apex and frenular region descend under the mucosa to widely distributed nodes: (*a*) Some pierce the mylohyoid in contact with the mandibular periosteum to enter the submental nodes and also pass anterior to the hyoid bone to the jugulo-omohyoid node. Vessels arising in the plexus on one side may cross under the frenulum to end in the contralateral nodes; efferent vessels of submental nodes, which are median, pass to both sides. (*b*) Some vessels pierce the mylohyoid to enter the anterior or middle submandibular node. (*c*) Some pass inferior to the sublingual gland and, accompanying the companion vein of the hypoglossal nerve, end in jugulodigastric nodes; one often descends further, superficial or deep to the intermediate tendon of the digastric, to reach the jugulo-omohyoid node. Some vessels from the lateral lingual margin cross the sublingual gland, pierce the mylohyoid and end in the submandibular nodes; others end in the jugulodigastric or jugulo-omohyoid nodes. Vessels from the posterior part of the lingual margin traverse the pharyngeal wall to the jugulodigastric lymph nodes.

(2) *Central vessels.* The regions of the lingual surface draining into the marginal or central vessels are not distinct. Central vessels descend between the genioglossi, some turning laterally through the muscles; but most pass between them and diverge to the right or left, following the lingual veins to the deep cervical nodes, especially the jugulodigastric and jugulo-omohyoid. Some pierce the mylohyoid to enter the submandibular nodes.

6.203 The lymphatic drainage of the tongue (after Jamieson & Dobson). Removal of the sternocleidomastoid has exposed the whole chain of deep cervical lymph nodes.

(3) *Dorsal vessels.* Vessels draining the region of the vallate papillae and behind them run postero-inferiorly, some near the median plane to both sides. They turn laterally to join the marginal vessels; all pierce the pharyngeal wall, passing around the external carotid arteries to reach the jugulodigastric and jugulo-omohyoid lymph nodes. One may descend posterior to the hyoid bone, perforating the thyrohyoid membrane to end in the jugulo-omohyoid node.

Lymphatic drainage of the pharynx and cervical part of the oesophagus. Collecting vessels from the pharynx and cervical oesophagus pass to the deep cervical nodes, either directly or through the retropharyngeal or paratracheal nodes. From the epiglottic region lymph vessels run to the infrahyoid nodes.

Lymphatic Drainage of the Upper Limbs

All lymphatic vessels from the upper limb (and superficial tissues of a wide area of ipsilateral trunk) drain to the axillary nodes, either directly or (a few) through a more peripheral group. Vessels internal to the deep fascia follow the principal vascular bundles; superficial vessels, except in the hand and dorsum of the forearm, converge towards the superficial veins, which they accompany.

Axillary nodes (**6**.205,207), which drain the whole upper limb and areas of the trunk indicated, are large, varying from 20–30, and may be divided into five not wholly distinct groups. Four of these groups are *intermediary*; only the apical group is *terminal*.

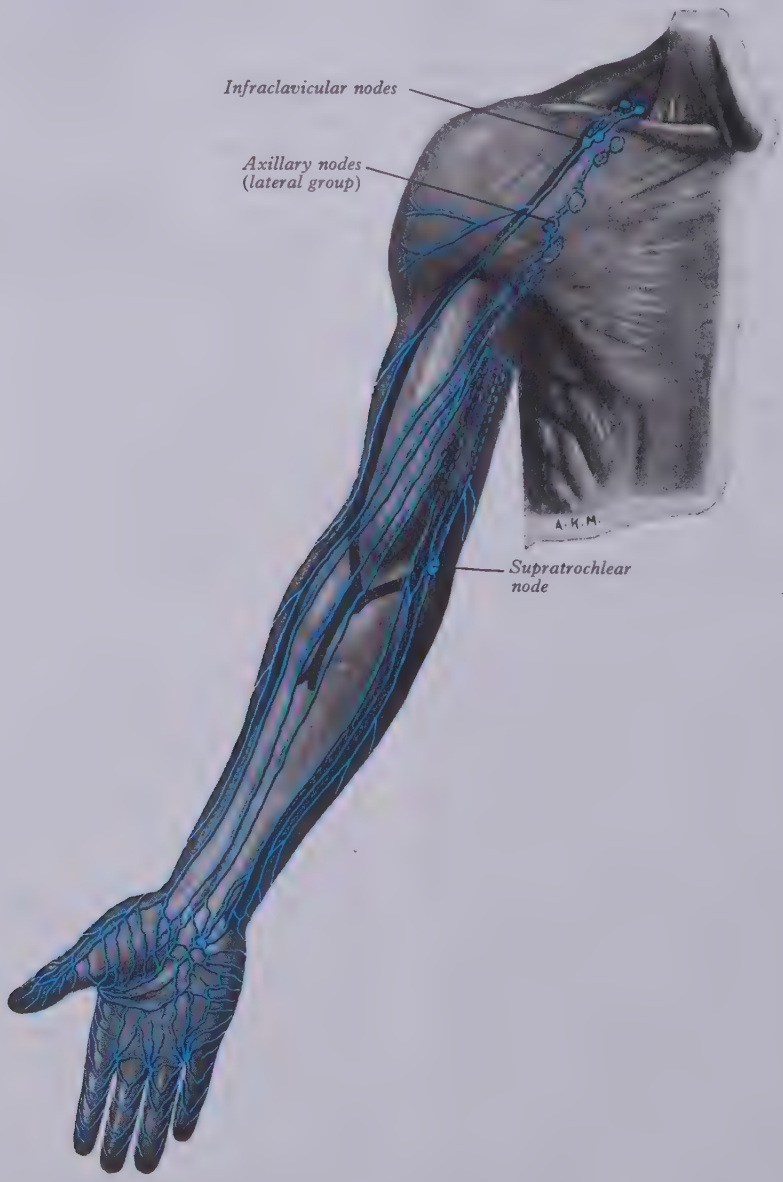
(1) *A lateral group* (**6**.204,207) of four to six nodes is posteromedial to the axillary vein, its afferents draining the whole limb except the vessels accompanying the cephalic vein. Efferent vessels pass partly to the central and apical axillary groups, partly to the inferior deep cervical nodes.

(2) An *anterior* or *pectoral group* of four or five nodes spreads along the inferior border of pectoralis minor near the lateral thoracic vessels. Its afferents drain the skin and muscles of the supra-umbilical anterolateral body wall and mammary gland (centrolateral part, p. 847); efferents pass partly to the central and partly to the apical axillary nodes.

(3) A *posterior* or *subscapular group* of six or seven nodes is deployed on the posterior axillary wall's inferior margin, along the subscapular vessels. Afferents drain the skin and *superficial* muscles of the inferior posterior region of the neck and the dorsal aspect of the trunk down to the iliac crest; efferents pass to the apical and central axillary nodes.

(4) A *central group* of three of four large nodes embedded in axillary fat receives afferents from all preceding groups: its efferents drain to the apical nodes.

(5) An *apical group* of six to twelve nodes is partly posterior to the superior part of pectoralis minor and partly above its superior border, extending to the axilla's apex medial to the *axillary vein*. The only *direct* territorial afferents are those with the cephalic vein and some draining the mammary gland (upper peripheral region); but the group drains all other axillary nodes. Its efferents unite as the *subclavian trunk*, draining directly to the jugulo-subclavian venous junction, the subclavian vein, or to the jugular lymphatic trunk or on occasion to a right lymphatic duct; the left trunk usually ends in the thoracic duct. A few efferents from apical nodes usually reach the inferior deep cervical nodes.



Extra-axillary outlying groups in the upper limb are few, comprising: (1) supratrochlear, (2) infraclavicular (both interposed in superficial routes), (3) isolated nodes occasionally appearing along principal blood vessels.

(1) *Supratrochlear nodes*, only one or two, are superficial to the deep fascia proximal to the medial epicondyle and medial to the basilic vein; their efferents accompany the vein to join the deep lymph vessels.

(2) *Infraclavicular nodes* appear beside the cephalic vein, one or two in the groove between the pectoralis major and deltoid, just inferior to the clavicle; efferents pass through the clavipectoral fascia to apical axillary nodes; more rarely some pass *anterior* to the clavicle to reach the inferior deep cervical (supraclavicular) nodes.

(3) Small isolated nodes sometimes occur along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, or in the arm medial to the brachial vessels.

Lymphatic drainage of the superficial tissues. Superficial lymphatic vessels in the upper limb begin in the cutaneous plexuses. *In the hand*, the palmar plexus is denser. Digital plexuses are drained along the digital borders to their webs, where they join the distal palmar vessels which pass back to the hand's dorsal aspect (**6**.204,206). The proximal palm drains towards the carpus, medially by vessels along its ulnar border and laterally to join those of the thumb. Several vessels from the central palmar plexus form a trunk winding round the indicial metacarpal bone to join the dorsal vessels from the index and pollex. *In the forearm and arm*, superficial vessels run with superficial veins. Collecting

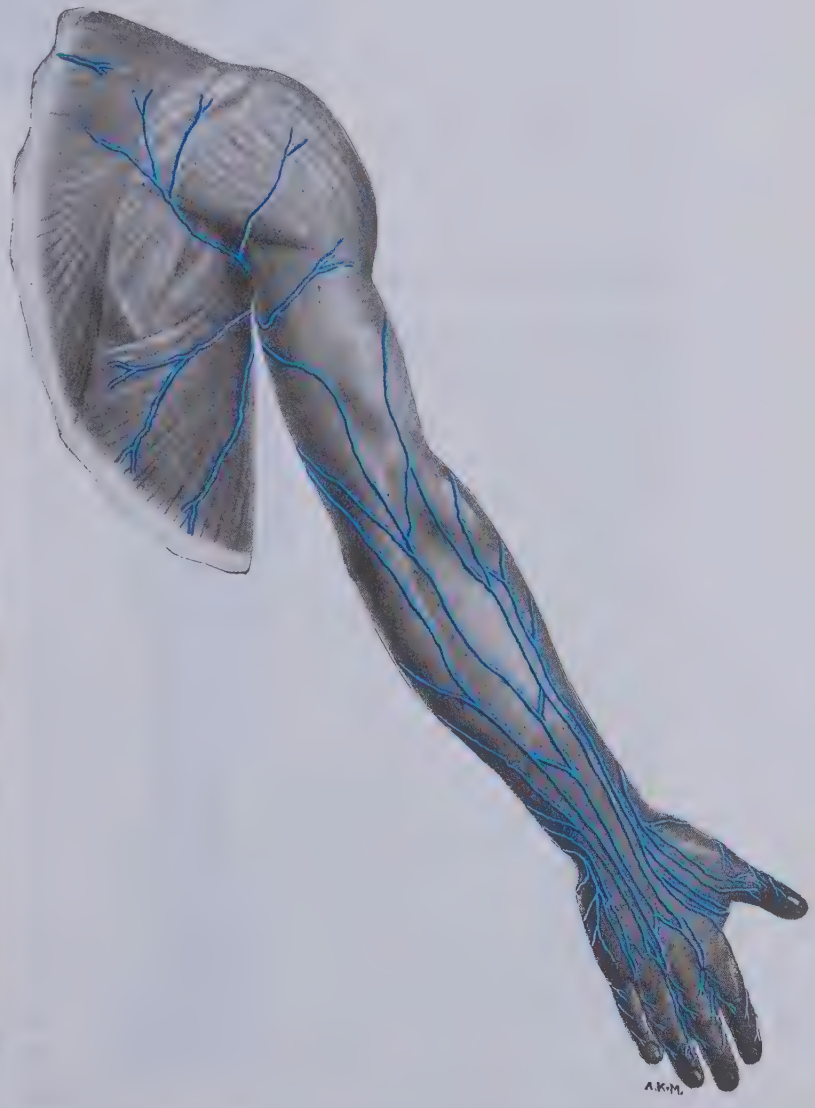
6.204 The lymphatic drainage of the superficial tissues of the upper limb: anterior aspect (semi-diagrammatic).

vessels from the hand pass into the forearm on all carpal aspects. Dorsal vessels, after running proximally in parallel, curve successively round the borders of the limb to join the ventral vessels (**6**.206). Anterior carpal vessels traverse the forearm parallel with the median vein of the forearm to the cubital region, proximal to which they follow the medial border of the biceps, then pierce the deep fascia at the anterior axillary fold and end in the lateral axillary lymph nodes.

Vessels which are lateral in the forearm follow the cephalic vein to the level of the tendon of the deltoid, where most incline medially to reach the lateral axillary nodes; a few, however, continue with the vein to the infraclavicular nodes. These lateral vessels receive those curving round the lateral border from the limb's dorsal aspect. Vessels which are medial in the forearm follow the basilic vein. Proximal to the elbow some end in supratrochlear lymph nodes, whose efferents, with the medial vessels which have bypassed them, pierce the deep fascia with the basilic vein to end in the lateral axillary nodes or deep lymphatic vessels. They are joined by vessels curving round the medial border of the limb.

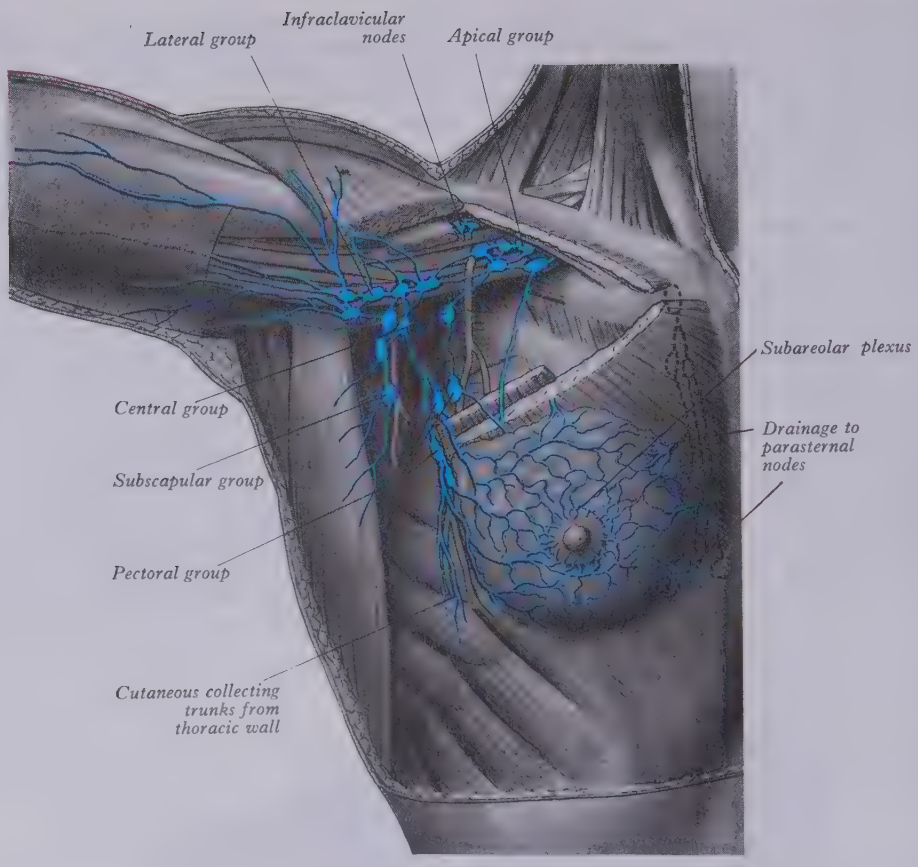
Collecting vessels from the deltoid region pass round the anterior and posterior axillary fold to end in the axillary nodes. The scapular skin drains either to subscapular axillary nodes or by channels following the transverse cervical vessels to the inferior deep cervical nodes.

Lymphatic drainage of the deep tissues of the upper limb. Deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) to the lateral axillary nodes. They are less numerous than the superficial vessels, communicating with them at intervals. A *few lymph nodes* occur along them. Scapular muscles drain mainly to the subscapular axillary nodes and pectoral muscles to the pectoral, central and apical nodes.



Mammary lymphatic drainage (**6**.207). Lymph vessels of the mammary gland start in a plexus in the interlobular connective tissue and walls of the lactiferous ducts, communicating with a cutaneous *subareolar plexus* around the nipple. The gland is also said to connect with a plexus of minute vessels on the subjacent deep fascia; this connection plays little part in normal lymphatic drainage nor in early spread of carcinoma (Turner-Warwick 1959). It offers an alternative route when the usual pathways are obstructed. Efferent vessels directly from the gland pass round the anterior axillary border through the axillary fascia to the pectoral lymph nodes; some may pass directly to the subscapular nodes. From the gland's superior region a few vessels pass to the apical axillary nodes, sometimes interrupted in the infraclavicular nodes or in small, inconstant interpectoral nodes. Axillary nodes receive more than 75% of lymph from the gland, the remainder largely draining to parasternal nodes from the medial and lateral parts of the organ; these vessels accompany perforating branches of the internal thoracic artery. Lymphatic vessels occasionally follow lateral cutaneous branches of the posterior intercostal arteries to the intercostal nodes.

Cutaneous lymphatic drainage is described on p. 856.



Applied Anatomy. Enlargement of the axillary nodes is frequent in malignant disease and infective processes affecting the upper back and shoulder, the front of the chest and mammary gland, upper anterolateral abdominal wall, or upper limb (*palpation*, see p. 840). In operations for mammary carcinoma, pectoralis major, its deep fascia and surrounding muscles were usually removed en bloc because of the wide ramifications of its lymphatics. Axillary nodes, the sternocostal head of pectoralis major and frequently pectoralis minor were also removed, to ensure complete removal of the affected lymphatics and nodes. (Some, particularly with more effective diagnostic techniques, now advocate less radical extirpation.)

6.205 Normal axillary lymphangiogram, four days after injection of ultrafluid lipiodol into a lymph vessel on the dorsum of the hand. 1. Lateral group of lymph nodes. 2. Pectoral group of lymph nodes. 3. Brachial lymph vessels. Supplied by J B Kinmonth.

6.206 The lymphatic drainage of the superficial tissues of the upper limb: posterior aspect (semi-diagrammatic).

6.207 Lymph vessels of the mammary gland and the axillary lymph nodes.

Lymphatic Drainage of the Lower Limbs

Most lymph from the lower limb traverses a large *intermediary* inguinal group of nodes; some may first traverse a few more peripheral intermediary nodes, however, these are less numerous in the lower limb than elsewhere. The inguinal nodes are superficial and deep to the deep fascia. (Although commonly stated as such, the inguinal nodes are *not* the terminal group for the lower limb; from them the lymph traverses the external and common iliac groups, followed by the lateral aortic group. Deep gluteal lymph reaches the same group through the internal and common iliac chains. The upper lateral aortic nodes *are terminal*, forming bilateral lumbar trunks which discharge lymph into the confluence of trunks, p. 843, and thence the thoracic duct.)

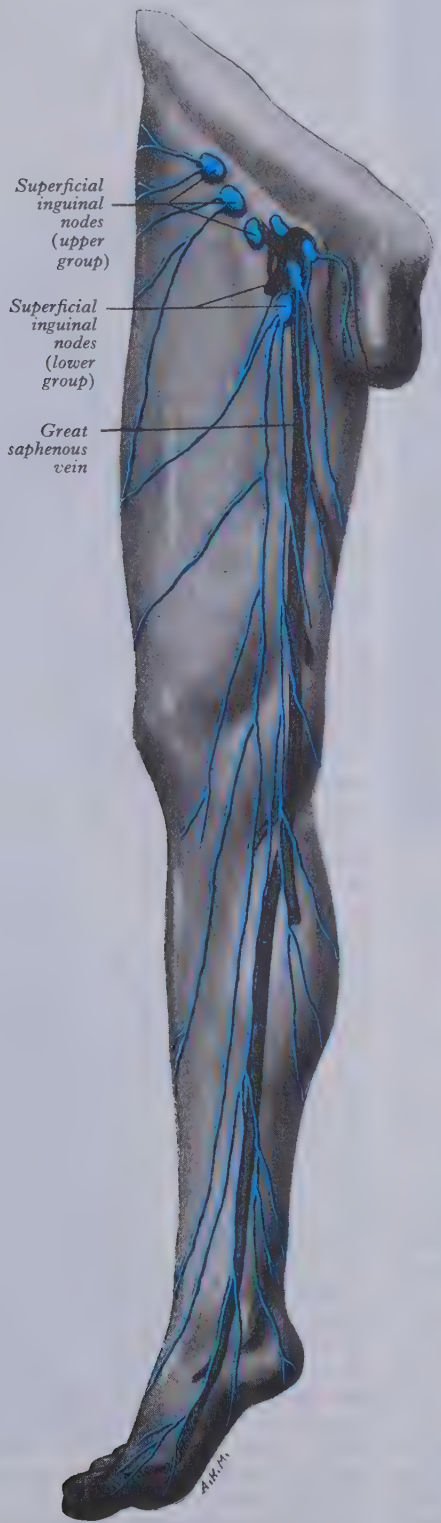
Superficial inguinal nodes (6.208,210,211,212) form proximal and distal groups. The *proximal* is usually of five or six nodes just distal to the inguinal ligament. Its lateral members receive afferent vessels from the gluteal region and adjoining infra-umbilical anterior abdominal wall. Medial members receive superficial vessels from: the external genitalia (including the inferior vagina), inferior anal canal and perianal region, adjoining anterior abdominal wall, umbilicus and the uterine vessels accompanying the round ligament. The *distal* group, usually four or five, along the termination of the great saphenous vein, receives all superficial vessels of the lower limb, except those from the calf's posterolateral region. All superficial inguinal nodes drain to the external iliac nodes, some via the femoral canal and others anterior or lateral to the femoral vessels. Numerous vessels interconnect individual nodes.

Deep inguinal nodes vary from one to three, situated medial to the femoral vein. One is just distal to the sapheno-femoral junction, one in the femoral canal; the most proximal one lies laterally in the femoral ring; the middle node is the most inconstant, the proximal node, however, is often absent. All receive deep lymphatics accompanying the femoral vessels, lymph vessels from the glans penis (or clitoridis) and a few efferents from the superficial inguinal nodes; their own efferents traverse the femoral canal to the external iliac nodes.

Peripheral nodes are few and are all deeply sited. Except for one sometimes proximal on the interosseous membrane near the anterior tibial vessels, they occur only in the popliteal fossa.

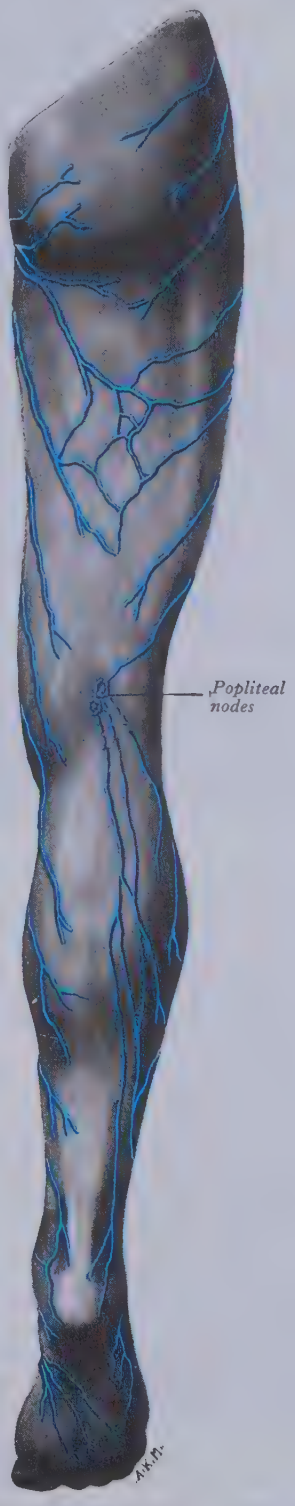
Popliteal lymph nodes (6.209), usually six of small size, are embedded in popliteal fat. One, near the end of the small saphenous vein, drains the superficial region served by the vein. Another is between the popliteal artery and posterior aspect of the knee joint, receiving direct vessels from the knee joint and those accompanying the genicular arteries. The remainder flank the popliteal vessels, receiving trunks accompanying the anterior and posterior tibial vessels. Popliteal efferents ascend close to the femoral vessels to reach the deep inguinal nodes but some may accompany the great saphenous vein to the superficial inguinal nodes.

Applied Anatomy. Inflammation of the popliteal nodes is often due to lateral lesions of the heel. Superficial inguinal nodes are frequently enlarged in disease or injury in their region of drainage (*palpation*, see p. 840). Thus in malignant or infective disease of the prepuce, penis, labia majora, scrotum, abscess in the perineum, anus and lower vagina or in diseases affecting skin and superficial structures in these regions, or the infra-umbilical part of the abdominal wall, the gluteal region — in all these the proximal inguinal nodes are almost invariably affected, the distal group being implicated only in disease or injury of the limb.



Lymphatic drainage of the superficial tissues in the lower limb. Superficial lymph vessels begin in subcutaneous plexuses. Collecting vessels leave the foot medially, along the great saphenous vein and, laterally, with the small saphenous.

Medial vessels are larger, more numerous and begin on the tibial side of the foot's dorsum, some ascending anterior and others posterior to the medial malleolus; thereafter both converge on the great saphenous vein and accompany it to the distal superficial



inguinal nodes. *Lateral vessels* begin on the fibular side, some crossing anteriorly in the leg to join the medial vessels and so to the distal superficial inguinal lymph nodes; others accompany the small saphenous vein to the popliteal nodes. Superficial lymph vessels of the gluteal region circle anteriorly to the proximal superficial inguinal nodes.

Lymphatic drainage of the deeper tissues in the lower limb. Deep vessels accompany the main blood vessels: anterior and posterior tibial, peroneal, popliteal and femoral. Deep vessels from the foot and leg are interrupted by popliteal nodes; those from the thigh pass to the deep inguinal nodes.

Deep lymph vessels of the gluteal and ischial regions follow their corresponding blood vessels. Those with the former end in a node near the intrapelvic part of the superior gluteal artery, near the superior border of the greater sciatic foramen; those which follow the inferior gluteal vessels traverse one or two of the small nodes below the piriformis and pass to the internal iliac nodes.

6.208 The lymphatic drainage of the superficial tissues of the lower limb: anteromedial aspect (semi-diagrammatic).

6.209 The lymphatic drainage of the superficial tissues of the lower limb: posterior aspect (semi-diagrammatic).

6.210 Lymphangiogram showing the inguinal lymph vessels and nodes taken immediately following injection of ultrafluid lipiodol into a lymph vessel on the dorsum of the foot. 1. Inguinal lymph nodes. 2. External iliac lymph node. Supplied by J B Kinmonth.

Lymphatic Drainage of the Abdomen and Pelvis

Lymph from most of the abdominal wall and all abdominal viscera (except a small hepatic region) is returned via the thoracic duct. Lymphatic vessels run with their corresponding arteries, the lymphatic nodes forming a large number of intermediary groups along the arteries concerned and a few terminal groups near the abdominal aorta. Although referred to as illustrative examples in the introductory paragraphs, they are summarized here with numerous additions.

Lumbar nodes (6.211,212) include three terminal groups, each of which although interconnected has its own large area of drainage, a number of intermediary groups and one 'subsidiary' group. These groups are *pre-aortic, lateral aortic* (right and left) and *retro-aortic*. The pre-aortic group drains viscera supplied by the *ventral splanchnic aortic branches*, i.e. the abdominal part of the alimentary canal (down to mid-rectum) and its derivatives. Lateral aortic groups drain viscera and other structures supplied by the *lateral splanchnic* and *dorsolateral somatic* aortic branches, receiving efferents from the large intermediary groups associated with the iliac vesels; their *upper members* are therefore terminal groups for suprarenal glands, kidneys, ureters, testes, ovaries, pelvic viscera (apart from the gut) and the deeper tissues of the posterior abdominal wall, the full thickness of the subumbilical abdominal, pelvic and perineal walls and the whole of the lower limbs. The retro-aortic group has no special area of drainage; though it may have been primarily associated with drainage of the posterior abdominal wall, it may be regarded as comprising peripheral nodes of the lateral aortic groups and interconnecting surrounding groups.

PRE-AORTIC NODES AND THEIR REGION OF DRAINAGE

Pre-aortic lymph nodes are anterior to the abdominal aorta, receiving lymph from the regional nodes associated with the subdiaphragmatic part of the alimentary canal, pancreas, liver and spleen. Their cranial efferents form *intestinal trunks* entering the abdominal confluence of lymph trunks (p. 839). They are divisible into coeliac, superior mesenteric and inferior mesenteric groups, being near the origins of these arteries.

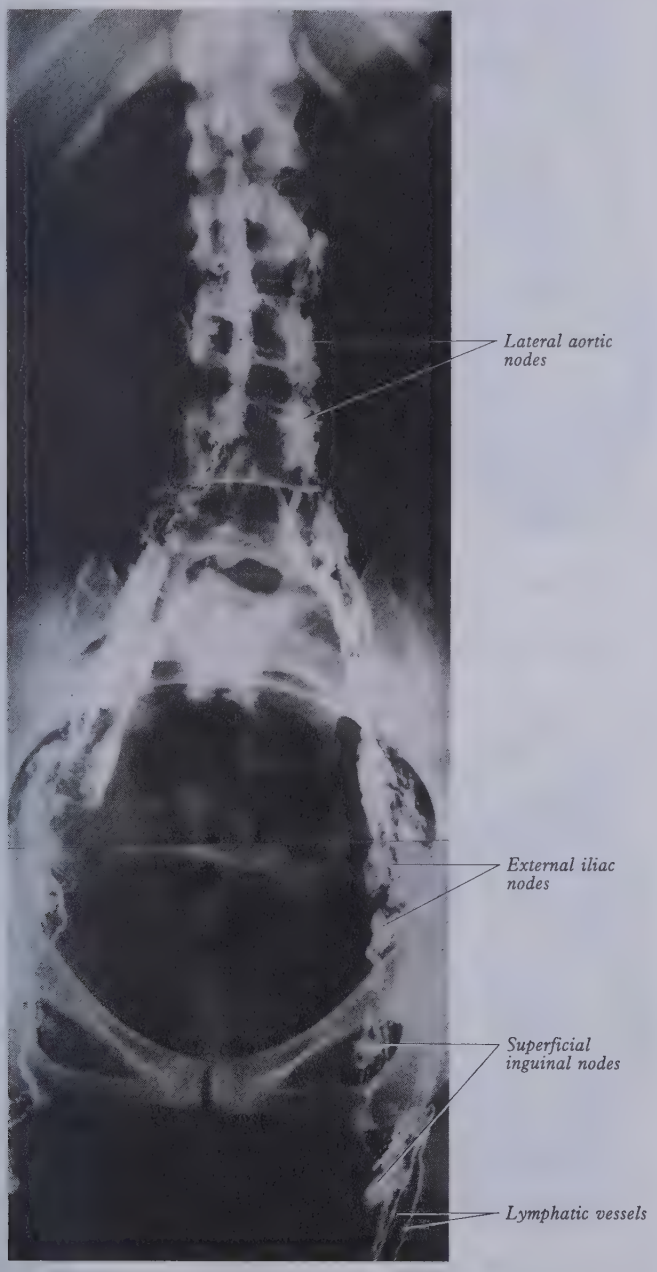
In the alimentary canal, lymph vessels begin as minute subepithelial radicles, blind at one end and opening into a *periglandular plexus*. In the small intestine each villus has a *central* vessel, known as a *lacteal* from its milk white appearance. From the periglandular plexuses vessels pierce the muscularis mucosae to join a *submucous plexus*, efferents from which traverse the muscularis, where they connect with or bypass the vessels draining it. The submucous plexus is also joined by vessels from the lymph spaces at the bases of solitary lymphatic follicles. Lymphatics of intestinal muscle drain into a plexus mainly between the longitudinal and circular strata. Collecting vessels leave the gut through the muscle to enter the larger vessels following their mesenteric arteries. Collecting vessels from the alimentary canal pass through local nodes before reaching the pre-aortic group.

COELIAC NODES

Coeliac nodes are anterior to the abdominal aorta around the origin of the coeliac artery. They are a terminal group, their efferents forming right and left intestinal lymph trunks. Their afferents are from the regional nodes along branches of the coeliac artery, forming three main groups: gastric, hepatic and pancreaticosplenic; and they also come from the lower pre-aortic groups.

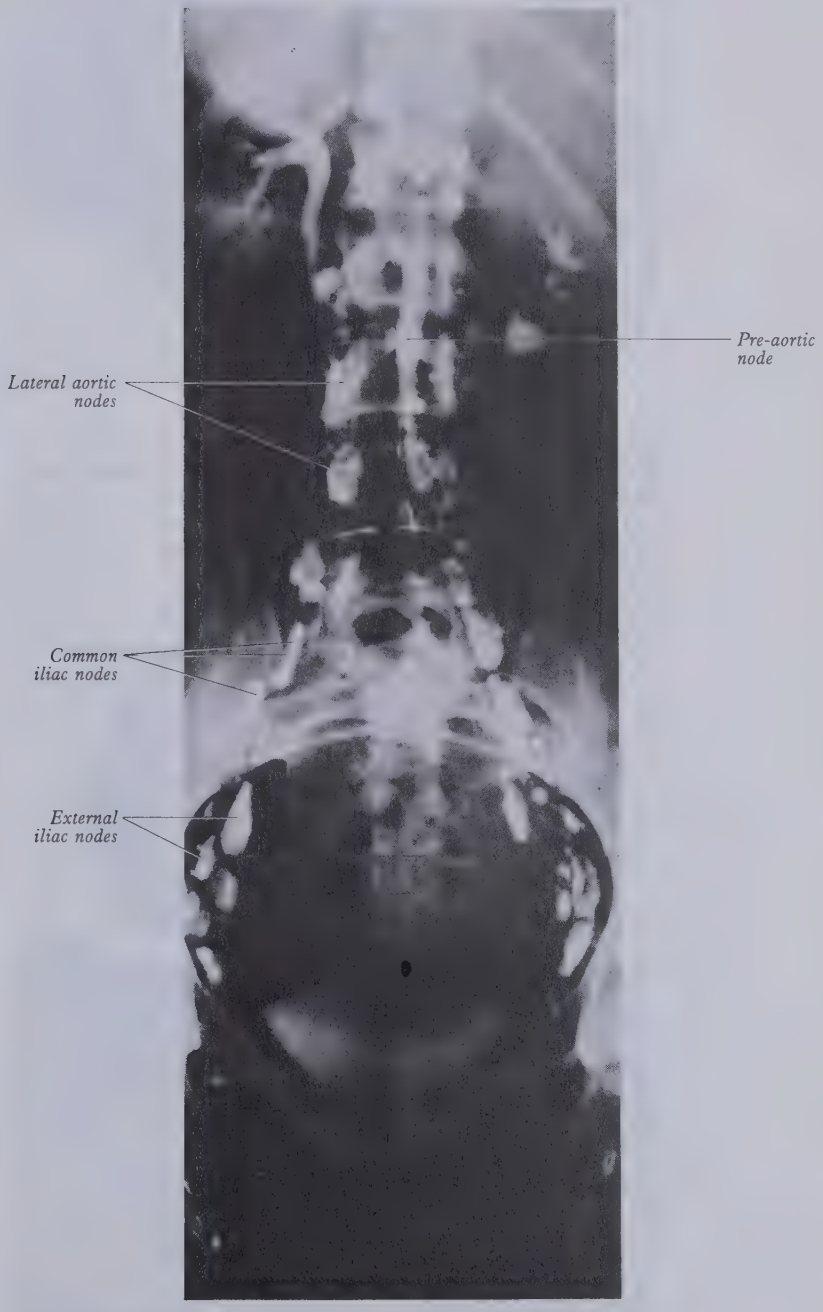
Gastric nodes (6.213,214) comprise the left gastric, right gastro-epiploic and pyloric groups. *Left gastric nodes*, along the left gastric artery, are divisible into subgroups: *superior* on the artery's stem and *inferior* with descending branches along the cardiac half of the lesser curvature in the lesser omentum and *paracardial*, a chain around the cardiac orifice. They receive lymph both from the stomach and the abdominal part of the oesophagus; their efferents pass to the coeliac group of pre-aortic nodes. *Right gastro-epiploic lymph nodes*, four to seven, lying in the greater omentum along the pyloric half of the greater curvature, receive afferents from the stomach; their efferents mostly pass to the pyloric nodes. Four or five *pyloric lymph nodes* are near the gastroduodenal artery's bifurcation, in the angle between the superior and the descending parts of the duodenum; an outlying node is sometimes sited above the duodenum near the right gastric artery. These nodes drain the pyloric part of the stomach, the first part of the duodenum and finally the right gastro-epiploic nodes; their efferents end in coeliac nodes.

Hepatic nodes (6.213) extend in the lesser omentum along the hepatic arteries and bile duct. They vary in number and site but almost constant are: one at the junction of the cystic and common hepatic ducts, the *cystic node*; and another alongside the upper bile duct, the *node of the anterior border of the epiploic foramen*. Hepatic nodes drain the stomach, duodenum, liver, gallbladder, bile ducts and pancreas; they drain to the coeliac nodes and thence to the intestinal trunks. Enlarged hepatic nodes may press on and obstruct the portal vein.



Pancreaticosplenic nodes (6.214) accompany the splenic artery, near the posterior surface and superior border of the pancreas; one or two are in the gastrosplenic ligament. Their afferents

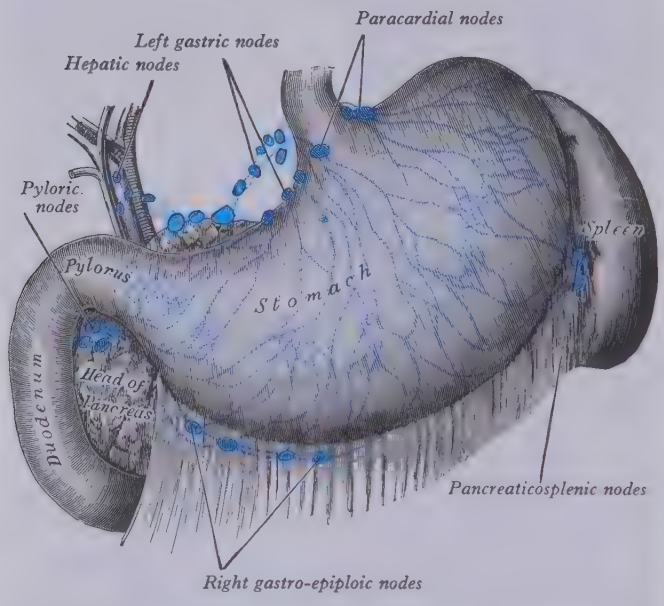
are from the stomach, spleen and pancreas; their afferents join the coeliac nodes.



Lymphatic drainage of the stomach and duodenum. Gastric lymphatics (6.213,214) are continuous at the cardiac orifice with the oesophageal vessels and at the pylorus with the duodenal channels. They largely follow blood vessels and form four groups: vessels of the first group accompany branches of the left gastric artery, receive from a large area on both gastric surfaces and end in the left gastric lymph nodes; a second group drains the gastric fundus and body left of a vertical from the oesophagus, accompanying the short gastric and left gastro-epiploic vessels to end in the pancreaticosplenic nodes; the third group drains the right half of the greater curvature as far as the pylorus, ending in the right gastro-epiploic nodes which drain to pyloric nodes; the fourth group drains the pyloric part of the stomach and drains to the hepatic, pyloric and left gastric nodes. Although these vessels communicate, their valves direct lymph from the right part of the stomach to the lesser curvature and from the left part to the greater curvature.

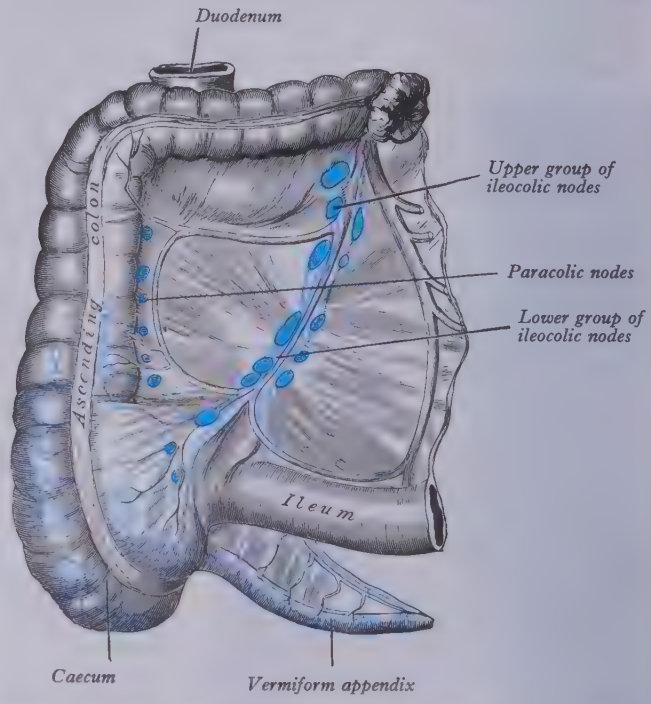
Duodenal lymphatics run anteriorly and posteriorly into the small *pyloric lymph nodes*, lying in the anterior and posterior grooves between the pancreatic head and the duodenum. They drain up to the hepatic and down to the pre-aortic nodes around the origin of the superior mesenteric artery.

Lymphatic drainage of the liver. Hepatic collecting vessels are divisible into superficial and deep systems. *Superficial hepatic vessels* run in subserous areolar tissue over the whole surface of the organ, draining in four directions: (1) From the middle part of its posterior surface, the caudate lobe, the posterior part of the convex surfaces of both lobes near the hepatic attachment of the falciform ligament, the posterior part of the inferior surface of the right lobe, vessels accompany the inferior vena cava to nodes

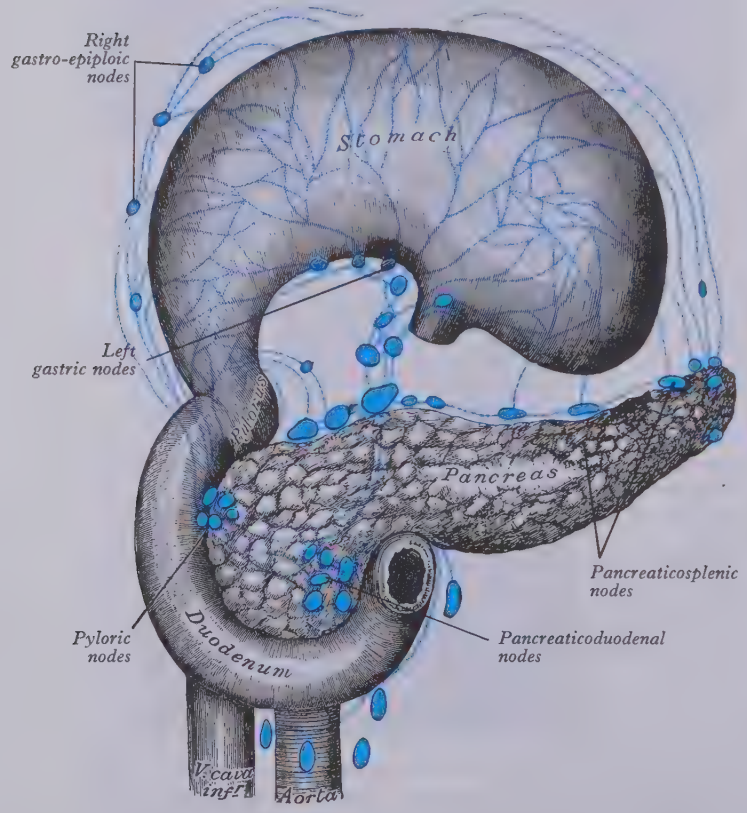


6.211 Lymphangiogram showing the lymphatic vessels and nodes of the iliac and lateral aortic regions taken approximately 3 hours after the injection of lipiodol into a lymphatic vessel on the dorsum of each foot. Supplied by G I Verney, Addenbrooke's Hospital, Cambridge; photographs prepared by Sarah Smith and K Fitzpatrick, Guy's Hospital.

6.212 Lymphangiogram showing the lateral aortic and proximal iliac lymph nodes, approximately 24 hours after the injection of lipiodol into a lymphatic vessel on the dorsum of each foot. Intravenous contrast was given to show the kidneys and ureters. Supplied and photographed as in 6.211.

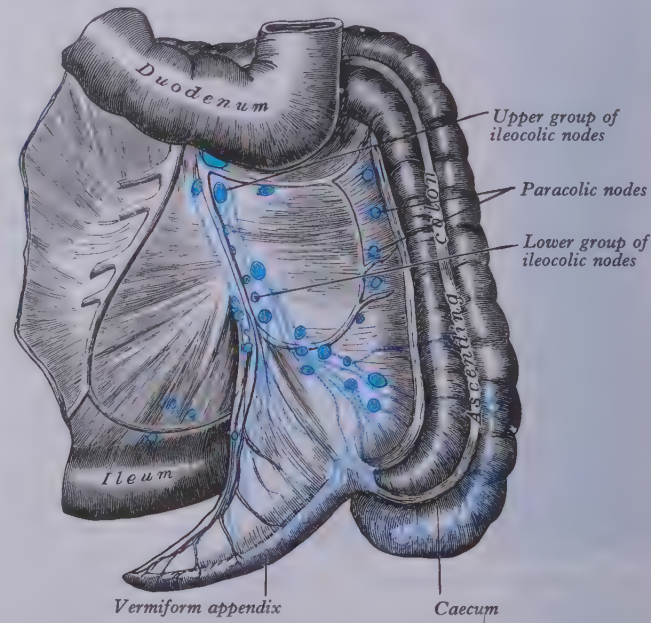


around its terminal part. Vessels in the coronary and right triangular ligaments may directly enter the thoracic duct without any intervening node. (2) Vessels from the rest of the inferior surface and anterior part of the convex surfaces of both lobes near the attachment of the falciform ligament all converge to the porta hepatis to end in the hepatic nodes. (3) From the posterior region of the left lobe a few vessels pass towards the oesophageal opening to end in the paracardial nodes. (4) From the remaining convex surface of the right lobe one or two trunks accompany the inferior phrenic artery across the right crus to the coeliac nodes.

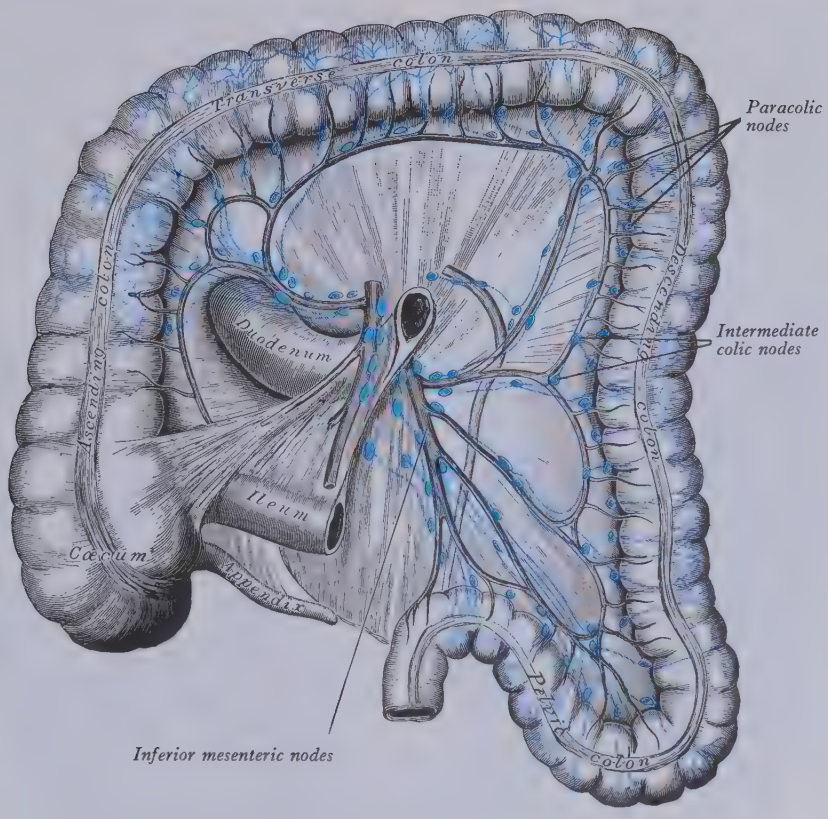


6.213 The lymphatic drainage of the stomach and duodenum (after Jamieson & Dobson).

Deep hepatic lymphatics form the ascending and descending trunks; the ascending trunks accompany the hepatic veins and pass through the vena caval opening to end in the nodes round the end of the inferior vena cava; the descending trunks emerge from the porta hepatis to end in the hepatic nodes (p. 1390).



Lymphatic drainage of the gallbladder and bile ducts. Numerous vessels run from the submucous and subserous plexuses on all aspects of the gallbladder and cystic duct, those on the former's hepatic aspect connecting sparsely with the hepatic vessels. They pass to the hepatic nodes, especially the cystic node and node of the anterior epiploic border (p. 850). Hepatic nodes also collect from vessels accompanying the hepatic ducts and the upper part of the bile duct, those of its lower part draining into the inferior hepatic and upper pancreaticosplenic nodes.



6.215 The lymph vessels and nodes of the caecum and vermiform appendix: anterior aspect (after Jamieson & Dobson).

6.214 The lymph vessels and nodes of the stomach, duodenum and pancreas. The stomach has been turned upwards (after Jamieson & Dobson).

6.216 The lymph vessels and nodes of the caecum and vermiform appendix: posterior aspect (after Jamieson & Dobson).

6.217A The lymph vessels and nodes of the colon (after Jamieson & Dobson).

Lymphatic drainage of the pancreas. Lymph capillaries commence around the acini and their continuations, following the blood vessels; there are no lymphatics in the pancreatic islets. Most vessels end in the pancreaticosplenic nodes, some in nodes along the pancreaticoduodenal vessels and others in the superior mesenteric pre-aortic nodes.

Lymphatic drainage of the spleen. Collecting vessels from the capsule end in the pancreaticosplenic lymph nodes.

SUPERIOR AND INFERIOR MESENTERIC NODES

Superior and inferior mesenteric nodes are anterior to the abdominal aorta near the origins of these arteries. They are preterminal groups for the alimentary canal from the duodenojejunal flexure to the upper anal canal and collect from outlying groups, including the mesenteric, ileocolic, colonic and pararectal nodes. They discharge into the coeliac nodes and thence intestinal trunks, confluence and thoracic duct.

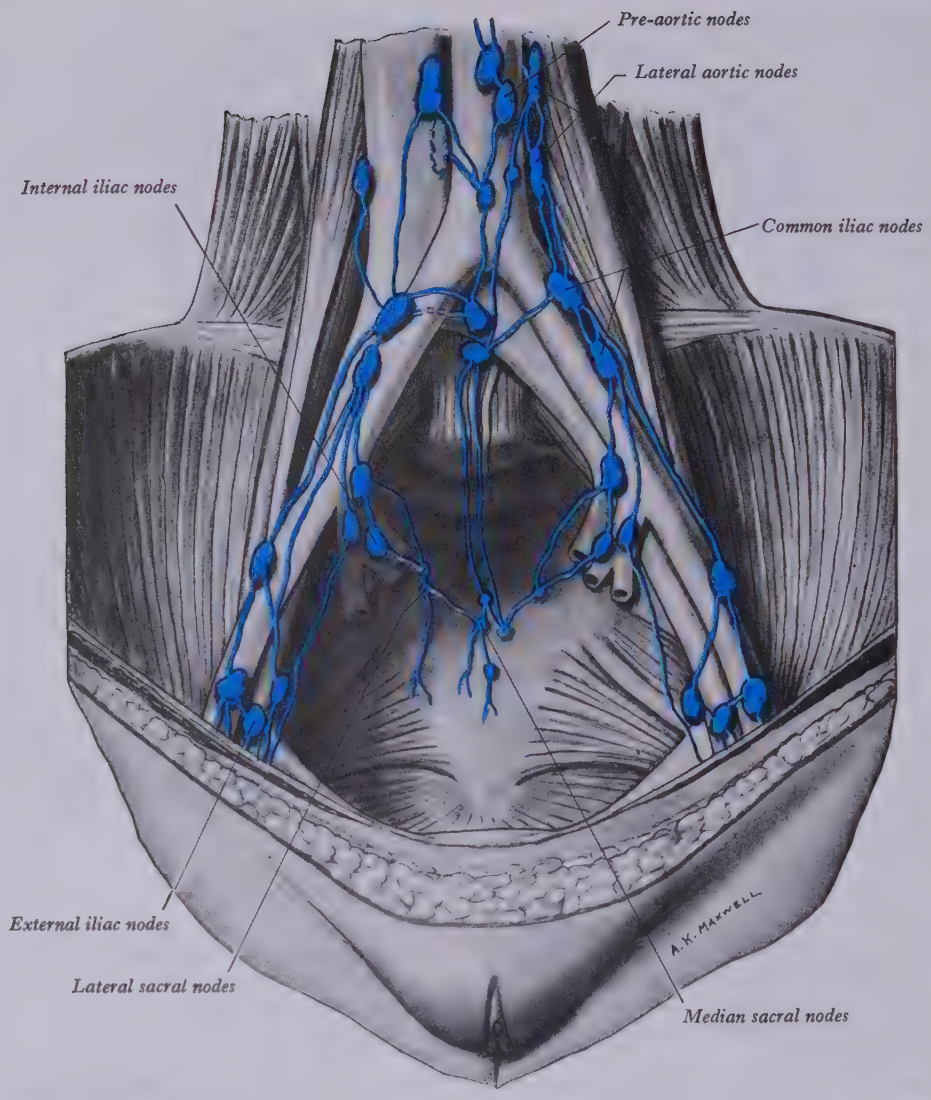
Mesenteric nodes, numbering 100–150, comprise three series: one close to the intestinal wall among the terminal rami of the jejunal and ileal arteries (*mural*); a second is among the loops and primary branches of the vessels (*intermediate*); and a third is along the upper trunk of the superior mesenteric artery (*juxta-arterial*). Vessels from the terminal centimetres of the ileum follow the ileal branch of the ileocolic artery to the ileocolic nodes.

Applied Anatomy. Enlargement of the mesenteric nodes occurs in many intestinal diseases, especially typhoid fever, tuberculous ulceration and malignant tumours. Enlarged nodes can often be palpated through the abdominal wall.

Ileocolic nodes (6.215,216) form a *chain* of 10–20 around the ileocolic artery but tend to form two groups: near the duodenum and along the artery's terminal part. The chain divides with the artery, into: (1) *ileal nodes* close to the ileal branch; (2) *anterior ileocolic nodes* (usually 3) in the ileocaecal fold, near the caecal wall; (3) *posterior ileocolic nodes*, mostly in the angle between ileum and colon but partly behind the caecum at its junction with the ascending colon; (4) an appendicular node in the meso-appendix.

Colic nodes form four groups; epicolic, paracolic, intermediate colic and preterminal colic.

Epicolic nodes are merely minute nodules on the colonic wall, sometimes in the appendices epiploicae. *Paracolic nodes* lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. *Intermediate colic nodes* lie along the right, middle and left colic arteries. *Preterminal colic nodes* adjoin the main trunks of the superior and inferior mesenteric arteries, near their corresponding pre-aortic nodes.



Pararectal nodes are in contact with the rectal muscular wall, draining to an intermediate group around the superior rectal artery and thence to nodes near the origin of the inferior mesenteric. Others drain to nodes at the bifurcation of the common iliac artery.

Lymphatic drainage of the jejunum and ileum. Lacteals pass between layers of the mesentery but, before reaching the superior mesenteric nodes, lymph traverses the mesenteric nodes.

Lymphatic drainage of the vermiform appendix and caecum (6.215,216). Lymphatic vessels are numerous, since

6.217B Preparation of the human colon and mesocolon displaying arterial arcades, neurovascular bundles, lymphatics and paracolic and intermediate lymph nodes. Provided by S Kubic, University of Zürich.

6.218 The lymph vessels and nodes of the pelvis.

lymphoid tissue abounds in their walls. From the body and apex of the vermiform appendix 8–15 vessels ascend in the meso-appendix, a few interrupted by one or more nodes in it. They unite to three or four larger vessels, ending in the inferior and superior nodes of the ileocolic chain. Vessels from the root of the appendix and caecum are anterior and posterior. Anterior vessels pass in front of the caecum to the anterior ileocolic nodes and nodes of the ileocolic chain; posterior vessels ascend behind the caecum to the posterior and inferior ileocolic nodes.

Lymphatic drainage of the colon (6.215,216,217A,B). Lymphatic vessels of ascending and transverse parts of the colon end in the superior mesenteric nodes, after traversing nodes along the right and middle colic arteries and their branches. Those of the descending and sigmoid parts are interrupted by small nodes on branches of the left colic arteries, ending in the pre-aortic nodes around the origin of the inferior mesenteric artery.

Lymphatic drainage of the rectum and anal canal. From the *upper half*, or more, of the rectum vessels emerge from its wall to *ascend* with the superior rectal vessels through the pararectal nodes to nodes in the lower sigmoid mesocolon and along the inferior mesenteric artery. From the *lower half* of the rectum and the anal canal, *above its mucocutaneous junction*, lymph vessels ascend through the wall to accompany the middle rectal vessels to the internal iliac nodes. Some are said to traverse the levator ani into the ischiorectal fossa, to accompany the inferior rectal and internal pudendal vessels to the internal iliac nodes. Lymphatics of the anal canal *below the mucocutaneous junction* descend to the anal margin, curving laterally to reach the most medial superficial inguinal nodes.

LATERAL AORTIC NODES (6.211,212)

The lateral aortic nodes flank the abdominal aorta anterior to the medial margins of the psoas major muscles, diaphragmatic crura and sympathetic trunks. On the right some are lateral to the inferior vena cava and anterior to it near the end of the right renal vein. Afferents reach these nodes from structures supplied by the lateral splanchnic and dorsolateral somatic aortic branches and from outlying nodes near the iliac arteries and their branches. Efferents form a *lumbar trunk* on each side, both terminating in the confluence of lymph trunks (occasionally a cisterna chyli, p. 842); a few may pass to the pre-aortic and retro-aortic nodes. Some of the efferents of the right lumbar lymph trunk and its nodes may cross to their left counterparts; or both trunks may divide forming a loose plexus.

Lymphatic vessels from the kidney, suprarenal gland, abdominal ureter, posterior abdominal wall, testis and ovary, uterine tube and upper part of the uterus all pass *directly* to the lateral aortic nodes. Lymphatics from the pelvis, most pelvic viscera and the anterolateral abdominal wall pass first to regional nodes largely related to the internal iliac arteries and their branches. These include the following groups: common, external, internal and circumflex iliac, inferior epigastric and sacral. It must also be emphasized that the external iliac group receives the

efferents from the inguinal nodes and the internal iliac group receives deep gluteal lymph; thus the lateral aortic groups ultimately drain the whole of *both lower limbs*.

Common iliac nodes (4–6) are grouped around the artery, one or two inferior to the aortic bifurcation and anterior to the fifth lumbar vertebra or sacral promontory (**6**.218). They drain the external and internal iliac nodes and send efferents to the lateral aortic nodes. They are usually in medial, lateral and intermediate (anterior) chains, the lateral being the main route.

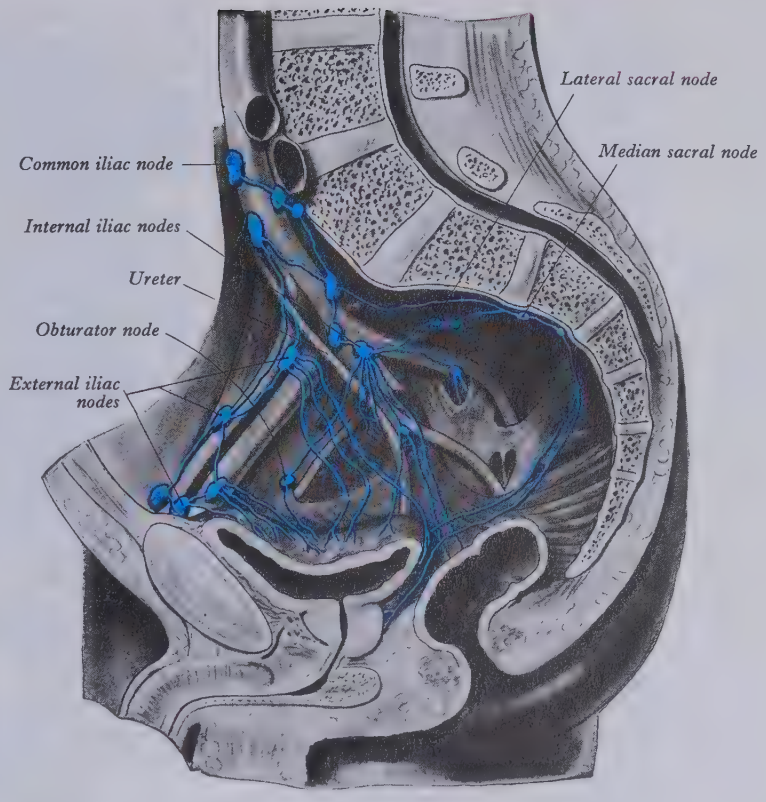
External iliac nodes (**6**.211,212,218) (8–10) are ranged along, usually in three subgroups: lateral, medial and anterior to the external iliac vessels; the anterior is inconstant. The medial nodes are considered the main channel of drainage, collecting from: the *inguinal nodes* (p. 848), the deeper layers of the infra-umbilical abdominal wall, the adductor region of the thigh, the glans penis or clitoridis, the membranous urethra, prostate, vesical fundus, cervix uteri and upper vagina. Their efferents pass to the common iliac nodes. **Inferior epigastric and circumflex iliac nodes** are associated with their vessels and drain the corresponding areas, being outlying members of the external iliac group and inconstant in number.

Internal iliac nodes (**6**.218,219,220) surround the vessels, receiving afferents from all the pelvic viscera, deeper parts of the perineum and gluteal and posterior femoral muscles. Efferents pass to the common iliac nodes. **Sacral nodes** along the median and lateral sacral vessels and an *obturator node*, sometimes occurring in the obturator canal, are outlying members of the internal iliac group.

There is considerable bypassing in the iliac groups of lymph nodes. Lymphangiographic studies have demonstrated the connections between the right and left groups.

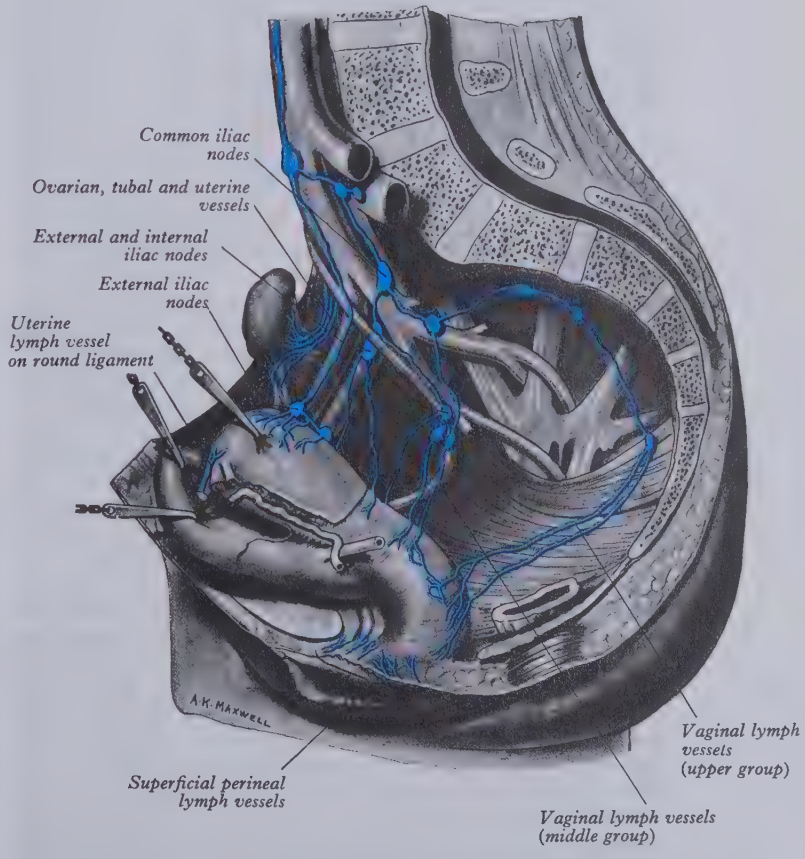
Lymphatic drainage of the urinary tract.

(1) *Renal.* Renal lymphatic vessels begin in three plexuses: one around the renal tubules, a second under the renal capsule and a third in the perirenal fat connecting freely with the second plexus. Collecting vessels from the intrarenal plexus form four or five trunks following the renal vein to end in the lateral aortic nodes; as they leave the hilum they are joined by the subcapsular collecting vessels. The perirenal plexus drains directly into the same nodes.



(2) *Ureteric.* Vessels begin in submucous, intra-muscular and adventitial plexuses which intercommunicate. Collecting vessels from the upper ureter may join the renal collecting vessels or pass directly to the lateral aortic nodes near the origin of the gonadal artery; those from its lower abdominal part go to the common iliac nodes; those from its pelvic part end in the common, external or internal iliac nodes.

(3) *Vesical.* Lymphatics (**6**.219) begin in the mucous, intramuscular and extramuscular plexuses. Collecting vessels, nearly all ending in the external iliac nodes, are in three sets: vessels from the trigone emerge on the vesical exterior to run superolaterally; those from the superior surface converge to the posterolateral angle and pass superolaterally across the lateral umbilical ligament to the external iliac nodes (one may go to the internal or common iliac group); those from the inferolateral surface ascend to join those from the superior surface. Minute nodules of lymphoid tissue may occur along the vesical lymph vessels.



(4) *Urethral.* (a) Vessels from the prostatic and membranous urethra in males and the whole female urethra pass mainly to the internal iliac nodes; a few may end in the external iliac nodes. Vessels from the membranous urethra accompany the internal pudendal artery. (b) Vessels of the male spongiose urethra accompany those of the glans penis, ending in the deep inguinal nodes. Some may end in superficial nodes, others may traverse the inguinal canal to the external iliac nodes.

Lymphatic drainage of the male reproductive organs.

(1) The *testis*. Testicular vessels commence in a superficial plexus, under the tunica vaginalis, and a deep plexus in the substance of the testis and the epididymis. Four to eight collecting trunks ascend in the spermatic cord and accompany the testicular vessels on the psoas major, ending in the lateral aortic and pre-aortic nodes.

6.219 The lymphatic drainage of the urinary bladder (semi-diagrammatic).

6.220 The lymphatic drainage of the female reproductive organs (semi-diagrammatic, after Cunéo & Marcille).

(2) The *ductus deferens, seminal vesicle and prostate gland.* Collecting vessels from the ductus end in the external iliac nodes, while those from the seminal vesicle go to the internal and external iliac nodes. Prostatic vessels end mainly in internal iliac and sacral nodes; a vessel from the posterior surface accompanies the vesical vessels to the external iliac nodes and one from the anterior surface gains the internal iliac group by joining vessels of the membranous urethra.

(3) The *scrotum and penis*. The skin of these parts is drained by vessels which, with those of all perineal skin, accompany the external pudendal blood vessels to the superficial inguinal nodes. Lymph vessels of the glans penis pass to the deep inguinal and external iliac nodes, from the erectile tissue and penile urethra to the internal iliac lymph nodes.

Lymphatic drainage of the female reproductive organs (6.220). (1) The *ovary*. The vessels, like the testicular, ascend along the ovarian artery to the lateral aortic and pre-aortic nodes.

(2) The *uterus and uterine tube*. Uterine lymphatics are superficial (or subperitoneal) and deep in the uterine wall. Collecting vessels from the cervix pass laterally in the parametrium to the external iliac nodes, posterolaterally to the internal iliac nodes and posteriorly in the sacrogenital fold to the rectal and sacral nodes. Some cervical efferents may reach the obturator or gluteal nodes. Vessels from the lower part of the uterine body pass mostly to the external iliac nodes, with those from the cervix. From the upper part of the body, the fundus and the uterine tubes, vessels accompany those of the ovaries to the lateral aortic and pre-aortic nodes, a few passing to the external iliac nodes. The region surrounding the isthmic part of the uterine tube is drained along the round ligament to the superficial inguinal nodes. Uterine lymph vessels enlarge greatly during pregnancy.

(3) The *vagina*. Vaginal lymphatic vessels link with those of the cervix uteri, rectum and vulva. They form three groups but the regions drained are not sharply demarcated. Upper vessels accompany the uterine artery to the internal and external iliac nodes, intermediate vessels accompany the vaginal artery to the internal iliac nodes; vaginal vessels below the hymen, from the vulva and perineal skin, pass to the superficial inguinal nodes but the clitoris and labia minora drain to the deep inguinal nodes and direct clitoridial efferents may pass to the internal iliac nodes (Kubik 1967).

Lymphatic drainage of the abdominal wall. These vessels are either superficial or deep to the deep fascia.

Superficial vessels accompany the subcutaneous blood vessels. Lumbar and gluteal vessels run with the superficial circumflex iliac vessels, those from the infra-umbilical skin with the superficial epigastric vessels. Both drain into the superficial inguinal nodes. The supra-umbilical region is drained by vessels running obliquely up to the pectoral and subscapular axillary nodes, a few to the parasternal nodes.

Deep vessels accompany the deep arteries, the posterior passing without interruption with the lumbar arteries to the lateral aortic and retro-aortic nodes; those from the upper anterior abdominal wall run with the superior epigastric vessels to the parasternal nodes; those of its lower part end in the circumflex iliac, inferior epigastric and external iliac nodes. Vessels of the pelvic wall follow the internal iliac artery and its parietal branches to end in the iliac or lateral aortic nodes.

Lymphatic Drainage of the Thorax

LYMPHATIC DRAINAGE OF THE THORACIC WALLS

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes. Those superficial to the trapezius and latissimus dorsi unite to form 10 or 12 trunks ending in the subscapular nodes. Those in the pectoral region, including vessels from the *skin* covering the periphery of the mammary gland and its subareolar plexus run back, collecting those superficial to serratus anterior, to reach the pectoral nodes. Vessels near the lateral sternal margin pass between the costal cartilages to the parasternal nodes but also anastomose across the sternum. A few vessels from the upper pectoral region ascend over the clavicle to the inferior deep cervical nodes.

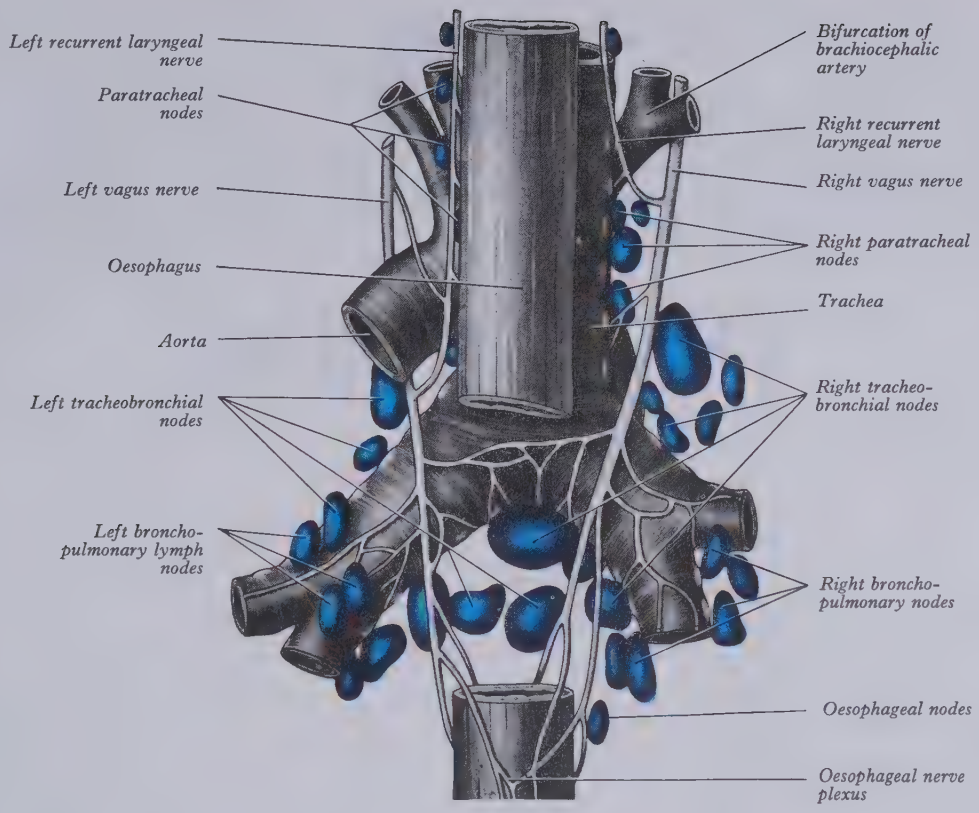
Lymph vessels from *deeper* tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymphatic nodes.

(1) **Parasternal (internal thoracic) nodes**, four or five on each side, are at the anterior ends of the intercostal spaces, along each internal thoracic artery. They drain afferents from the mammary gland, deeper structures of the supra-umbilical anterior abdominal wall, the superior hepatic surface through a small group of nodes behind the xiphoid process and deeper parts of the anterior thoracic wall. Their efferents usually unite with those from the tracheobronchial and brachiocephalic nodes to form the *bronchomediastinal trunk*; this may open, on either side, directly into the jugulo-subclavian junction into either great vein near the junction or may join the *right* subclavian trunk, the right lymphatic duct or, on the left, the thoracic duct.

(2) **Intercostal nodes** are posterior in intercostal spaces near the heads and necks of the ribs. They receive deep lymph vessels from the posterolateral aspects of the chest and the mammary gland; some are interrupted by small lateral intercostal nodes. Efferents of nodes in the lower four to seven spaces unite into a trunk *descending* to the abdominal confluence of lymph trunks or to the commencement of the thoracic duct (p. 843). Efferents of nodes in the left upper spaces end in the thoracic duct, those of the right upper spaces end in one of the right lymph trunks.

(3) **Diaphragmatic nodes**, on the thoracic surface of the diaphragm, comprise: anterior, right and left lateral and posterior groups. The *anterior* group consists of two or three small nodes behind the base of the xiphoid process, draining the convex hepatic surface, and one or two nodes on each side near the junction of the seventh rib and cartilage, which receive anterior lymph vessels from the diaphragm. The anterior group drains to the parasternal nodes. The *lateral* groups each contain two or three nodes, close to the entry of the phrenic nerves into the diaphragm. On the right some nodes lie within the fibrous pericardium anterior to the intrathoracic end of the inferior vena cava. Their afferents are from the central diaphragm, the right also draining the convex surface of the liver. Their efferents pass to the posterior mediastinal, parasternal and brachiocephalic nodes. The *posterior* group contains a few nodes on the back of the crura, connected with the lateral aortic and posterior mediastinal nodes.

Lymphatic drainage of the deeper tissues. Collecting vessels of the deeper thoracic tissues include the following:



(1) Lymphatics of muscles attached to the ribs: most end in axillary nodes, some from pectoralis major in the parasternal nodes.

(2) Intercostal vessels draining the intercostal muscles and parietal pleura; those from the anterior thoracic wall and pleura end in the parasternal nodes, the posterior in intercostal nodes. (3) Vessels of the diaphragm form two plexuses, thoracic and abdominal, anastomosing freely and best marked in areas covered respectively by pleurae and peritoneum. The *thoracic plexus* unites with lymph vessels of the costal and mediastinal pleura, its efferents being: *anterior*, passing to the anterior diaphragmatic nodes near the junctions of the seventh ribs and cartilages; *middle*, to nodes on the oesophagus and around the end of the inferior vena cava; *posterior*, to nodes around the aorta where it leaves the thorax. The abdominal *plexus* anastomoses with the hepatic lymphatics and peripherally with those of the subperitoneal tissue. Efferents from its right half end partly in a group of nodes on the inferior phrenic artery, others in the right lateral aortic nodes. Those from the left half of the abdominal diaphragmatic plexus pass to the pre-aortic and lateral aortic nodes and nodes near the terminal oesophagus.

LYMPHATIC DRAINAGE OF THORACIC CONTENTS

Lymph from thoracic viscera traverses one or other of three groups of nodes, brachiocephalic, posterior mediastinal or tracheobronchial, before entering the thoracic duct, the right lymphatic duct or some other lymph trunk entering one of the great veins at the root of the neck.

Brachiocephalic nodes are in the superior mediastinum, anterior to the brachiocephalic veins and large arterial trunks springing from the aortic arch. They drain the thymus and

6.221 The lymph nodes of the trachea, bronchi and lungs. Note the large 'carinate' node lodged between the bifurcation of the principal bronchi.

thyroid glands, pericardium, heart, and lateral diaphragmatic nodes; their efferents unite with those of the tracheobronchial nodes to form the right and left bronchomediastinal trunks.

Posterior mediastinal nodes are behind the pericardium, near the oesophagus and the descending thoracic aorta. Their afferents are from: the oesophagus, posterior pericardium, diaphragm, lateral and posterior diaphragmatic nodes, and sometimes the left lobe of the liver. They drain chiefly to the thoracic duct but some join the tracheobronchial nodes.

Tracheobronchial nodes (**6**.221) are in five main groups, including some of the largest nodes: (1) *paratracheal*, flanking the thoracic trachea but continuous above with the *cervical paratracheal nodes*; (2) *superior tracheobronchial*, in the angles between the trachea and the bronchi; (3) *inferior tracheobronchial* in the angle between the bronchi (commonly termed *carinate nodes* in clinicopathological parlance); (4) *bronchopulmonary*, in the hilum of each lung (*hilar nodes*); (5) *pulmonary*, in the lung substance on larger branches of the principal bronchi. These groups are not sharply demarcated; pulmonary nodes become continuous with the bronchopulmonary and they in turn with the inferior and superior tracheobronchial nodes, continuous with the paratracheal group. Afferents of tracheobronchial nodes drain the lungs and bronchi, thoracic trachea, heart and some efferents of the posterior mediastinal nodes. Their efferent vessels ascend on the trachea to unite with efferents of the parasternal and brachiocephalic nodes as the *right* and *left bronchomediastinal trunks*; the right trunk may occasionally join a right lymphatic duct or another right-sided lymph trunk and on the left the thoracic duct; but more often they open independently in or near the jugulo-subclavian junction on their own side.

Applied Anatomy. In all town dwellers large quantities of dust and carbonaceous pigment may be freely inhaled and are continually swept into these nodes from the bronchi and alveoli.

Lymphatic drainage of the heart. Cardiac lymphatic vessels form subendocardial, myocardial and subepicardial plexuses, the first two draining into the third, efferents of which form the *left* and *right cardiac collecting trunks*. Two or three *left* trunks ascend the anterior interventricular sulcus, receiving vessels from both ventricles; reaching the coronary sulcus, they are joined by a large vessel from the diaphragmatic surface of the left ventricle, which first ascends in the posterior interventricular sulcus and then turns left along the coronary sulcus. The vessel formed by the union of these two ascends between the pulmonary artery and the left atrium, usually ending in an inferior tracheobronchial node. The *right* trunk receives afferents from the right atrium and right border and diaphragmatic surface of the right ventricle. It ascends in the coronary sulcus, near the right coronary artery, and then anterior to the ascending aorta to end in a brachiocephalic node, usually on the left.

Lymphatic drainage of the lungs and pleurae. Pulmonary lymphatic vessels originate in a superficial subpleural plexus and a deep plexus accompanies the branches of pulmonary vessels and bronchi. In larger bronchi the deep plexus has submucous and peribronchial parts; in smaller bronchi a single plexus extends to the bronchioles but not to the alveoli, whose walls have no lymphatic vessels. Superficial efferents turn round borders and the margins of fissures to converge in the bronchopulmonary nodes; deep efferents reach the hilum along the pulmonary vessels and bronchi, ending mainly in the same nodes. There is little anastomosis between the superficial and deep lymphatics, except in the hilar regions. In peripheral parts of the lungs small channels connect superficial and deep lymphatic vessels, capable of dilatation to direct lymph from the deep to the superficial channels when outflow from deep vessels is obstructed by pulmonary disease. Deep in the fissures, lymphatic vessels of adjoining lobes connect; hence, though there is a tendency for vessels from the upper lobes to pass to the superior tracheobronchial nodes and those from lower lobes to the inferior tracheobronchial group, these connections are not exclusive. At the level of pulmonary lobulation the arrangement of lymphatic vessels follows both the central artery of a lobule and its peripheral veins (Kubik 1970), confirming the findings of Celtis & Porter (1952). Policard (1950)

has described lymphoid aggregations, non-follicular in appearance, in peribronchial sites and in '*placoid*' formations adjoining pulmonary pleura.

Pleural lymphatic vessels exist in visceral and parietal layers, those of the visceral pleura draining to the superficial pulmonary efferents, forming a plexus beneath the pulmonary pleura (vide supra). Those of the parietal pleura end in three ways: (1) those from the costal region join vessels of the internal intercostal muscles to reach the parasternal nodes; (2) those of the diaphragmatic pleura form a plexus on its thoracic surface (p. 856); (3) those of the mediastinal pleura end in the posterior mediastinal nodes.

Lymphatic drainage of the thymus. Thymic lymphatic vessels end in the brachiocephalic, tracheobronchial and parasternal nodes.

Lymphatic drainage of the oesophagus. Efferent vessels from the cervical oesophagus drain to the deep cervical nodes, those from its thoracic part to the posterior mediastinal nodes and those from its abdominal part to the left gastric lymph nodes. Some may pass directly to the thoracic duct (p. 842).

Introduction

The dependence of organisms upon sources of environmental energy and the essentially dynamic nature of their life processes have been emphasized elsewhere (pp. 3–6). A major aspect of this dynamism is the ability of organisms to interact continually with a fluctuating environment without any loss of structural integrity. Successful adaptations ensuring survival can be related to long or brief scales of time (p. 6): through many generations natural selection operates on genetic variation engendered by sexual reproduction and occasional gene mutations, resulting in species with greater adaptability to environmental changes. Alternatively, within the lifetime of a complex organism, adaptive responses range from behavioural patterns in mating, rearing, procuring food, escape or combat, etc. to innumerable transient readjustments, e.g. of posture or the maintenance of a constant composition in the body fluids. These are examples of *homeostatic responses*, a central feature of behaviour, simply summarized in illustration 7.1.

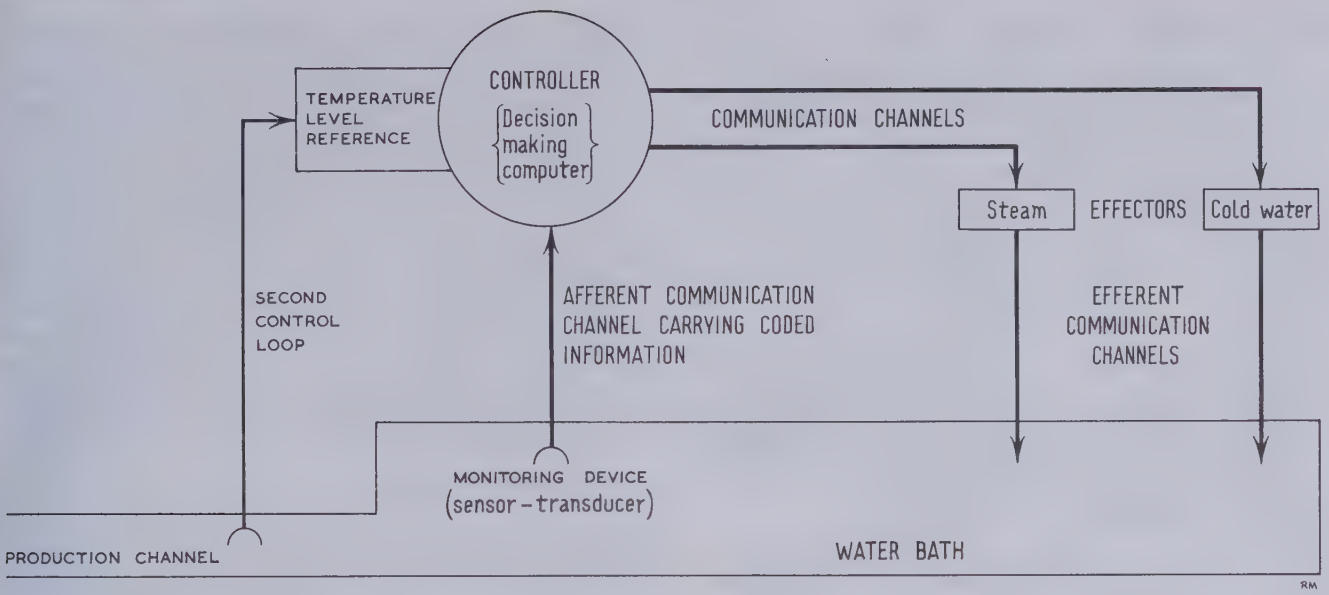
7.1 The relationsip between a stimulus (S) and a response (R) emphasizing its closed-loop nature.

An environmental change (S or *stimulus*) to which an organism can react entails an appropriate *response* (R), which is usually to preserve the constancy of the internal state within the limits necessary for the continued life of its cells and to preserve the whole organism. It should be noted that the relation of an organism to a stimulus is altered by this response (7.1); the sequence of events is therefore a *loop*, not an *arc*. In the simple case illustrated, the organism's structural organization (the result of its phylogenetic history) limits the range of stimuli to which it can react and its repertoire of responses, whether mechanical, chemical, photic or electrical. Hence environmental disturbances to which it is *unable* to respond, or disturbances too intense for an adequate response, cause the organism to die and dissolve into its environment. In this example, *genetic memory*, selected through countless generations, has determined the range of receptivity and response and hence the fitness to reproduce in a particular environment. Such mechanisms may lead to stereotyped behavioural responses such as those of insects; but in more complex organisms selection has added flexible *memory stores* operating throughout life (7.2). In these, the general sequence of the stimulus–response loop remains similar, but information from a particular event is stored for comparison with previous experience. Thus a choice can be made (from the different alternatives available) of the response likely to be the most effective in the prevailing circumstances. In some way, the effectiveness of a response is assessed and transferred to memory, which is modified accordingly, the probability of this particular response being chosen again in like conditions being raised or lowered. Thus the memory store (or hierarchy of stores) is continually modified and refined by further experience, i.e. the organism *learns*.

7.2 The stimulus-response loop with the added flexibility of a memory store.

Homeostatic responses are innate in *all* living organisms; but, with increasing size and complexity of structure, the range and flexibility of responses has steadily increased in parallel with the evolution of a *nervous system*.

The human nervous system is the most complex, widely investigated, and yet poorly understood physical system known to mankind. Its structure and activities are inseparable from every aspect of life: physical, cultural and intellectual. Investigators from many disciplines, with many methods, motives and persuasions, converge in its study; there are therefore many more or less appropriate ways of undertaking such a study: developmental, phylogenetic, structural, physiochemical, energetic, cybernetic, behavioural and ethological. In the present account the detailed anatomy of the arbitrary but convenient divisions of the human nervous system is preceded by a consideration of the relevant experimental methods, the biology of its component cells, a brief review of the organization of nervous systems in general and a comparison of nervous systems with information-processing, communication and mechanisms of control of simple homeostatic machines. (For a further discussion consult Young 1964, 1978.)



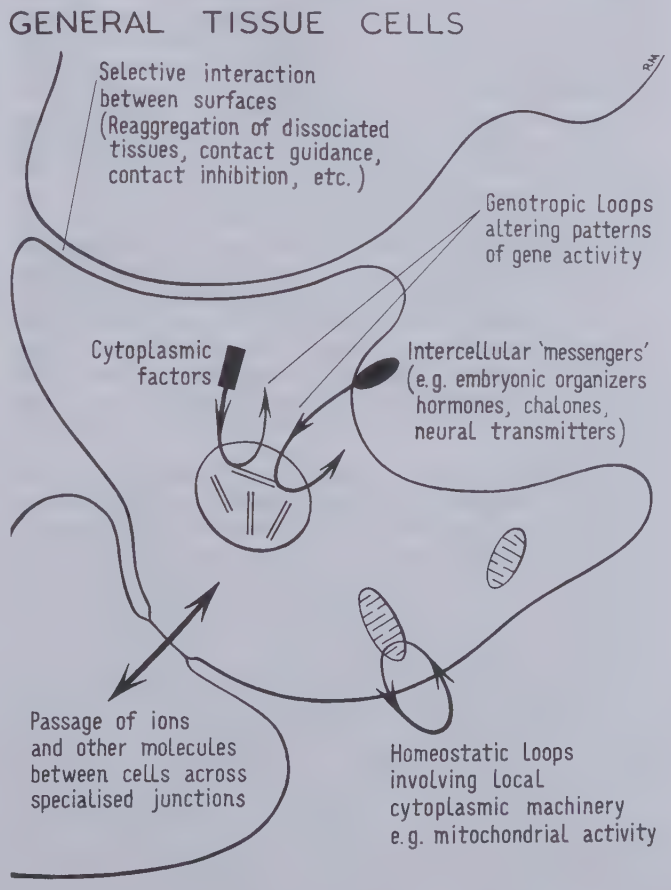
SIMPLE HOMEOSTATS

In considering mechanisms of homeostasis, it is helpful to draw an analogy with devices such as a simple thermostat. In diagram 7.3 the *energy level* (temperature) of a water bath is continuously *monitored by a sensor* or *receptor* (thermocouple), fluctuations in temperature being converted into variations in the flow of a *pattern of signals* or *coded information* (current flow) along an *afferent communication channel* to a *controller*, which *integrates* the flow of information along its afferent channel, compares it with a reference level of temperature and *decides* between the activities (*responses*) of two *effectors* (steam or cold water). If the bath's temperature falls enough to be detected by the sensor, the change excites signals in the afferent channel resulting, after comparison and computation in the control centre, in an increased flow of steam. It is inherent in the design of *control loop systems* that a return of the temperature to the reference level will not be smooth or immediate; an overshoot occurs, followed by oscillations of decreasing amplitude, gradually approaching reference level. All features in this homeostat have counterparts in a primitive nervous system, which include: various sensors able to monitor the rate and magnitude of some environmental change, *afferent* channels for coded information (nerve fibres bearing temporo-spatial patterns of impulses), computing and decision-making centres (geometric patterns of contact between neurons) and *efferent* channels (nerve fibres) to glands or muscles to stimulate them to ordered responses. All these features will be considered later in further detail.

As depicted in 7.3, such simple control loops, which are present in all organisms (and also widely used in engineering), are frequently *coupled* to others for more complex responses; many features of more complex nervous systems are thus referable to an *integrated hierarchy of control loops*.

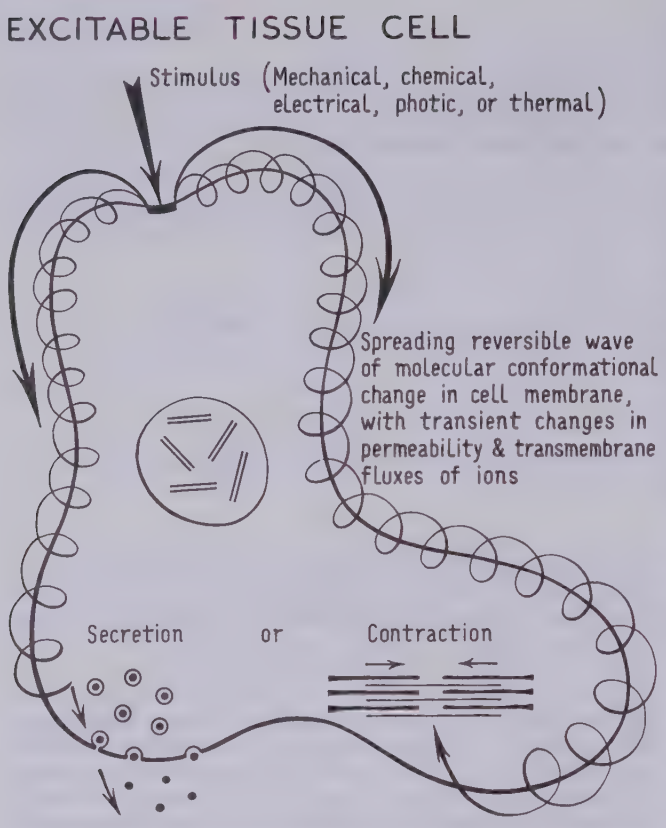
Intercellular Communication

Many aspects of intra- and intercellular communication (7.4A,B) are noted elsewhere; these include selective interactions between closely apposed cell surfaces, the phenomena of contact guidance and contact inhibition (p. 115), the structure and informational role of nucleic acids (p. 115) and current theories of modes of action of local cytoplasmic factors or intercellular chemical messengers (embryonic induction factors, hormones, etc.) in changing genotropic control loops, resulting in enhancement or repression of patterns of gene activity (pp. 40, 108). Where cells are particularly close, as at 'gap' junctions (maculae communicantes), some ions and molecules can pass between the cytoplasm of adjacent cells (p. 24). Chemical messengers, such as secretions of endocrine glandular cells, pass into circulation and then diffuse via tissue fluid to remote cells; such mechanisms essentially operate *slowly*.



7.3 The essential features of a thermostat coupled to an industrial production line. This is an example of a man-made homeostatic device; see text for further details and discussion. From Young 1964, with permission.

EXCITABLE TISSUES



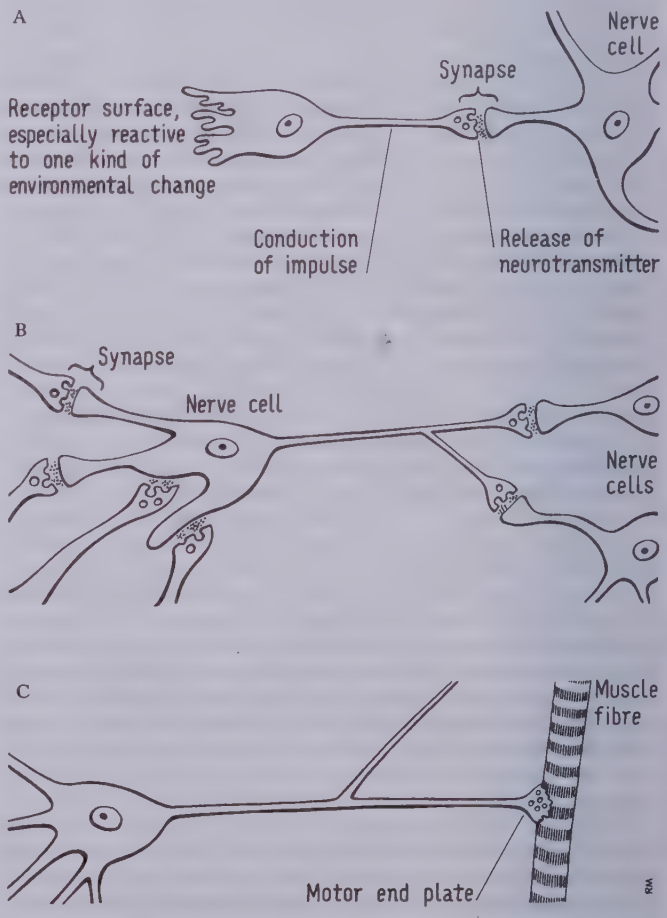
More rapid mechanisms of intracellular and intercellular communication have evolved in special *excitable tissues* (receptor, neural, muscular and some glandular cells). Some of the general features of excitable cells are shown in 7.4B. All cells possess a plasma membrane separating them from the surrounding tissue fluid (p. 15, 1.5). Due to the membrane's selective permeability the ionic composition of intracellular fluid differs from that outside; hence a large electrical potential exists across it. A suitable *stimulus* applied to its surface leads to a transient, reversible wave of change spreading over the surface from this point. Though details of this change in molecular terms are uncertain, alterations in the permeability of the membrane (conductance) result. Presumably a rapid local redistribution of ions occurs across the membrane as these flow down concentration gradients, ceasing as its permeability returns to its resting state. These ionic fluxes can be recorded as variations in electrical potential and are also accompanied by minor, but detectable thermal exchanges between the cell and its environment. Such properties of excitable cells, discussed in detail elsewhere, entail *trains* or *volleys* of *impulses* caused by prolonged stimulation, the stimulus strength being related to the impulse pattern (number and frequency of impulses). The impulse, spreading over the surface, causes various effects in the cells they innervate, e.g. the release of specific secretory products or the contractions of actin–myosin complexes, depending upon the type of cell. Cells co-operating in nervous function are modified in various ways and exhibit the properties of excitable tissues to a variable extent (7.5A,B,C). Thus, in *protozoa* and some primitive metazoa, *single cells* can give effector responses to stimuli but in most multicellular creatures possessing nervous systems a *division of labour* occurs between the excitable cells in the system. This marks the emergence of *receptor* cells, specialized to react to stimuli: *neurons* for their conduction and integration, and *effectors* (contractile or glandular) for responses. The cytology, evolution and function of these is detailed on p. 904 et seq. but, before their details, the overall pattern of the nervous elements will be considered in general terms.

RECEPTOR CELLS

Within the epithelial layers clothing the body's surfaces and their subepithelial connective tissue, within the walls of blood vessels and of the solid and hollow viscera and in muscles, tendons and ligaments are arrays of *receptor cells*. These have specialized plasma membranes responding selectively to changes in the internal or external environment of the body. Some are responsive to physical deformation, others to thermal, chemical, electrical or photic variations. Views concerning the *specificity* of individual receptors have been modified much during the last 150 years. Since the law of *specific nerve energies* was proposed by Johannes Muller in 1840, many have held that receptors react preferentially to only one type of energetic change and this determines its normal physiological role. A receptor was held to show a *low threshold* to this form of stimulation, i.e. it reacted to *small* variations in energy level, whereas, to all other changes it showed a *high threshold*, reacting only if stimulation were intense, perhaps

7.4A Various forms of cellular and intercellular communication systems.

7.4B A summary of the main events which may follow the application of an effective stimulus to the surface of an excitable tissue cell.



abnormally so. Experiments on mammalian cutaneous innervation, however, prompted an opposite conclusion: that cutaneous receptors are *non-specific*, sensory perception depending on *spatio-temporal patterns* of impulses in a *common set* of neural pathways (Weddell 1941). With the subsequent refinement of methods of recording from single fibres and nerve cells there has been a partial return to the specificity theory but with complexities, subtleties and grades of interaction not envisaged in earlier theories (Mountcastle & Powell 1959, Sinclair 1967, Wall 1967). Thus, nerve fibres have been described which serve receptors reacting to more than one kind of change (*polymodal receptors*). Receptors may be fast or slowly adapting; the former respond to a brief stimulus with a sharp volley of nerve impulses ending with the stimulus or, if this is maintained, dropping to a resting frequency. Slowly adapting receptors may generate volleys of impulses for prolonged periods if the stimulus strength persists. Other varieties show a resting level of discharge which may be raised or lowered by changes in environment. These variants will be further considered with individual receptor cells (p. 906).

The molecular mechanisms by which environmental change, mechanical, chemical or thermal, excites a receptor cell remain obscure (excepting photosensitive pigments in retinal receptors, p. 1198). Recordings from many receptors show that exposure to an adequate stimulus leads to a change of ionic permeability in the cell's specialized receptor surface; ions which in the unstimulated state are differentially concentrated in intra- and extracellular compartments flow along concentration gradients, through molecular channels in the receptor membrane; microelectrodes record these ionic fluxes as variations constituting the *receptor potential*. The circuit for ionic flow is completed by an equal and opposite flow across adjacent non-specialized (but excitable) regions of receptor cell membrane, resultant *graded variations* in potential being the *generator potential*. The consequences of fluctuations of the generator potential have been analysed in only a few sites, but they vary with the type and geometry of different receptors. In some sites, e.g. lingual gustatory cells, the generator potential may *directly* affect the levels of activity at the points of synaptic contact between the receptor cell and a peripheral process of a neuron (vide infra); in others, e.g. Pacinian corpuscles, whose specialized receptor surface is the periphery of a long cytoplasmic conducting process (nerve fibre) proceeding to the central nervous system, other events occur; if the variation in generator potential reaches *threshold* level, a dramatic but rapidly reversible series of changes in ionic permeability ensue in the cell membrane bordering the receptor surface. The consequent ionic fluxes, recordable as an *action potential*, start a self-generating wave of similar changes along a conducting process as a *nervous impulse*. The maintenance of the generator potential at an adequate level above threshold results in a *volley of impulses* passing centrally. The *frequency* of impulses in the volley is related approximately logarithmically to the energy or *intensity* of the stimulus. Receptors thus act as *transducers*, whereby fluctuations in environmental energy levels are transformed to coded volleys of nerve impulses.

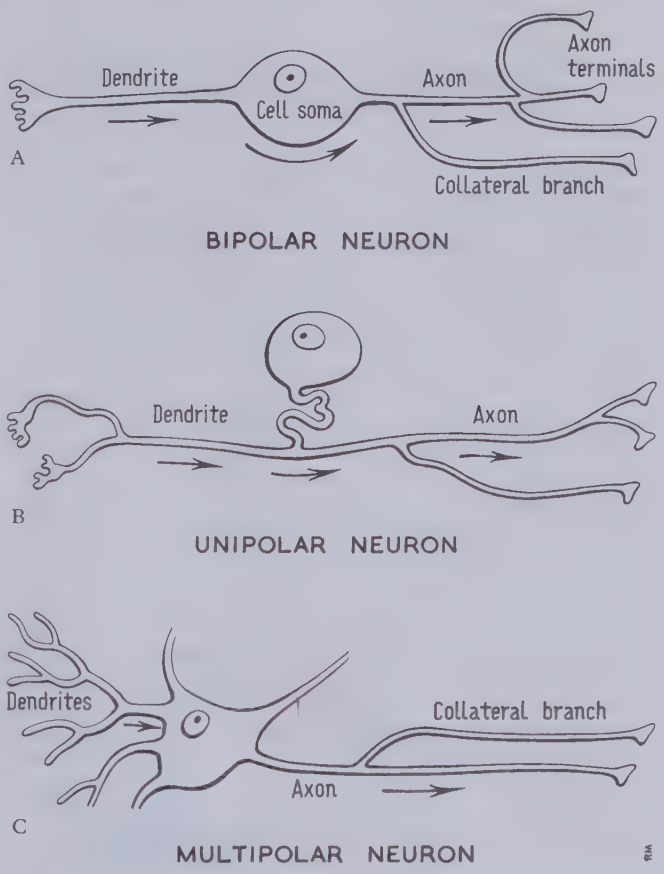
SYNAPTIC CONTACTS

Excitable cells (receptors, neurons and effectors) communicate at specialized intercellular contacts termed *synapses*, which are of two main kinds. Most common are *chemical synapses*, where *neurotransmitters* released by one cell stimulate the plasma membrane of another, altering its permeability to certain ions and hence its electrical state. Such junctions occur in all nervous systems. Less frequent is an *electrical synapse*, identical to *communicating junctions* or *nexuses* existing between many types of cell (e.g. cardiac and non-striated myocytes, etc., pp. 557, 562). Here adjacent cells have channels of direct ionic communication between their cytoplasm, one cell exciting the other without release of transmitter.

At most mammalian synapses (as in most other vertebrates and invertebrates) transmission is chemical; cell membranes are

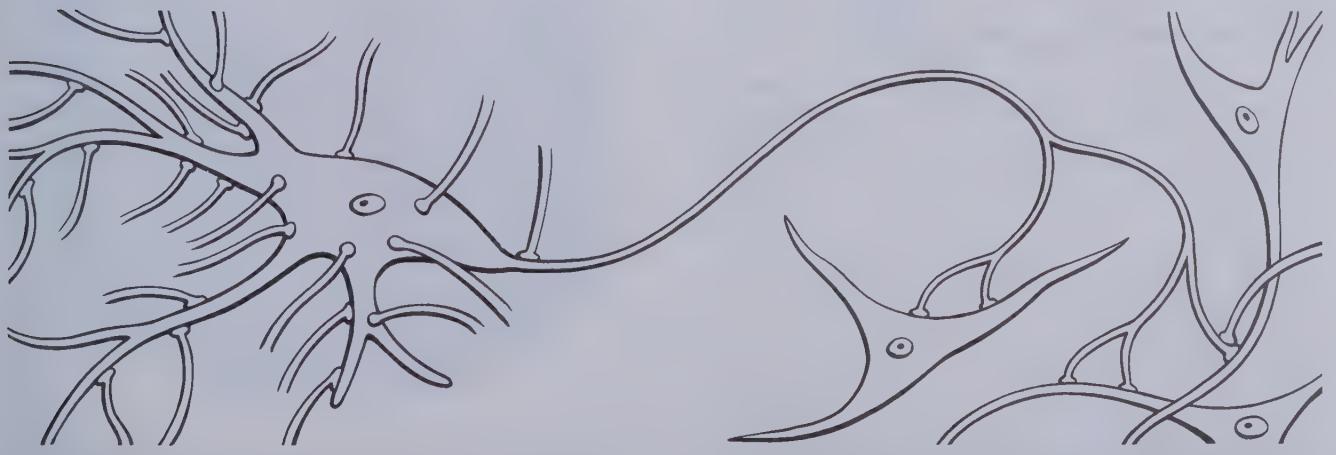
7.5 The three main avenues of differentiation which may be followed by a primitive nerve cell: A. a receptor neuron; B. an interneuron; C. an effector neuron. See text for further discussion.

separated by a *synaptic cleft*. In the great majority of synapses transmission is unidirectional; the synapse is *polarized* and bounded by a *presynaptic* and a *postsynaptic* membrane. As a nerve impulse spreading over the surface of a presynaptic cell (receptor or neuron) approaches the presynaptic membrane, it causes the release of a *neurochemical transmitter* which rapidly diffuses across the synaptic cleft to the postsynaptic membrane, whose ionic permeability it alters. The transmitter is often removed or broken down almost at once by a specific enzyme or is removed by neighbouring cells and inactivated. The type of change in postsynaptic permeability varies with the chemical nature of the transmitter and the detailed composition of the membrane at a synapse. In some cases the change induces a flow of ions to *depolarize* the postsynaptic membrane, i.e. to *reduce* the electric potential difference due to the asymmetrical distribution of ions across a 'resting' cell membrane. Such synapses and transmitters are *excitatory* with respect to postsynaptic cells (vide infra). Other neurotransmitters *hyperpolarize* postsynaptic membranes and are *inhibitory*. These effects, as recorded from postsynaptic cells, are respectively, *excitatory* or *inhibitory postsynaptic potentials* (EPSPs or IPSPs) (pp. 865, 886). In other examples more subtle and complex interactions may occur which may render the postsynaptic membrane less, or more, excitable (or inhibitable) when another neurotransmitter reaches it. These effects are termed *neuromodulation* and not only may occur at synapses in the strict sense but may also be effected at considerable distances from the site of chemical release, which therefore may reach a number of different neurons by diffusion (*paracrine secretion*, see p. 887). To clarify some of the features of these interactions, the general structure of neurons will now be considered.



NEURONS

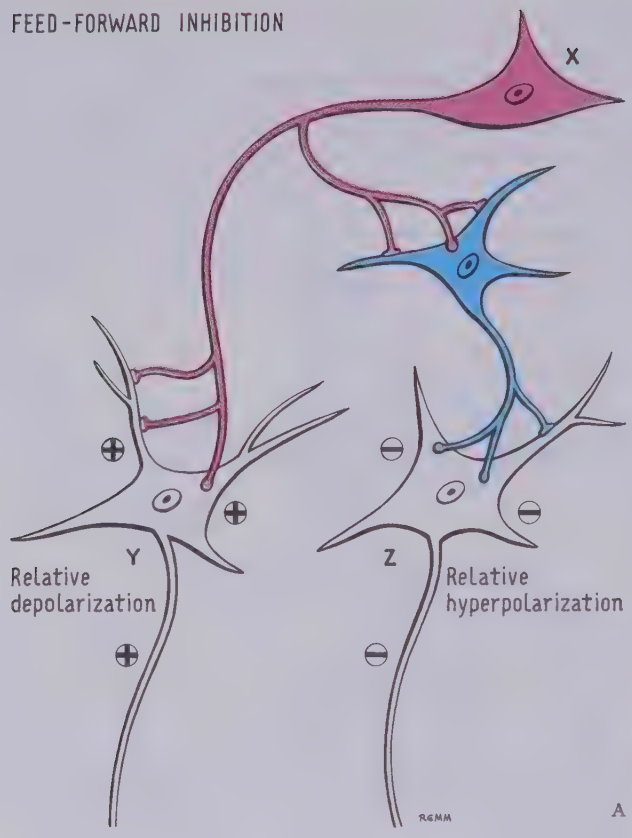
Neurons are excitable cells, specialized for the *reception*, *integration*, *transformation* and *transmission* of coded information. Vertebrate neurons consist of a *cell body* (the nerve cell or *soma*), a mass of specialized cytoplasm with a diploid nucleus and an excitable membrane, from which project one or more *neurites*. These are branching, cytoplasmic processes, enclosed by excitable plasma membrane, which extend for varying distances from the soma. Neurons are classified as *unipolar*, *bipolar* or *multipolar* according to the numbers of these extensions (7.6A–C). Most neurites conduct towards or directly influence the soma, as *dendrites*; only one (which may branch) conducts away from it, the *axon*.



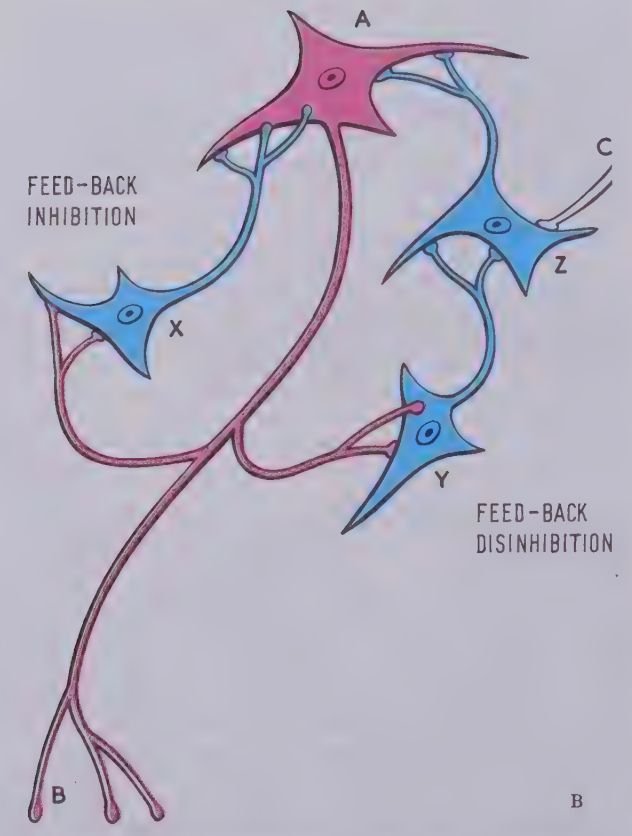
Neurons vary in shape, size and interconnections, in different species and regions of a nervous system, as will be described later. Here it is to be noted that the dendrites of many bipolar or unipolar neurons either synapse with specialized, peripheral receptor cells or, by means of their dendritic terminals, themselves function as specialized receptors. Almost all neurons of vertebrate *central* nervous systems (brain and spinal cord) are multipolar (7.7).

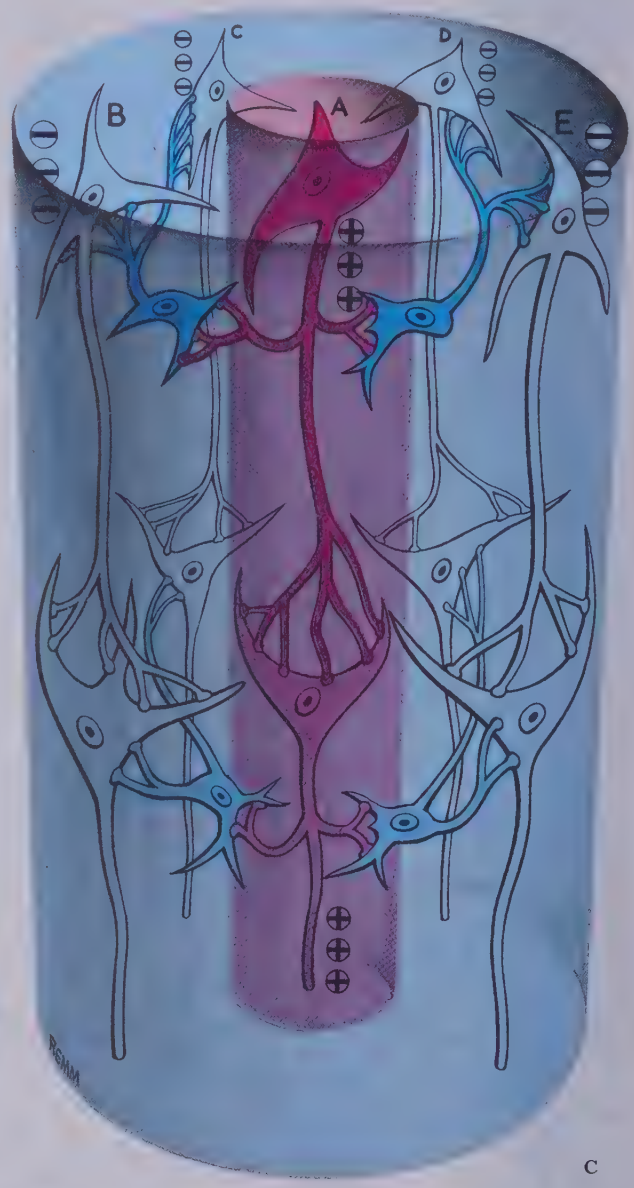
The surfaces of dendrites and somata provide large areas for synaptic contacts from other neurons. These may be sparse but usually number many thousands, usually derived from the axonal branches of hundreds of other neurons. Such presynaptic neurons may be widely scattered and highly varied paths may *converge* on a single neuron.

Synapses may thus be *axodendritic* or *axosomatic* in their siting on the postsynaptic membrane; less common are: *axoaxonic* synapses, involving initial axonal segments or presynaptic



7.6 Three general morphological groups of neurons classified according to the number of neurites which arise from the surface of the cell soma: A. bipolar neuron; B. unipolar neuron; C. multipolar neuron. For a more detailed analysis of the branching patterns of neurites, see 7.17.





7.7 A generalized multipolar neuron and the parts of its surface upon which synaptic terminals from other neurons may converge. These include the surfaces of the dendrites, the cell soma, the initial segment of the axon and the proximal surface of its own axonal synaptic terminals. For a more detailed representation of the cytology and surface contacts of a multipolar neuron see 7.20.

terminals of the neurons concerned, *dendrodendritic*, *reciprocal* and *serial* synapses and synaptic *cartridges* and *glomeruli* around neurites, aggregated in complex geometrical patterns. Glomeruli are *higher integrative units* or *microcircuits*. Cytological details of these and their possible modes of operation are described in pp. 877, 888.

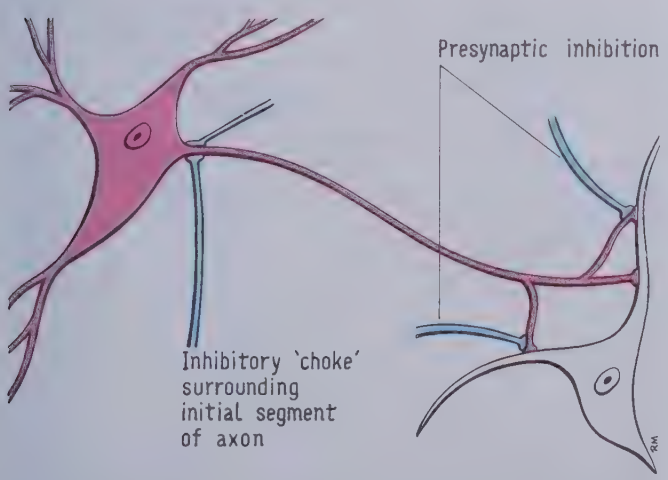
Of the numerous synaptic terminals clustered on dendrites and soma of a multipolar neuron some are *excitatory* while those from other sources are *inhibitory*. Depending on the activity or quiescence of such sources, the ratio of active excitatory and inhibitory synapses continuously varies. Their effects summate; the *excitatory state*, i.e. the levels of depolarization or hyperpolarization of the cell membrane, also fluctuates. When depolarization reaches *threshold level*, a local electrochemical current flows, encircling the dendrites and soma; if it is sufficient to alter the permeability of the *initial axonal segment*, an action potential is generated and spreads along the axon as a *nervous impulse*. If such excitation is maintained, a *volley* of impulses traverses the axon and its branches. Since a neuron's excitatory level *continuously* reflects numerous variations in the patterns of paths converging upon it, it resembles an *analogue computing device*; but

7.8 Examples of elementary circuits (excitatory neurons shown in red, inhibitory neurons in blue): A. a direct excitatory circuit (on the left) is compared with a simple feed-forward inhibitory circuit (on the right); B. feed-back circuits of two orders of complexity with one (on the left) and two (on the right) inhibitory interneurons interposed on the recurrent pathway; C. lateral inhibition. A central excitatory train of neurons is surrounded by a hollow cylindrical zone of inhibition, mediated by shells of inhibitory interneurons which are activated by the central column. See text for further discussion.

the outflow, the axon, works on an *all or none* basis, being either quiescent or conducting discrete, identical impulses; only their frequency varies. In this the axon acts like a *digital computer*.

Axonal terminals of a particular neuron may be few, concentrating their effects on one or only a small group of post-synaptic cells. Sometimes *collateral branches*, which may be numerous, leave an axon along its course, each arborizing and *diverging* to many destinations. The 'many to one' *convergent* channels integrating many different effects and the 'one to many' *divergent* channels are both basic features of all advanced nervous systems.

INHIBITORY CIRCUITS



Some elementary circuits, proposals from microelectrode studies, are illustrated in 7.8A–C.

In **feed-forward inhibition** (7.8A) an excitatory neuron (X) is linked with two others (Y and Z). However, it is clear that when X is active, the interposition of an inhibitory neuron on the second path reduces the excitatory level of Z, while that of Y rises. In reality other local circuits would also be active but the principle illustrated here probably accounts in part for, e.g. the increase in the force of contraction of one muscle group, while the contraction in an antagonistic group is progressively reduced.

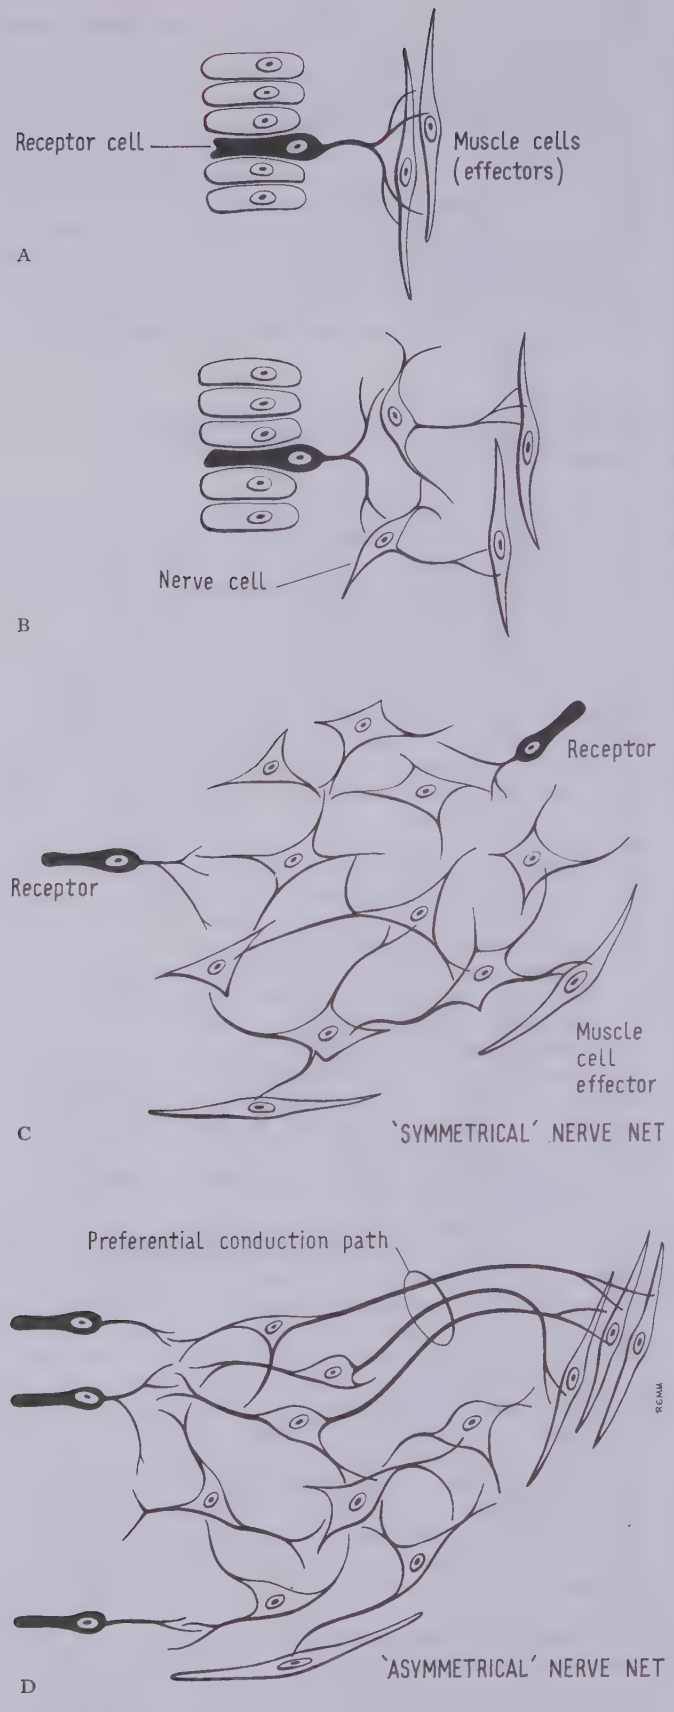
In **feed-back inhibition** (7.8B), impulses from a multipolar neuron (A) traverse its axon to the main synaptic terminals (B). The persistence of the volley is limited by a feed-back loop: an axonal collateral synapses with an inhibitory neuron (X), whose terminals go back to synapse with the dendrites and soma of A, in effect terminating the volley. Such feed-back circuits vary in complexity; in some *two* inhibitory neurons (Y and Z) may form a recurrent loop; the inhibitory effect of neuron Z on A, perhaps from an alternative source (C), may be diminished by the inhibitory neuron Y. Such a release from an inhibitory effect by a second neuron, in series with the first, is called *disinhibition*.

In 7.8C is shown a form of feed-forward inhibition, *lateral inhibition* or an *inhibitory surround*, which is prominent in many sites in the nervous system: parallel paths A–E, carrying functionally similar information, may be imagined to transmit sporadically with a low information content; if the excitatory state of one (e.g. A) significantly exceeds that in the others, activity in B–E is reduced by adjacent 'surrounds' of interposed inhibitory neurons. The central activated path is thus surrounded by a quiescent zone, reducing confusion caused by random activity in the others. The discriminative value of the central channel is thus greatly increased, a phenomenon termed *neural sharpening*, examples of which will be referred to later.

Two further sites of inhibition occur (7.9), though less commonly and with completely contrasting roles. An inhibitory terminal at an initial axonal segment is well placed to *prevent* outflow from a neuron, while *presynaptic inhibitory terminals* may *selectively inhibit* at some terminals while others remain unimpeded; examples will also be encountered later.

7.9 The multipolar neuron, (shown in red), has inhibitory synaptic terminals (blue) applied to the initial segment of its axon and others to the surfaces of its own axonal synaptic terminals.

It should be stated here, however, that our knowledge of the detailed geometry of dendritic trees, cell somata and axonal branching, of three-dimensional interneuronal connections and the distribution of synaptic types, are all very limited, especially in quantitative terms. How individual neurons and co-operative groups transform patterns of information and how they relate to the operation of the whole nervous system and the organism's overall economy remain enigmas. For this reason, much current research is concentrated on the developmental mechanisms of neurogenesis, to determine which neuronal features are specified by the genome and which are modifications occurring during an organism's life.



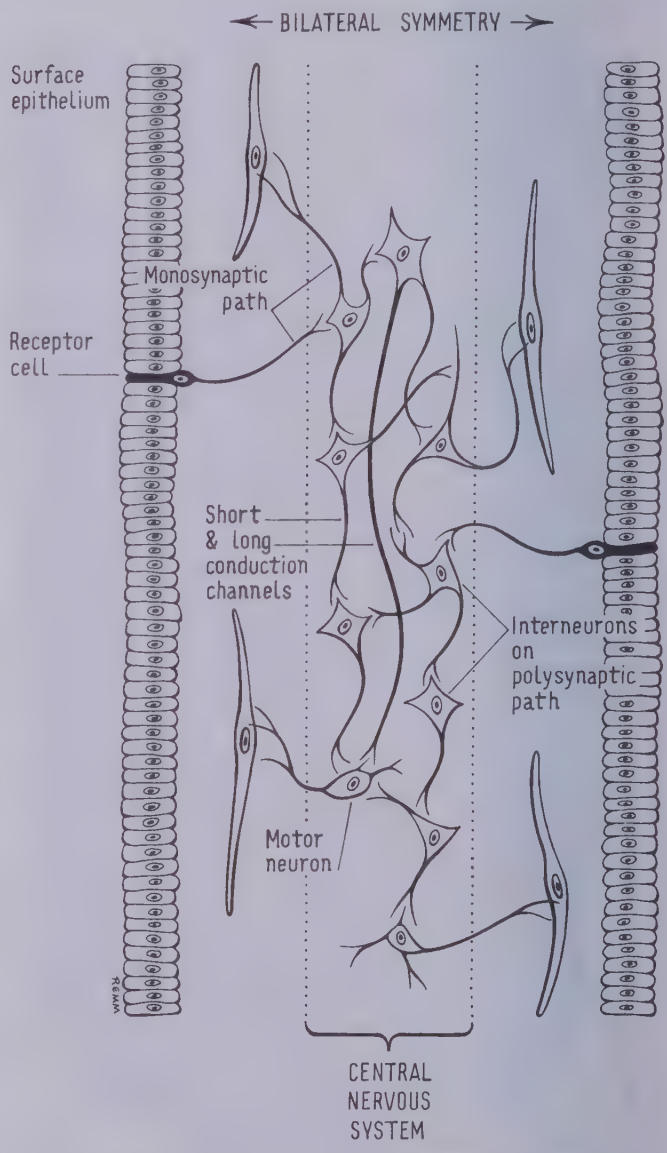
Some General Features of Neural Organization

An outline of some aspects of the overall patterns of organization in simpler nervous systems is a necessary introduction to complex arrangements in vertebrates, especially humankind. This account, which is too brief to reflect a phylogenetic history, will be limited to the organization of simple neuronal arrays.

In protozoans a single cell acts as receptor, conductor and effector but simple multicellular forms possess *independent effectors*, such as contractile cells around pores in sponges, or the stinging organs of coelenterates. The latter are the simplest metazoans with a nervous system: in various species different orders of complexity can be recognized (7.10). In some sites special receptor cells among other epithelial cells send a conducting process from their bases to contact underlying effectors (myocytes); but many processes of sensory cells discharge into a subepithelial *rete* or *network* of neurons interconnected in a tangential plane; from this neural processes pass to the effectors. Connections or 'synapses' between cells in the network allow stimuli at any point on the surface to activate large areas of the nerve net, to cause widespread motor effects. Superficially the network appears random (7.10C); but some regions have more inputs, some parts of it are denser and in some regions conducting fibres are longer and have a distinct orientation: features which presumably reflect the more complex behaviour in capturing prey or in escape in these simple organisms; these structural patterns foreshadow similar fundamental arrangements which occur in more complex nervous systems, including those of Mammalia.

In simple organisms with *bilateral symmetry* we see the emergence of a *central nervous system* (7.11). Receptors are still largely situated in the surface layers but their basal conducting processes are longer, traversing other tissues and passing towards the median region, where many neuronal somata and their neurites are concentrated as a central nervous system, in which synaptic ends of receptor cell processes terminate. The somata of motor (effector) neurons are located in this concentration, their axons leaving it to reach the effectors. Other neurons connect with receptor terminals and motor neurons. They may have short or long axonal processes and constitute *interneurons* (*intercalated* or *internuncial neurons*). Paths of varying complexity thus connect the receptor cell input to the motor output; some of these pathways are *polysynaptic*, with a chain of interneurons, while in others there is a direct receptor–effector *monosynaptic* path. It is in such a diversity of *connectivity* that the variations in speed and complexity of behavioural response to environmental conditions reside.

In higher invertebrates, with *metametric segmentation*, arrangements are similar. Receptors are still largely epithelial and their *centrifugal* nerve fibres collect into bundles as *sensory nerves* in each segment before entering the central nervous system, which contains masses of interneurons and motor neurons, usually aggregated as a ventral pair of 'ganglia' in each segment. Each of these pairs is connected by axonal processes *across the midline* and also with those of adjacent segments by bilateral groups of *longitudinal* axons, forming a ladder-like structure. A series of *motor nerves* emerges in each segment. The transverse connections are formed by axons of interneurons to mediate bilateral responses.



7.10 Simple nervous systems: A. direct interaction between a receptor cell and the muscle cell effectors; B. interneurons which make functional contacts with each other are interposed between the receptor cell terminals and the muscle cell effectors; C. receptor cell terminals feed into a fairly symmetrical network of interneurons which in turn makes contact with the effectors; D. the interneurons between the receptors and effectors are organized where 'diffuse' multisynaptic conduction pathways predominate and others where more direct routes are present.

Short axons connect adjacent segments in both directions and longer axons connect more distant segments, including an increasingly important 'head' end whose receptors often dominate behaviour.

During embryogenesis (p. 133) in all classes of *Chordata*, including the mammals and humankind, the central nervous system develops in the dorsal midline as a hollow tube-like structure containing a *central canal*, expanding cranially to form a *brain*, with extensions of the central canal termed *ventricles*. In all vertebrates the brain and spinal cord consist of interneurons and proportionately less numerous motor neurons, with non-excitable glial cells and blood vessels. Two regional varieties of nervous tissue appear, *grey matter* and *white matter*, distinctly recognizable in the freshly cut brain or spinal cord.

Grey matter consists of the somata, dendritic trees and initial axonal segments of neurons and the terminal segments and synaptic endings of axons reaching them from receptors, with the glial cells and blood vessels between these various structures. Some short axons are confined to the grey matter but many leave it in bundles or *tracts*. In the **white matter** there are no neuronal somata or dendrites but numerous nerve fibres, many of them ensheathed by myelin (p. 902). These sheaths are essential for the

7.11 Some features of the nervous system in a primitive organism with bilateral symmetry. Note the intra-epithelial positions of the receptor cells and the aggregation of interneurons and motor neurons near the plane of symmetry as a central nervous system. Note also the different orders of complexity of the conduction pathways and the possibility of cooperative actions involving both sides of the body.

efficiency of conduction, enhancing the velocity for a given diameter of nerve fibre and reducing its energetic requirements (p. 901). They impart a pinkish-white opalescence to fresh tissue: hence the term white matter.

The central canal in vertebrates is largely lined by ciliated columnar epithelium termed *ependyma*; in early embryogenesis the grey matter develops around it, with white matter more peripherally placed. At first this arrangement is found throughout the neural tube and in the spinal cord the relationship persists; but with the development of hind-, mid- and forebrain vesicles some masses of grey matter remain in the primitive peri-ependymal position, while others migrate outwards between the developing tracts. Moreover, profuse secondary migrations of developing grey matter occur into the roof of each brain vesicle, where they form a superficial series of laminae, structures of greatest significance in the higher evolution of the nervous system.

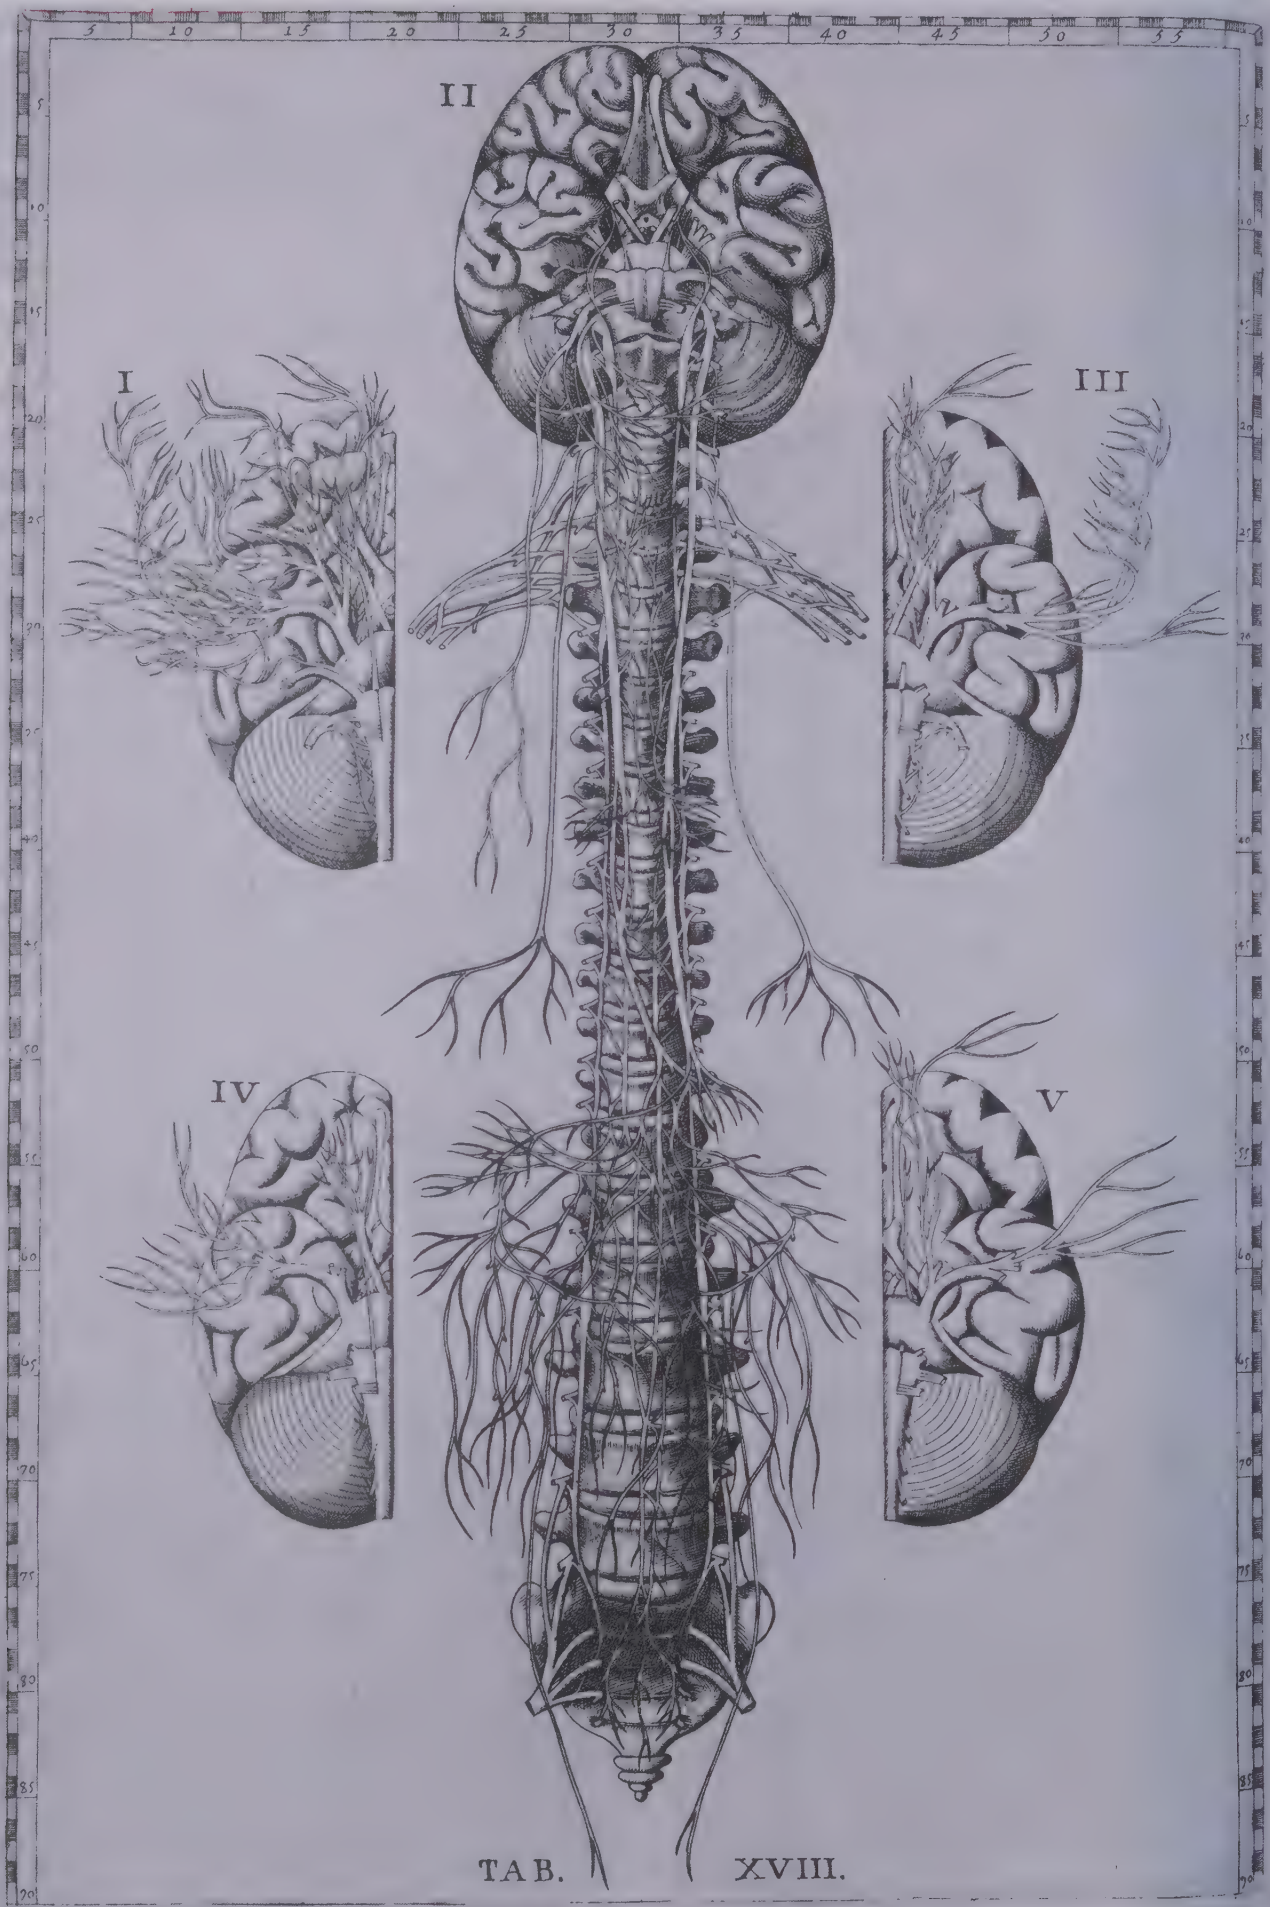
TECHNIQUES AND DEVELOPMENT OF NEUROANATOMY

The previous section has been largely an analysis of nervous systems, based on a long accumulation of data, hypotheses and explanations by a succession of observers and experimenters (see e.g. the Anglo-American Symposium 1958, Brazier 1959, Singer & Underwood 1962, Clarke & O'Malley 1968, Meyer 1971, Bellairs & Gray 1974, Neurosciences Study Programs 1967, 1970, 1974). All were limited by the technical means available. It is hence appropriate to note the *methods* by which major advances, leading to our current knowledge, have been achieved, with a brief survey of neuroanatomical and other relevant techniques. The names of innovators should perhaps be kept alive by habitual citation but this is scarcely practicable in the textbooks of today. The ensuing pages may help to correct this deficiency.

Progress in neuroanatomy, always dependent on the contemporary means of observation and experiment, was initially slow: about two millennia separate the earliest recorded observations from the advent of even simple lenses. The great advances in the nineteenth and twentieth centuries coincided with a great flowering of technical innovation. At first physiology lagged centuries behind anatomy, a frustration to all who found function the chief interest of structure; but in the explosion of technical progress functional studies have overtaken the purely structural in many fields, sometimes carrying concepts of function beyond structural knowledge. In neurology this provided a much needed intellectual stimulus to morphologists, as indeed it continues to do.

FROM THE GREEKS TO THE RENAISSANCE

Even allowing for the fact that only simple means were available, the paucity of neurological observation or even (recorded) speculation before ancient Greek times is surprising. Injury, sacrifice and mummification provide obvious opportunities for such studies but the earliest descriptions are limited to optic nerves (Alcmaeon *c.*500 BC) and the recognition in the Hippocratic Collection (*c.*400 BC) of the cleft between the cerebral hemispheres, with a belief that the brain is the seat of the intelligence. Even Aristotle (384–322 BC) confused nerves with tendons (with effects still visible in the term 'aponeurosis') and he set intelligence in the heart, unlike Plato (429–347 BC), who favoured the brain. Biology was already permeated by the Four Elements of Empedocles (*c.*493–433 BC) and the Four Humours of Polybus (*c.*390 BC). The latter were to dominate and obstruct biological thought for almost two thousand years.



Recorded human dissection began in the rising Alexandrian School, led by Herophilus and Erasistratus (*c.*300–250 BC), still regarded (somewhat vaguely) as 'father figures' of anatomy and physiology. How far Egyptian embalming influenced early dissection is unknown (Cave 1958). Herophilus distinguished the cerebrum, cerebellum and fourth ventricle, even its calamus scriptorius, also differentiating motor and sensory nerves. Erasistratus detailed the ventricles, entangling their functions in humoral concepts, his teaching complicated further by the idea of *pneuma* or vital spirit, an impediment lingering long after the Renaissance; but he equated elaborate human gyri with intelligence, a prophetic speculation.

With the Roman invasion (50 BC) the Alexandrian School decayed; but Galen (AD 129–199) studied there and in Rome. His role, as dissector and experimentalist, is well known (Sarton 1954, Singer 1956). He classified cranial nerves, with some errors, uncorrected in the ensuing 1500 years. He was dogmatic and theoretical but his work on the spinal cord was based on *experiment* (and not improved until Bell and Magendie's observations in the nineteenth century). Section between the first two vertebrae, he concluded, led to instant death and between the third and fourth to respiratory arrest, while at lower levels it caused paralysis of the bladder, intestines and legs. Much of his prolific output was pervaded by humoral and vitalistic ideas, a serious brake on progress for many centuries, due to the veneration accorded him. After Galen, biology and medicine entered a long suspense, the classical legacy being all but extinguished in Europe. Greek texts survived in Arabic translation but with little addition to knowledge. In the general intellectual lethargy, neuroanatomy marked time for a thousand years; indeed, its accuracy decayed. Astrology and the early Christian authority's insistence on the unimportance of man's physical estate displaced interest from his own true fabric. From the eleventh century, Greek medical manuscripts were translated into Latin, at first from Arabic. Though this reawakened European reason, progress was slow, centuries remaining barren of biological advances. Hippocrates, Aristotle and especially Galen were the almost unchallenged sources of medieval anatomy. Even in nascent universities of the twelfth and thirteenth centuries, natural phenomena were neglected; achievements were literary. Dissection reappeared and was practised at first to confirm established dogma. Even the *Anathomia* of Mondino (1316), often styled the first modern text, ascribed the functions dictated by the antique teachings to the brain ventricles, adding nothing to neuroanatomy. Though dissection continued in Bologna, spreading in Italy and to Montpellier, the fourteenth and fifteenth centuries brought little more than direct translations from Greek. The sixteenth century anatomical Humanists were absorbed in the replacement of Arabic anatomical terms by Greek and Latin; but great exceptions from these drab polemics were at work.

FROM THE RENAISSANCE TO THE NINETEENTH CENTURY

The naturalist movement among Renaissance artists in the late fifteenth and early sixteenth centuries culminated in Leonardo da Vinci (1452–1519) (see Belt 1956). Like Dürer, Michelangelo and Raphael, he turned to dissection for direct observation of human structure. Though his contemporary influence is uncertain, he brilliantly symbolizes the revival of enquiry in Europe, rebelling against traditionalism and scholastic orthodoxy. His contribution to neuroanatomy, though limited, was impressive: remarkable figures of the brain depicting wax casts of brain ventricles, a technique invented by him. The movement represented by Leonardo, with the improved techniques of engraving, paved the way for Vesalius.

Vesalius (1514–64) has received almost excessive adulation; his plates, starkly structural compared with Leonardo's functional style, marked a new era of accuracy (see O'Malley 1964). Impatient of Galenic errors and the near sanctity accorded them despite ascertainable facts, he revised human anatomy by dissections. In neuroanatomy he excelled in detail and precision, with somewhat lesser success in describing the peripheral nerves. He sectioned the brain (an innovation), showing the basal nuclei, hippocampus, fornix, internal capsule, pulvinar, colliculi, fourth

ventricle and many other details, for the first time with almost modern accuracy. Eustachius (1550–74), a contemporary, has received less than just acclaim; his work, like Leonardo's, became generally known only after his death. He depicted the sympathetic nervous system (7.12) and cranial nerves more accurately than Vesalius and the pons (Varolii) more so than Varolius.

Vesalius' less famous successors at Padua nevertheless exerted much influence on visiting scholars. Thus, Coiter of Montpellier (1534–76), an early comparative anatomist, studied under Fallopius, improving on Vesalius and Eustachius by describing the roots of spinal nerves and distinguishing white and grey matter. Fabricius taught Harvey (1578–1647), whose discovery of circulation was oddly combined with Galen's views in other matters, though he did reject his flow of 'spirits' in hollow nerves, a break with dogma worthy of his contemporary, Bacon (1561–1626), whose contempt for scholastic orthodoxy and inductive approach to experiment and factual verification of hypothesis were the first advance beyond Aristotle's logic. This new attitude, though philosophy rather than technique, has perhaps influenced subsequent endeavour as deeply as Harvey's experimental genius. After them the tempo of discovery increased, the focus on 'humours' in blood or nerves, as avenues of communication, slowly transferring to the nervous system.

So far study was only by dissection and the simplest experiments, with the unaided eye; but during the seventeenth and eighteenth centuries discoveries in parallel fields, especially of electrical phenomena and optics, were to become of basic importance in neural investigation. The experiments of Gilbert (1540–1603) on magnetism foreshadowed the electrical stimulation of nerves by Galvani (1737–98) and Volta (1745–1827), heralding neurophysiology. Simple microscopes enabled van Leeuwenhoek (1632–1723) to dispute the hollowness of nerves; compound instruments soon followed, notably exploited by Hooke (1635–1703) but not widely used in neuroanatomy till the early nineteenth century.

Meanwhile topographical neuroanatomy prospered; Willis (1621–75) and Vieussens (1641–1716) hardened the brain by soaking in wine or boiling, allowing its dissection, an advance upon slicing methods. Willis pioneered macroscopic dissection of the brain, the only technique available for almost two centuries. He also came near to formulating modern concepts of reflex activity. Late in the eighteenth century the speculations of Willis, von Haller, Whytt and others regarding reactions to stimuli were being resurrected. Microscopes were improving and in the nineteenth century techniques of fixation, microtomy and staining were evolving. Enquiry was turning from external features to internal structure; some neuroanatomists preferred comparative morphology and development, and workers were becoming more specialized, as also was technical progress.

COMPARATIVE ANATOMY AND EMBRYOLOGY

Though Erasistratus is sometimes dubbed the first comparative neuroanatomist, modern studies stem from Willis (1664) (Cole 1944, Needham 1959). Function rather than evolution became the primary consideration; in this Willis anticipated the nineteenth-century interest in localization, especially in the cerebral cortex. Gall and his pupil, Spurzheim, though achieving in phrenology a notoriety undeserved by Gall, initiated the concept of cortical localization (Gall & Spurzheim 1810–19). Tiedemann (1860) described human fetal brains, Reil (1807) development and comparative anatomy of the cerebellum and insula. Owen (1868) added the concept of cerebral weight and volume to comparative techniques. Others extended the range of species studied, especially primates, and the advent of Darwinism was a spur. Comparative and embryological data were amassed to bolster up homologies in the now forgotten arguments of the 'localizationists'. All observations were macroscopic, but with Campbell, the Vogts and Brodmann (1909), extending into the twentieth century, microscopy of the cortex burgeoned. Vast cytoarchitectonic investigations, familiar in 'Brodmann maps' were later equalled only by Conel's on the developing cortex (1939–59).

Great advances in neurohistology and neurophysiology in the same period have overshadowed comparative neuroanatomy; but with new histological techniques classic work such as that of C. J. Herrick (1931) and Larsell (1937) on the cerebellum and Polyak (1957) on the visual system continued to appear. The compendia of comparative neuroanatomy by Ariens Kappers must also be noted (Kappers 1920–21, Kappers et al 1936).

Embryology and comparative anatomy were early associated with each other; Arnold (1842) described hippocampal development in primates; Wilhelm His (1874) distinguished 'complete' fissures and secondary sulci. More significant were the embryological studies of growth at the microscopic level; His (1887) demonstrated the axons of neuroblasts, foreshadowing the tissue culture studies by Harrison (1907). Held (1893), confirming neuronal individuality, nevertheless stated that this disappeared in maturation. Flechsig (1876) discovered that myelination proceeds (before and after birth) at different speeds in different tracts, thus introducing a *myelogenetic technique* for the investigation of connections.

DEVELOPMENT OF NEUROHISTOLOGICAL TECHNIQUE AND LIGHT MICROSCOPY

(See Clay & Court 1932, Brachet & Mirsky 1960, Clark 1961.)

Leeuwenhoek (1674) visualized nerve fibres with a simple lens, with which Swammerdam (1675) even dissected the nervous system of mayfly larvae. Jansen (1590) had already constructed a compound microscope, put to non-biological use by Galileo. Kepler is also credited with a similar invention, realized by Scheiner (1611). Huygens (*c.*1684) introduced a compound eyepiece. Malpighi (1666) is said to have been the first to see nerve cells with a microscope, but reconstruction of his crude microscope has demolished this claim (Clarke & Bearn 1968). Fontana (1781) described nerve fibres but did not distinguish between axons and their sheaths. Further advances depended on improved microscopy. Lister (1837) and Amici (1827) manufactured *achromatic* objectives; but Lister's pioneer efforts were sustained by no British interest, further development passing to Germany, where Abbe, with Zeiss, constructed *apochromatic* objectives in 1886, using the new Jena glasses and also improving the condenser and devising compensating eyepieces. Darkfield condensers (Wenham *c.*1853) and immersion objectives (Tolles 1874, Abbe 1878) accelerated refinement of late nineteenth-century microscopes. The immediate result was a flood of descriptions of animal tissues. Botanical *cells* had been portrayed long before by Hooke and so named by him (1665). Nerve cells, a discovery often accorded to Schwann in enunciating his cell theory with Schleiden (1839), are now considered first fully defined by Ehrenberg (1833); but undoubtedly Schwann first described the cells which bear his name. Progress now rested on the provision of new optical resources and techniques of preparation and staining.

Preparation of Material for Microscopy

Early microscopists used teased or squashed samples of fresh or, at most, partially preserved tissues to examine the structure of nervous tissue. Hardening being essential for sectioning animal tissues, Reil's introduction of alcohol (1809) for this purpose was an important step; Hannover (1840) used chromic acid as a hardener. Stilling (1842) used both, sometimes with freezing, on the spinal cord (1846) and cut transverse and longitudinal sections, also advocating serial sections, as did Virchow (1846) in studies of neuroglia. Formalin was later introduced by Blum (1893). Stilling & Wallach (1842) devised a simple microtome for cutting sections of tissue and this was improved by Welcher (1856); improvement of design made by Jung, Thoma and others soon followed and Von Gudden & Catsch (1875) were able to cut sections of whole cerebral hemispheres. Rutherford & Cathcart (1873) introduced

7.12 (*opposite*) The brain and autonomic nervous system depicted by Bartolomeo Eustachio (1550–74), a contemporary and rival of Vesalius (1514–64), from *Tabulae Anatomicae*, published posthumously in 1714 by Lancisi. The copperplates of Eustachio (or Eustachius) are not only anatomically more accurate than the woodcuts of Vesalius, but also technically superior. By courtesy of the Trustees of the British Museum.

freezing microtomes. By the 1880s semi-automatic microtomes such as the Cambridge Rocker produced thin serial sections, embedding in paraffin wax having been introduced by Klebs in 1869. Embedding in collodion (Duval 1879) and celloidin (Schiefferdecker 1882) followed and led to the use of such modern materials as soluble waxes, freeze-drying and cryostat techniques.

Tissue Staining Methods in Neuroanatomy

Much was achieved by the early nineteenth-century microscopists without any staining, although these methods were used sporadically from the beginning of microscopy (see the accounts by Baker 1960, Gurr 1965, Pearse 1968). Remak's early description (1836) of axons and their sheaths was made from unstained embryonic material. Using similar methods Purkinje (1837) confirmed this and also described the cerebellar neurons named after him; he used acetic alcohol for clearing and Canada balsam for permanent mounts. Waller's study of neural degeneration (1850) was made from teased nerves, unfixed and unstained, while Kuhne's discovery of motor endings (1862) resulted from the treatment of tissues with weak hydrochloric acid.

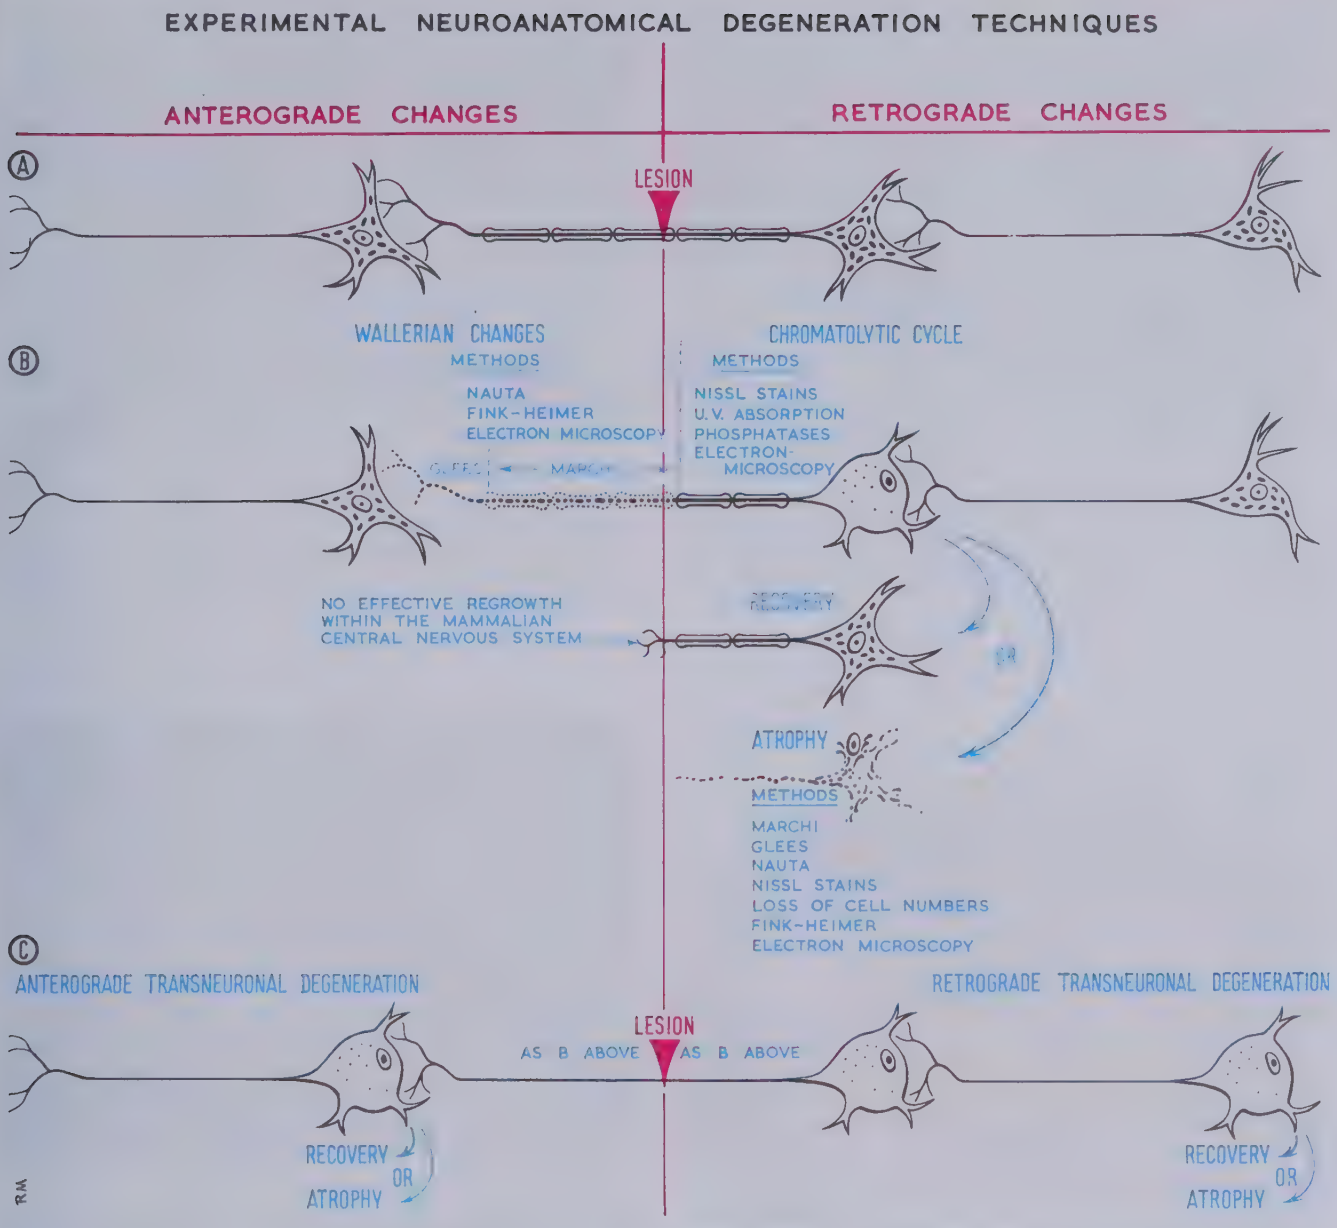
The first neurohistological stain was probably the carmine and gold method of Gerlach (1858), which he used to advance the *reticular* or *net* theory of neural organization. The controversy between the protagonists of this and the rival *neuron theory* reverberated down the rest of the nineteenth century into the twentieth. Though Faraday had discovered benzene in 1825 and Perkins the first aniline dye, mauveine, in 1856, the industrial development of dyes was quickly taken up in Germany, largely a by-product being a range of dyes available for histological use, from 1862 onwards (see Conn 1948). Deiters (1865) used carmine to distinguish between dendrites and axons. Ranvier's (1871) classic work on nodes depended on silver impregnation of chromic acid fixed tissue; Golgi (1878) further elaborated silver staining to visualize neurons in their entirety. It is interesting that Golgi's technique, nowadays usually applied only to small samples, was used by him, as by some recent workers, on whole human brains (see Kemali et al 1977). Ramon y Cajal (1908) adopted Golgi's methods, added some refinements and was thus able to accumulate such an overwhelming weight of evidence for the individuality of nerve cells that the neuron theory prevailed, though this proof is often ascribed to Waldeyer. Only with the application of electron microscopy to the nervous system was it possible to adduce more convincing evidence for the correctness of Ramon y Cajal's teaching. Even as late as 1933, a year before the first electron microscope was constructed, Cajal found it necessary to re-emphasize his views. He also used Nissl's methylene-blue method for staining 'chromatin granules' (vide infra); Ehrlich (1886) had used it, as the first vital stain, to delineate peripheral nerve fibres to their terminals; being an axonal stain, it has survived in modification for peripheral non-myelinated autonomic nerve fibres, although it has been largely replaced by more modern methods such as those using fluorescent dyes and horseradish peroxidase (p. 874).

Nissl (1892) discovered the *acute response* of the nerve cell soma to axonal damage, typified by the breakdown of Nissl or *chromatin granules (chromatolysis)* and other manifestations such as swellings of the soma. These retrograde changes are described on pp. 916–919.) This proved most valuable in tracing axons back to their somata. Weigert (1882) had already found a technique for staining *normal* myelin sheaths (consisting of pre-treatment with potassium bichromate followed by acid fuchsin) and was already using collodion for embedding, xylol for cleaning and balsam for mounting sections. Marchi's osmic acid method for staining *degenerating* myelin soon followed, an early histochemical technique (Marchi & Algeri 1885–86). Gudden (1870) had studied the later sequelae of neuronal damage, noting the atrophy of injured neurons, such changes being more rapid in young animals. Both Gudden and Nissl made considerable personal contributions using their own techniques; Gudden's work on thalamocortical connections was carried further by his pupil, von Monakow (1882), who also discovered the optic connections of the lateral geniculate body. It is noteworthy that both problems were re-examined by the same technique half a century later (Le Gros Clark & Penman 1934, Le Gros Clark 1936).

NEURON TRACING TECHNIQUES

The researches of Waller, Gudden, Golgi, Weigert, Marchi and Nissl were all published in the last 30 years of the nineteenth century, apart from the basic observations by Waller in 1850. His demonstration that damage to nerve fibres induces microscopically identifiable changes proved a most fruitful beginning for this brilliant period of neuroanatomy and neuropathology. His immediate successors established the broad basis of neuronal morphology and the major techniques for an unequalled volume of enquiry into the organization of the nervous system. Many modifications and some additions have followed but their methodology remained substantially unchanged until the introduction of the modern alternatives of retrograde or anterograde labelling with axonally transported dyes (vide infra).

The essential features of degeneration in neurites are shown in illustration 7.13. When the soma is ablated or fatally damaged, all of its neurites including the axon and its sheath degenerate and may finally disappear (p. 918); Wallerian changes can be shown by Marchi staining of the degenerating myelin. Terminal branchings of axons and synaptic boutons also degenerate but, being devoid of myelin, these do not stain by Marchi's technique. Glees (1946) and Nauta & Gygax (1951), with modifications by others, developed methods for staining them; and ultrastructural changes have ultimately been utilized.



It is difficult to place small experimental lesions in a mass of nervous tissue; there is no method of ablating *somata alone* within central nervous structures; in all experiments, dendritic trees, synaptic terminals from other neurons, blood vessels and other structures are also affected. Clearer results follow when axons are cut along their course; certain terms are used for various regions of the resultant degeneration, which will be briefly summarized here.

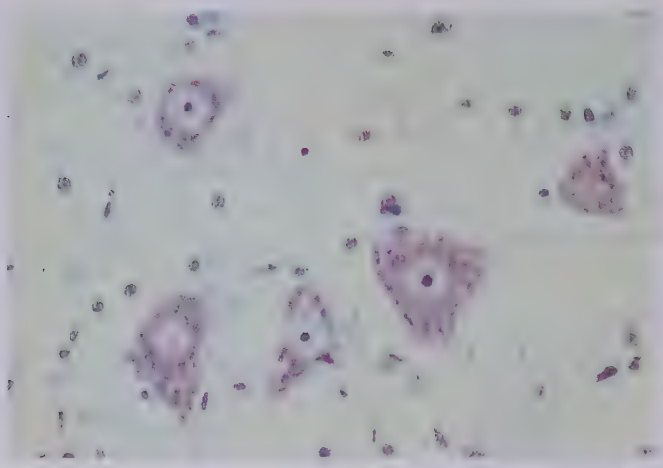
Firstly, effects confined to the parts of a damaged neuron *distal* to the lesion are said to be *anterograde*; those affecting the soma and axon *proximal* to the lesion are *retrograde* changes. Secondly, changes in undamaged neurons connected synaptically with the damaged one are *transneuronal* (*transynaptic*) changes and may be *primary*, *secondary*, etc, depending on the number of cells interposed; they also may *anterograde* or *retrograde*.

Following axonal damage, anterograde degeneration (of the Wallerian type involving its axon, axon terminals and myelin sheath) occurs distal to the lesion spreading in a wave towards the axon terminals. After suitable intervals, they may be examined by the methods of Marchi, Glees, Nauta, Fink-Heimer and by various histochemical or ultrastructural techniques. Proximal to the site of damage a fibre is often negative to Marchi staining, though Ramon y Cajal described retrograde Wallerian degeneration as far as the first node proximal to the point of injury; this was long disbelieved but it is now accepted that changes do sometimes occur in this direction and may extend to the soma as *retrograde atrophy*, accompanied by the degeneration of *all* neurites (although this late sequel of Nissl's *acute retrograde* (*chromatolytic*) *response* is not always followed by chronic atrophy). The degenerative changes in the fibres are thus *retrograde* in the sense that they occur proximal to the lesion but proceed *centrifugally* from the cell soma to the lesion.

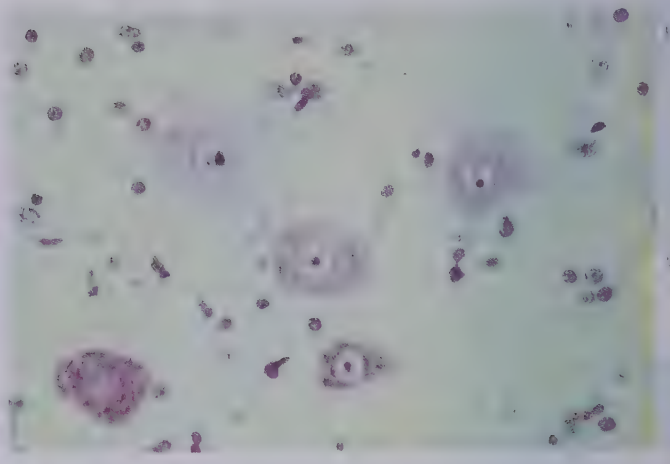
The above phenomena are more marked in newborn or young animals, as Gudden noted. Brodal (1940) introduced a so-called *modified Gudden technique*, using young animals in which acute and chronic retrograde changes occur more rapidly. The most suitable methods of approach to any problem and their application require careful consideration and the timing of the interval between placing a lesion and the inspection of its sequelae is critical. Discussions of these problems are given by Glees (1961) and Brodal (1969).

The ultimate fate of a damaged neuron is not always the same and the following remarks apply to the long-term results of natural and experimental injury. When severely damaged, e.g. by focal lesions (vide infra), the whole neuron and all of its processes degenerate and disappear. When the damage is to the axon, an acute retrograde reaction may be followed by recovery over some weeks or alternatively by chronic retrograde atrophy. Such phenomena have been investigated quantitatively by Turner

7.13 The sequelae of interruption of the fibres of central nervous system neurons. As shown, regeneration or atrophy may follow the response to injury, both in the neuron primarily damaged and in those affected transneuronally. Transneuronal effects may occasionally supervene in neurons more remotely associated with the damaged neuron. See text for further details.



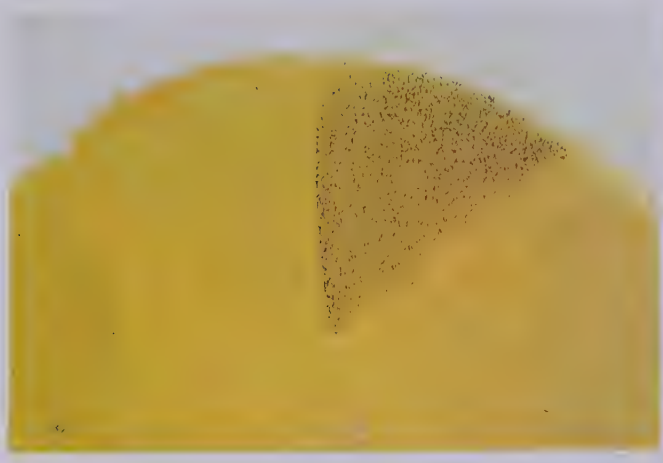
(1943), Bodian & Mellors (1945) and others. If a neuron survives, its pattern of Nissl granules returns and the axon proximal to the injury recovers, its severed part being absorbed, sometimes very slowly; in the spinal cord degenerating tracts have been identified a year or so after injury (Smith 1951).



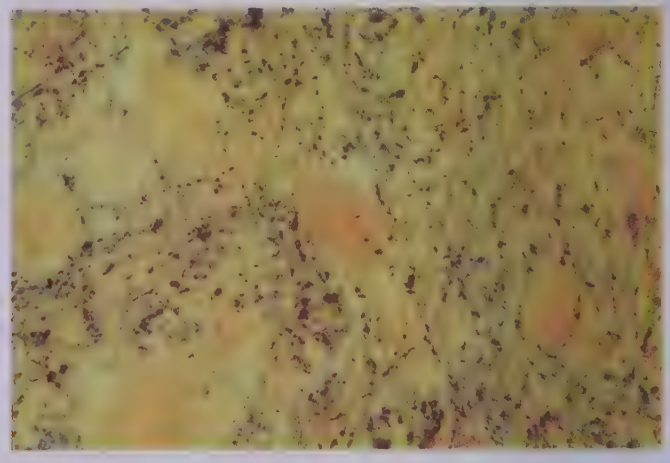
So far the responses to injury *in a single neuron* have been considered. Early this century, however, it was recognized that degenerative effects are sometimes transmitted from one neuron to another in the same functional pathway, as *transneuronal* or *transynaptic degeneration*. *Anterograde transneuronal degeneration* occurs in the visual pathway: retinal lesions not only affect the fibres of the injured ganglion cells as far as the lateral geniculate body, but also the geniculate neurons with which they synapse; the process may even involve neurons in the striate cortex in a chain of *primary* and *secondary* transneuronal degenerations. This kind of response appears only sporadically and may be limited to neurons receiving impulses predominantly, perhaps exclusively, from a single source and are therefore difficult to use for experimental purposes. However, ventral grey column neurons receive afferents from many sources and yet may exhibit transneuronal degeneration when the dorsal spinal roots are cut; such claims have been severely criticized but, however that may be, the technique offers obvious possibilities in tracing pathways.

Retrograde transneuronal degeneration has received less attention, although its occurrence in Gudden's cortical ablations is now generally beyond doubt; these cause degeneration in anterior thalamic neurons, whose axons reach the cortex, *and* also in other thalamic nuclei known to be in primary and secondary functional relation to the anterior thalamus (Cowan 1970). Gudden used surgical ablation, a method still used where appropriate, although more precise methods of making highly selective lesions have also been devised.

Selective Lesions and Stereotaxis



Tracing techniques require an accurate method of delivering accurate and controlled neural damage. Simple nerve section may suffice in peripheral nerves or superficial central tracts; crushing or repeated injury in the former is sometimes more effective. Superficial targets, such as the cerebral cortex, can be ablated or devascularized by removing the pia mater. Most targets are at some depth and the surgical approach may invalidate some experimental results by unplanned damage to other regions. This



7.14 A. Large multipolar neuronal perikarya in the magnocellular part of the feline red nucleus, showing prominent Nissl's granules, bases of dendrites and axon hillocks. The nuclei are euchromatic and vesicular, with prominent nucleoli. The small nuclei scattered in the surrounding neuropil are characteristic of the various categories of neuroglial cells.

B. A field similar to that depicted in (A) but after previous contralateral hemisection of the spinal cord at the level of the fifth cervical segment, thereby severing the rubrospinal tract. The section shows characteristic chromatolytic retrograde changes in the cytoplasm of three large neurons. Two smaller neurons are unaffected. A and B. photography by Kevin Fitzpatrick, Anatomy Dept, Guy's Hospital Medical School, London.

C. Transverse section through dorsal funiculi of feline cervical spinal cord, after unilateral dorsal column section at a more caudal level. Note anterograde Wallerian degeneration of ascending nerve fibres: degenerating myelin sheaths are stained black by Marchi technique. Provided by E W Baxter, Dept. of Biology, Guy's Hospital Medical School, London.

D. A high-power light micrograph showing preterminal degeneration of afferent axons ending in relation to neurons of the red nucleus of a rat, after the previous placing of a cerebellar lesion. The preparation was stained by the Nauta-Gygax method. Supplied by K E Webster, King's College, University of London.

difficulty has prompted other techniques, such as the use of fine electrodes, for stimulation *and* electrocoagulation, or of fine probes producing intense cold at their tips. Destructive substances such as alcohol, hydrocyanide, carbon dioxide snow or radioactive yttrium have been implanted. Focused ultrasound (Warwick & Pond 1968) or proton beams (Malis et al 1957) can cause deep damage without any disturbing entry, an advantage when large or irregular structures require repeated overlapping lesions. Antibody-antigen reactions have also been used (to destroy the caudate nucleus).

Most methods of making selective lesions entail the use of *stereotaxis*, i.e. some means of aligning an electrode, beam transducer or the like relative to a target (Carpenter & Whittier 1952). The heads of experimental animals are commonly fixed in a rigid frame in which the electrode, etc. can be adjusted in three planes to co-ordinates established by measurements in serial sections or by an X-ray guidance system, using air-filled ventricles or tracers for reference points. Since co-ordinate data vary a little from brain to brain, the accuracy obtainable is often limited, but is acceptable for all but very small structures. Horsley & Clarke (1908) constructed the prototype stereotactic apparatus; a succession of improvements have followed and similar apparatus has been used in neurosurgery.

Modern Histochemistry, Electron Microscopy and Neurophysiology

The morphological approach must, of course, be complemented by other methods for an understanding of connectivity and general neural organization, and various combined techniques have been applied with much success in recent years. With improving neurophysiological instrumentation the study of electrical activity has undergone a revolution and the refinement of electrodes allows smaller groups of fibres and single cells to be examined. The techniques of *evoked potential* measurement by controlled stimulation at one point with recording elsewhere are also used extensively and the impact of computer-based analysis has been particularly effective in this area. It is also possible to examine the activity of neuronal populations by relatively non-invasive methods such as positron emission tomography which allows the behaviour of even small

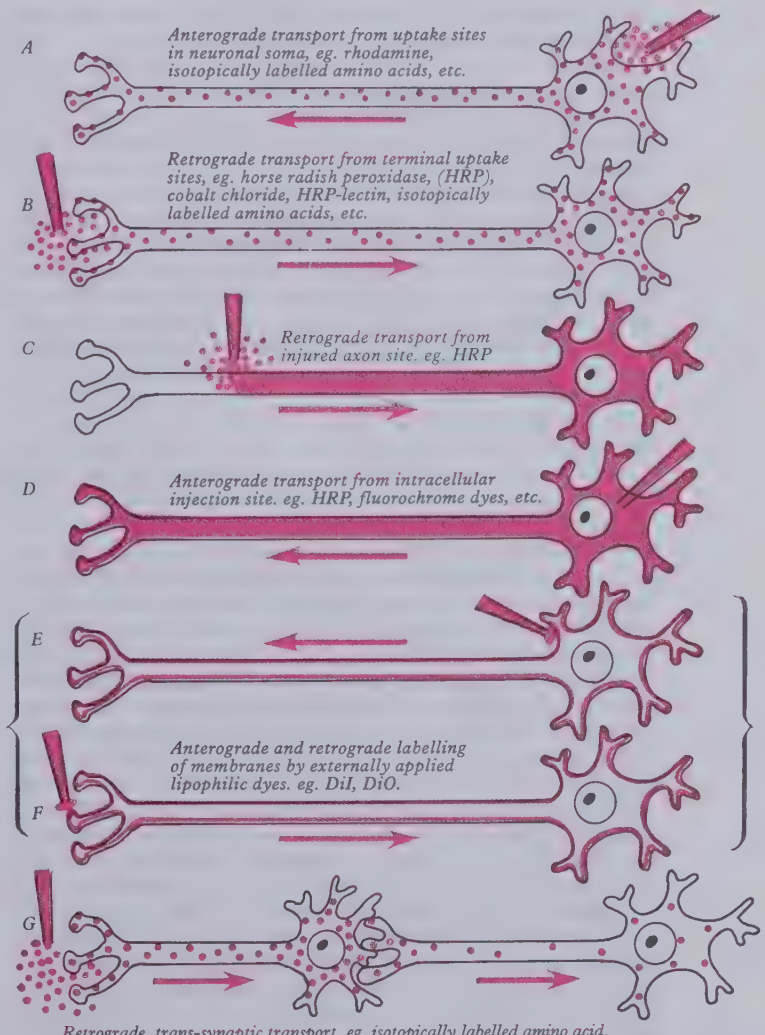
areas of the brain to be visualized in conscious human subjects.

These experimental approaches are often departmentalized as either anatomical or physiological but each inescapably contains an element of the other, providing complementary advantages and an important check on each other. With either approach the precise details of routes between points of stimulation or destruction and the sites of distant effects require repeated experiment for their full elucidation. The distance between sites of experimental targets may vary and intermediate blockage is used to elucidate pathways. It is often valuable to use the same electrode to stimulate and then to destroy a localized area, with immediate recording and study of subsequent degeneration.

By combination of all these methods a great volume of data concerning central and peripheral nervous connections has accumulated and continues to grow. More recently the intimate connections of single or small groups of neurons have attracted much attention. The insertion of microelectrodes or micropipettes into single neurons allows the recording of their activity and such cells can be marked with tracers for subsequent structural work by injecting them with dyes or other substances from the recording electrode. By recording simultaneously from several cells linked together in small '*integrative units*' or '*microcircuits*' and combining the results with those from detailed studies of neuronal connections, a new era of analysis has begun (e.g. Lissak 1967, Shepherd 1974, Rakic 1975, Schmitt et al 1976). As a result of such methods, complex neuronal interactions have been explored, including: excitation, inhibition, facilitation, disinhibition, disfacilitation, and pre- and postsynaptic inhibition, neuromodulation and the like, in a somewhat inelegant neology! The role of synapses in all these events is fundamental; for the analysis of the latter structures other structural methods have allowed more detailed explorations and histochemical (particularly immunocytochemical) methods and electron microscopy have provided techniques of great importance.

PHYSIOLOGICAL TECHNIQUES FOR TRACING NERVE FIBRES

By the 1900s the disciplines of structural analysis of neural tissue by microscopy were well advanced and the general features of nerve cells and fibres had been in large measure established, their types detailed and the neuron theory widely accepted. The overall cellular arrangement of the central and peripheral nervous systems, including their autonomic components, were defined in terms sufficient to be highly useful in clinical diagnosis, though the underlying mechanisms remained largely obscure. Much had been contributed by neurologists, both in the nineteenth century, when combined clinical and laboratory activities were perhaps easier, and in the twentieth, despite the difficulties engendered by specialization and the increasing complexity of experimentation. By this stage, also, neurophysiological studies were proving very successful in localizing function and reflex activity. The spectacular evolution of electronics was beginning to provide accurate instrumentation for examining the functions of nerve fibres, the behaviour of synapses and various aspects of integrated cerebral electrical activity. The study of synapses was even more potently stimulated by the discovery of transmitter substances (Loewi, Dale and others), such as acetylcholine and adrenalin, with immense physiological, biochemical and pharmacological consequences. With these brilliant advances, structural investigation continued with the impetus of new microscopic techniques, including histochemical developments and electron microscopy.



DEVELOPMENTS IN LIGHT MICROSCOPY

The light microscope has become a highly flexible instrument, with refined optics, dark-field illumination, polarization, phase contrast, contrast interference (Nomarski), ultraviolet fluorescence, and other auxiliary techniques including: warmed stages for tissue culture, recording cameras for still, cine and time-lapse photography, computer-linked devices for micromeasurement, microdensitometry and equipment for microdissection and micro-injection. The phase-contrast microscope (Zernicke 1935) and its congeners, the interference (Francis Smith 1947) and contrast interference (Nomarski) microscopes have initiated a new era in cytology. Phase microscopy is extensively applied to nerve cells and neuroglia (Geiger 1963, Murray 1965). Interference and contrast interference microscopy can assess the refractive index, even in parts of one cell, and concentration, water content and dry mass in living cells (Ross 1967). Incident illumination of living tissue in situ is also a powerful method for analysis, e.g. of myelinated nerves (see, e.g. Williams & Hall 1970, 1971).

Ultraviolet microscopy can also offer increased resolving power and, far more importantly, selective absorption of frequencies by various substances, especially nucleoproteins. Caspersson (1936) evolved a technique applicable to single cells, which was widely applied in quantitative assessments of DNA and RNA in nerve cells by Hyden (1960), although little used in more recent years.

NEUROHISTOCHEMISTRY

Phase, interference and ultraviolet microscopy are adjuncts to histochemistry, especially cytochemistry. Histochemistry perhaps began with Raspail, a botanist, as long ago as 1830 but accelerated greatly with the discovery of methods for the identification of biological compounds (Pearse 1968). Many such tests are available for nervous tissues, both normal and pathological (Adams 1965). Specially valuable are the methods for identification of transmitter substances and associated enzymes in nerve

7.15 Some widely used methods of tracing the connections of neurons by intracellular labelling.

cells, fibres and synapses, ranging from the original chromaffin reaction of Henle (1865) to modern modifications (Coupland 1965, p. 1465), the Gomori method (1943), fluorescence techniques, and immunocytochemical methods. The latter two techniques in neuroanatomy (Falck & Hillarp 1959, Falck 1962, Fuxe et al 1970, Fuxe & Jonsson 1974, Nieuwenhuys et al 1978) have led to a new classification of nerve cells. Thus, the mammalian brain has been 'mapped' extensively in terms of the distribution of noradrenergic (NA), dopaminergic (DA), serotonergic (ST) and many other classes of transmitter-specific neurons and tracts (p. 889).

In the general field of neurohistology some other innovations must be mentioned. The staining methods such as the silver impregnation techniques of Bodian (1936) for nerve fibres, Glees (1946), Nauta (1950) and Fink-Heimer for terminal axonal degeneration and the dye methods of Einarson (1932) and Kluver (1953) for 'Nissl' granules (Kluver's method also stains axons) have all augmented the armory of experimental techniques.

In a resurgence of the use of Golgi's technique, its various modifications (e.g. Fox et al 1951) have been particularly applied to analyse the interrelations of small neuronal groups, especially interneurons. Golgi staining has an unexplained peculiarity in affecting only a fraction of cells, making the unravelling of intricate connections easier and often allowing the implication of quantitative histology, including microreconstruction and mathematical analysis of dendritic branching (p. 878). Such studies, carried out in a wide variety of vertebrates and invertebrates, have led to a rapprochement between the electrophysiological and anatomical investigation of small networks and individual neurons (e.g. Eccles et al 1967). Another potent technique in drawing together workers in separate disciplines has been electron microscopy.

ELECTRON MICROSCOPY

Though electron microscopes have been in use since the Ruska prototype of 1933, years elapsed before reliably thin sections could be prepared. Pearse & Baker succeeded in doing this in 1948, with an adapted Spencer microtome. Sjostrand (1967) has described these early struggles and the emergence of the modern ultramicrotome. Biological electron microscopy would have been impractable without the development of glass and diamond knives to cut the hard embedding media required: from the 1950s all the basic requirements were met and biological material was submitted to the increasingly high resolutions and magnifications of continuously improving electron microscopes, transforming structural cytology. Nearly four decades of application of supporting techniques has followed: heavy metal shadowing, replication methods, production of homogenate films, heavy metal staining including negative contrast, autoradiography, densitometry, elemental microanalysis, microreconstruction, cell fractionation methods depending upon differential centrifugation (of fundamental importance in neurochemistry), electron diffraction, scanning microscopy (including scanning transmission), freeze-fracture and freeze-etch methods, cytochemical and immunocytochemical staining and other techniques have multiplied the potentialities of electron microscopy. At the same time, there was a rapid advance in the interpretation of greatly enlarged intracellular detail and the growth of an experimental attitude and quantification in electron microscopy; otherwise the combinations of cytology, biochemistry, biophysics and molecular biology which have been so fruitful would not have occurred. In neuroanatomy such bonds have been most effective; the elucidation of the structure of myelin sheaths and of synapses are notable examples of their power. With improved cutting methods and orientation two main defects of electron microscopy have been largely countered: the small scale of sampling and the difficulty in equating the findings of light and electron microscopy. Techniques involving alternate thick and thin sections, for appropriate staining and examination, and even serial ultra-thin sections, have overcome some of these difficulties, and the development of scanning electron microscopy has introduced a new dimension, literally.

7.16 Part of a whole-mount preparation of a retina (rat) after prior horseradish peroxidase injection into the optic nerve. The tracer has passed in retrograde fashion to fill many ganglion cells and their processes. Polarizing illumination. Provided by E L Rees, Anatomy Department, UMDS, Guy's Campus, London.

OTHER MODERN TECHNIQUES (7.15)

In tracing neuronal circuitry, both central and peripheral, two new techniques have proved particularly valuable: the autoradiographic identification of labelled substances, absorbed by neurons and transported along neurites, and the retrograde transport of identifiable 'marker' substances (e.g. horseradish peroxidase, fluorochrome dyes). Both depend on physiological activities, in contrast to 'degeneration' techniques which use pathological reactions to experimental injury. They are also claimed to be more reliable (Jones & Hartman 1978) but each has peculiar advantages and disadvantages. The autoradiographic technique, introduced by Lasek (1968) and Hendrickson (1969), was popularized by Cowan et al (1972). Radioactively labelled amino acids or sugars are injected among neurons, which absorb and transport them along axons (usually combined in various macromolecules), where they are revealed by autoradiography with light or electron microscopy (Rogers 1973, Hendrickson 1975). The method can be either *anterograde* or *retrograde*, since movements occur in both directions within axons. However, the anterograde labelling technique is usually employed for autoradiography. These methods are now widely applied, confirming many previous findings but also revealing many new ones, e.g. the hypothalamo-spinal autonomic and olivo-cerebellar paths. It has also been shown to produce transneuronal effects (e.g. in the visual pathways).

The horseradish peroxidase, fluorochrome and other dye methods also depend on axonal flow (Matsumoto 1920, Lubinska 1964, and others, p. 881); but not until 1971 did Kristenson & Olsson show that labelled albumin and horseradish peroxidase could be used in tracing axons. The LaVails (1972) quickly confirmed this. Solutions of the enzyme are injected into nervous tissues or the cut surfaces (e.g. a severed peripheral nerve) are immersed in them. Uptake by nerve terminals and axons can be greatly enhanced by using a tracer linked chemically to a lectin such as wheat germ agglutinin, which stimulates endocytosis by the neuron. Iontophoretic injection into neural tissue can be used to reduce local damage. Material absorbed by axons is transported to the somata where it can be identified histologically. Alternatively the tracer can be injected or iontophoresed into neuronal somata through micropipettes and is then transported along axons in the anterograde direction (7.15). The method is applicable to all neurons and can be used with both light and electron microscopy. A large literature on this topic has accumulated (Winer 1977, Jones & Hartman 1978) and a wide variety of tracers is becoming available for this type of study.

Another notable development in research is the widespread applications of immunological techniques to neurobiological problems; e.g. immunohistochemical methods have helped to

localize neurotransmitters and their enzymes, pituitary hormones and their releasing factors and other specific proteins, with resolution often superior to customary staining or biochemical assays (Jones & Hartman 1978). These methods involve the production and identification of sites of antibody–antigen interaction in tissue sections. Several factors influence the distribution of such sites, complicating interpretation. These factors are as follows: (1) Production and purification of specific antibodies which bind only to the substance being investigated; however, the use of monoclonal antibodies has largely circumvented this problem, although there are other problems in their use, e.g. cross-reaction with other proteins which may share some amino acid sequences. Recently, molecular genetics has provided a relatively simple means of preparing highly purified antigens which can be used to refine antibody specificity greatly. (2) Adequate preparation of tissues, especially during fixation. Fixation is mostly designed to achieve an optimum compromise between preservation of structure and retention of antigenicity. The commonest fixative in use is formaldehyde; other aldehydes, with stronger cross-linking abilities, have proved less effective, although such combinations as periodate-lysine-paraformaldehyde has been used with advantage (Nakane & Kawaoi 1974). Freeze-drying and freeze-substitution and also cryosectioning can also be employed to minimize exposure to chemicals prior to labelling. (3) Selection of an appropriate visual marker, e.g. fluorescein isothiocyanate (FITC), rhodamine, horseradish peroxidase (HRP) or colloidal gold. FITC emits a high yield of green fluorescence (517 nm) when excited with blue light (peak excitation 490–500 nm), which in combination with modern fluorescence microscopes permits examination of, e.g. fine adrenergic fibres (Hartman 1973); disadvantages are: (*a*) lack of permanent preparations due to quenching in mountant or photodecomposition with time; and (*b*) fluorescent markers cannot be used in electron microscopy. HRP is used as a marker in two different ways. As a marker in immunohistochemical studies it can be conjugated directly with antibodies by a number of bifunctional cross-linking reagents, but this results in partial inactivation of peroxidase activity. A more recent development, the peroxidase-antiperoxidase method (PAP), in which antibodies to HRP are bound to peroxidase without inactivating it, had a great impact on immunohistochemistry, especially at ultrastructural level (Sternberger 1974). The large size of the PAP molecule (*c.*420 000 daltons) may, however, entail problems of penetration (e.g. in fine nerve terminals). A recent extension of the method has involved the use of suitably labelled antigens to identify different neurons and satellite cells, either in suspension after isolation from whole tissue or growing and differentiating in culture prior to fixation. Thus oligodendrocytes can be labelled in vitro with anti-galactocerebroside, astrocytes with anti-glial fibrillary acidic protein (GFAP), Schwann cells with anti-RAN I and some neurons with antitetanus toxin (Raff et al 1978). Moreover, antisera to certain components of the myelin sheath and to neural growth factor are used in studies of the control of myelinogenesis and of ontogenetic and pathological mechanism in nervous tissues.

Another label which is proving very useful is colloidal gold, to which can be attached antibodies for detecting antigens as described above. The particles can be prepared in a wide range of sizes (5–50 nm) and can be used for both light- and electron-microscopic detection.

Other relevant techniques include: autoradiography (Rogers 1967, 1973), cine and time-lapse photography (Rose 1963), microreconstruction (Gaunt & Gaunt 1978), microphotometry, micromanipulation (Kopac 1960), neuronal counting techniques (Konigsmark 1970, Corsellis et al 1975), morphometric analysis (Weibel & Elias 1969), the construction of models as functional analogues (Weiner & Schade 1963) and various methods of computerized image analysis. Enough has been said to show the dependence of neuroanatomy on technical developments. Despite widespread misapprehension, neuroanatomy (and anatomy in general) has never been an entirely morphological, merely descriptive discipline, though it can descend and frequently has to this sterile level. However, there have always been those, such as Willis, Harvey or Sherrington, who ignore the artificial separation of structure and function in the nervous or any other system. Unfortunately, the contribution of one or the other is often imbalanced. After a considerable and regrettable period early in this century of separation of the disciplines concerned in morphology and function (perhaps chiefly due to exigencies of teaching organization in medical schools), the resulting isolationism now shows signs of dissolution, particularly in studies of the nervous system. Preoccupation with the minutiae of form or with the nervous impulse have borne their separate fruit and we can now pass on to wider prospects. As morphologists become more experimental and functionalists examine the structural arena of their experiments more closely, instrumentation and outlooks are becoming increasingly similar and promise a new cohesion. We may at least be much nearer to a comprehension of the basic units in central nervous function. It is to the individual elements so organized that we must now turn.

CYTOLOGY OF THE NERVOUS SYSTEM

The two previous general sections have concerned the general principles of the organization of the nervous system and methods of approach to it. We will now consider its cellular elements, an understanding of which is essential to any concept of brain function (Schmitt et al 1967, 1970, 1977). Nervous tissue contains two major components: (1) excitable *neurons*; and (2) non-excitable *neuroglia* and *ependyma* in the central nervous system, and Schwann *cells* (lemmocytes) and related cells in its periphery.

The Neuron

Neurons vary considerably in shape and size but they possess many common features. In comparison with other cells, all have a large surface area, specialized by their molecular composition for reception, conduction and transmission of information. The nucleus of each neuron is surrounded by a cytoplasmic mass containing various organelles, together constituting the *soma*, *perikaryon* or *cell body*. The narrow processes extending from the soma, collectively termed *neurites*, are either *dendrites* or *axons*; a neuron's dendrites are usually multiple and conduct excitation towards the soma, while axons are single and conduct away from the soma. The cytoplasm of the soma contains numerous basophilic *Nissl bodies* or *granules* (7.17), except at a conical projection leading to the axon, the *axon hillock*, its continuation being the *initial segment* of the axon. Sometimes an axon emerges from the base of a dendrite and in a few highly specialized small neurons an identifiable axon is altogether lacking. From other angles of the soma spring *primary dendrites*, branching repeatedly to form a *dendritic tree*. An axon may have *collaterals*, usually of finer calibre than the main stem. Axons usually end in several fine *axon terminals* or *telodendria*, apposed to other neurons at *synapses*, or with effectors such as muscle fibres at *neuromuscular junctions* or with glands; adipose tissue also receives efferent terminals (p. 908). In some cases neurons synthesizing neurohormones have axon terminals which end on blood vessels, into which they release their secretions directly. The axonal plasma membrane is the *axolemma*; its contained cytoplasm is *axoplasm*.

Neurons range in size from microneurons, with somata 7 μm or less across, to some of the largest cells of the body, e.g. spinal ganglia have somata 120 μm in diameter. In some of the larger neurons (e.g. cerebellar Purkinje, cerebral Betz neurons) the soma, which is proportionately large, has a tetraploid chromosomal content (Herman & Lapham 1969). The size of the

soma and its nucleus is related to the large volume of cytoplasm contained in its dendrites and axon; the axon may be as much as a metre in length and more than a hundred times the volume of the soma.

HISTOLOGICAL DEMONSTRATION OF NEURONS

Our knowledge of neuronal structure has in large measure resulted from the use of special neurohistological techniques (p. 869) which will now be briefly considered. Though the general methods of light microscopy show neuronal somata, their neurites are not stained sufficiently to trace them with any confidence. Various methods of metallic impregnation, particularly with silver salts, do stain the neurites as well as the somata. The most informative of these techniques, in terms of individual cell structure, are the Golgi methods (p. 870) which entail the precipitation of silver chromate in individual neurons, which can be shown in their entirety in thick sections; since only a small percentage of cells are stained, they may be demonstrated with great clarity, their black spidery profiles contrasting with a clear background (7.17). Although in earlier years the method was attacked as merely demonstrating artefactual deposits of metallic salts, electron microscopy has confirmed that it gives an accurate representation of neuronal structure in finest detail. Other methods of demonstrating entire neurons involve the use of various tracers, either microinjected directly into the somata of living cells or taken up and transported actively by their axons (vide infra).

Various techniques stain *sections* with silver salts, some of them preferentially precipitated by the neurofilaments (*neurofibrillary* stains) (Gray & Guillery 1966), others staining the entire cytoplasm (7.18D); these include the ammoniacal silver nitrate methods of Bielschowsky and subsequent modifications, Bodian's silver proteinate and the silver nitrate techniques by Holmes, Palmgren and others. Ramon y Cajal's block staining method is a similar process except that tissues are bulk stained, then sectioned afterwards. Modified reactions to silver salts have been used to show anterograde axonal and terminal degeneration in sections, the staining of normal axons being suppressed (Nauta and Glees methods) (7.14, see also p. 870). Modifications of such techniques for use in electron microscopy (e.g. Fink-Heimer) have been introduced but have been largely superseded by tracer methods, e.g. with horseradish peroxidase (vide infra).

The sheaths of myelinated fibres (p. 902) require special methods because the myelin, which is mainly lipid, is removed by routine histological processing. Salts of the metal osmium are soluble in lipid and precipitate to give it a black or brown colour, and so can be used in the fixation of neural tissues to preserve myelin. However, myelin sheaths also contain some protein and may be lightly stained with such stains as haematoxylin and Luxol fast blue (7.18C). Staining with chromium salts can demonstrate *degenerating* myelin sheaths (Marchi), now rarely used because of uncertainties of interpretation (p. 870). General cytological stains can be used to demonstrate various organelles, the most useful, Nissl stains, being basic dyes combining strongly with nucleic acids which are abundant in neuronal nuclei and cytoplasm (mainly ribosomal RNA). Cresyl fast violet (7.14) and toluidine blue are also widely used for this purpose. Some stains also demonstrate mitochondria, particularly in axon terminals and modifications of these methods can show *degeneration of axon terminals* due to experimental trauma.

Electron microscopy has revolutionized our concepts of neuronal structure and has provided a wealth of detailed data not obtainable by any other method. However, light microscopy is also an essential tool, particularly when correlated with electron microscopy, since three-dimensional reconstruction from electron micrographs is laborious and limited even when assisted by computer technology.

All the above methods are applicable to dead material; however, much may also be learnt from neurons stained by supra-vital methods. Methylene blue was early found to stain the entire cytoplasm of neurons, showing individual cells as strikingly as Golgi methods; but its use is restricted largely to thin or small whole tissue mounts of e.g. peripheral and embryonic nervous systems, where penetration and staining are rapid.

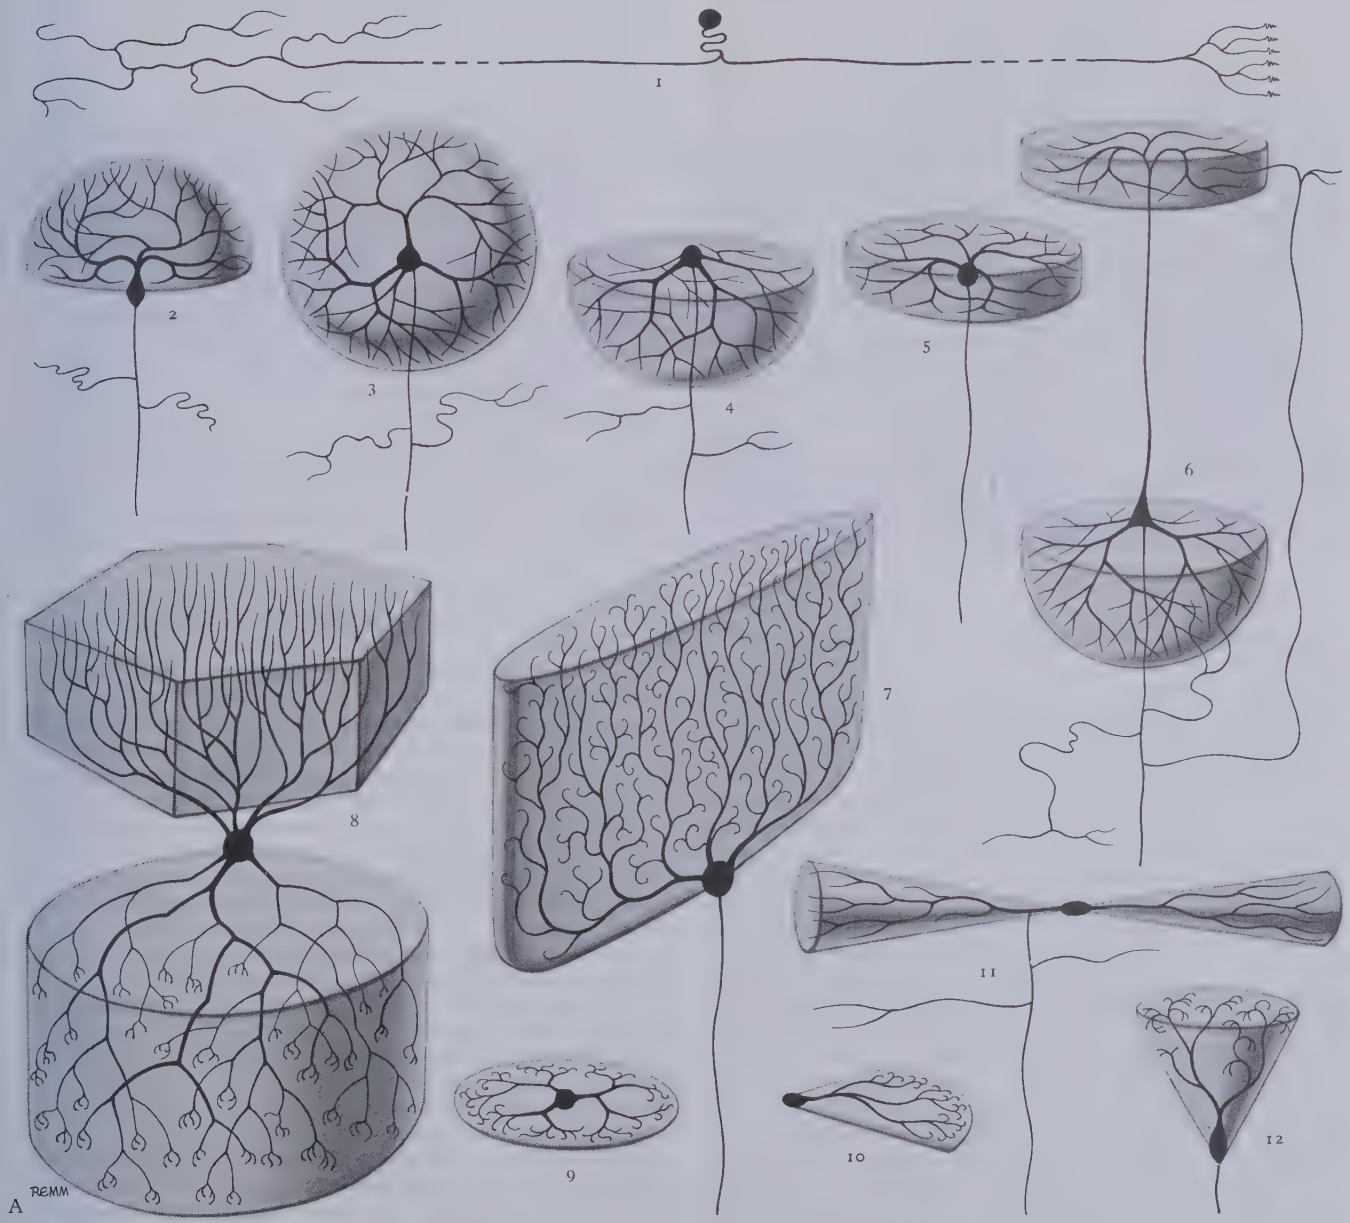
Tracer methods have been used extensively in recent years to demonstrate the pathways of axons and the positions and structures of their cell bodies. Such techniques are generally applied to living animals; two distinct methods of approach can be used, *anterograde* and *retrograde* (see p. 870). In anterograde methods, a tracer substance is generally injected through a micropipette into individual neuron cell bodies, then time is allowed for axonal and dendrite transport (p. 881) to carry the tracer to its extremities (i.e. in the same direction as axonal conduction). The tissue is then fixed and sectioned and the tracer visualized. In *retrograde* methods, a tracer is placed by injection in the vicinity of the axon terminals or, after slight damage or complete section, close to non-terminal regions of axons. The tracer is taken up by the axon by active processes and transported back against the direction of nerve conduction to the cell body (and dendrites in some cases), where again it can be visualized after fixation. The most widely used tracer is horseradish peroxidase, whose presence can be detected by its action on hydrogen peroxide in the presence of a chemical reactant which produces a coloured precipitate. This can be seen clearly as a red-brown deposit or more conveniently can be visualized by dark-field microscopy.

Other tracers include enzymes or particulate substances conjugated with lectins (e.g. wheat germ agglutinin), which are more readily taken up by axons, and coloured dyes (e.g. procion yellow, true blue). Many of these can fill neurons to give a result strikingly similar to those of the Golgi methods, as well as providing data on the connectivity of neurons. In general, such techniques have in the last 20 years revolutionized the whole subject of detailed neuroanatomy and it has become apparent that many of the 'classic' pathways have to be re-examined by modern methods.

Neuro-immunohistology

Another approach which is bearing much fruit is the application of immunohistochemistry to nervous tissue. These methods use antibodies raised against specific chemicals (e.g. neurofilament proteins, transmitter enzymes), which can detect the presence of these chemicals in tissue sections by immunofluorescence or immuno-electron microscopy. Thus, e.g. it is possible to determine the presence of growing axons in developing or regenerating tissue even when routine neuroanatomical methods fail, and the type of neurotransmitter(s) used by particular neurons can be determined. The use of this technique has also helped to revolutionize our understanding of the nervous system in all its wide variety (see also p. 889).

GENERAL STRUCTURE OF NEURONS



Neurons may be classified according to their pattern of neurites, their physiological actions, transmitter substances and various other features. Several schemes of classification based on cell shape are current, mostly based on the ramification of neurites. A traditional approach (p. 863) distinguishes: (1) *unipolar neurons*, in which a single extension from the soma divides into both dendritic and axonal branches, e.g. mesencephalic trigeminal sensory neurons, dorsal root ganglion neurons (sometimes termed *pseudo-unipolar* because their unipolar form is secondary during development); (2) *bipolar neurons* with an extension at each pole, e.g. retinal bipolar cells, neurons of the cochlear and vestibular ganglia; (3) *multipolar neurons*, with several neurites, e.g. most central neurons. Though this scheme (7.17A) is descriptively useful, it has limited physiological significance. Central neurons may also be grouped as large, Golgi type I neurons with long axons connecting remote regions (Ramon y Cajal 1911) and small Golgi type II neurons (microneurons) with short axons ending near their somata or else entirely absent (7.17). The latter type are often inhibitory, e.g. periglomerular cells in the olfactory bulb (p. 1030). Some microneurons lack an axon, conduction being apparently bi-directional along dendrites, e.g. in *amacrine cells* of the retina (p. 1202) and granule cells of the olfactory bulb. They may be a typical element of all main sensory pathways. Small inhibitory neurons appear to be responsible for an important interaction between neurons in sensory pathways, by which maximally excited neurons inhibit less excited adjacent neurons through inhibitory interneurons, thus 'sharpening' sensory patterns at

various levels (7.8 and p. 865), a process termed *lateral inhibition*.

Central neurons are also classified by the shape of their dendritic fields (7.17). Those with dendrites filling a spherical volume are termed *stellate*, a type common in the cerebral cortex and some nuclei of the brain stem and spinal cord. The soma of *pyramidal neurons* is appropriately pyramidal or conical and *basal dendrites* emerge from its basal angles to fill a hemispherical volume, an *apical dendrite* often emerging from the soma to give a second dendritic field at some distance from it, e.g. cortical pyramidal neurons. Somata with dendrites emerging at one or both ends are described as *fusiform*.

Many variations exist depending on the pattern of the afferent fibres, the synaptic sites and the mechanical or other effects of neighbouring neurons. A most remarkable dendritic field is that of the cerebellar Purkinje neurons (7.17B), in which a primary apical dendrite branches to form a complex radiating nearly two-dimensional array. *Glomerular neurons* may have a few dendrites with highly recurved short apical branches, where most synaptic contact occurs, e.g. olfactory mitral and tufted neurons (p. 1030), and in the lateral geniculate nucleus, certain thalamic nuclei (p. 1001) and cerebellar granule cells (p. 972).

Attempts to classify dendritic patterns by their geometry, though useful for description, have an uncertain functional significance at present. Perhaps more important is the mathematical analysis of dendritic patterns by their frequency, dimensions, the spatial distribution of the branches and their mode of ramification, their surface and volume, and the frequency, type and spatial location of their synaptic endings, since all these parameters are linked to electrical activity. Such studies are still in their early stages, but computer technology has greatly facilitated this area of research and shows much promise as a powerful approach to understanding the structural basis of electrical activity in neurons.

7.17A Scheme showing pattern variations of neuronal geometry: (1) unipolar, sensory ganglionic neuron; (2) bipolar neuron; (3) stellate (isodendritic) neuron, with (4), (5), and (11) which are modifications of this pattern; (6) pyramidal neuron with an apical and a series of basal dendrites and recurrent axon collaterals from the cerebral cortex; (7) Purkinje neuron from the cerebellar cortex; (8) Golgi neuron from the cerebellar cortex; (9) and (10) amacrine cells lacking axons; (12) glomerular neuron (mitral cell) from the olfactory bulb, showing recurved dendritic tips.

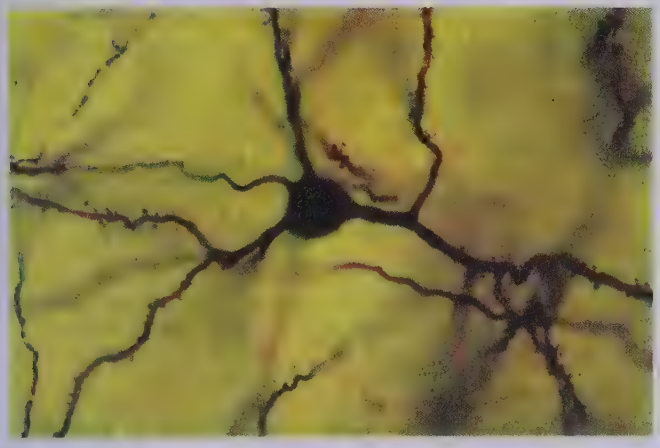
7.17B Purkinje neuron from the cerebellum (rat) stained by the Golgi-Cox method, showing the extensive two-dimensional array of dendrites. Provided by Martin Sadler and M Berry, Anatomy Department, UMDS, Guy's Campus, London.

STRUCTURAL PARAMETERS OF DENDRITES

As already stated, there is considerable variation in the geometry of dendritic trees; however, detailed analysis of their development and adult morphology indicates that there are some common laws which govern their initial generation and final form. These have two aspects: firstly the mechanisms by which dendritic trees are built and maintained; secondly, the functional significance of dendritic patterns in terms of neuronal electrical behaviour.

Techniques of dendritic tree analysis have developed considerably since the pioneering work of Sholl (1953) (see also Aitken & Bridges 1961) who studied the mathematical features of cortical stellate neurons by counting the frequencies of intersections between dendrites and a series of imaginary spheres constructed concentrically around the cell body. This technique proved difficult to apply to less symmetrical neurons and more detailed quantitative studies were made by serial reconstruction (e.g. Mannen 1968) or by examining special types of neurons which lent themselves particularly well to planar measurement. A neuron that has provided a useful model for dendritic analysis has proved to be the cerebellar Purkinje cell, which has an extremely flat dendritic tree accessible to computer-assisted assessment of different parameters (length of dendrites, frequency of branching, types of branching, etc., see the review of this subject by Berry 1980). The mathematical basis of such studies (including the subject of network analysis) is beyond the scope of this account (for details, see Ten Hoopen & Reuver 1970, Hollingsworth & Berry 1975, Berry 1980).

To summarize these results briefly, it has been found that more than 80% of the neuronal surface area (excepting the axon) is situated in the dendritic tree. Most branches are dichotomous in form and occur randomly within a volume determined by various factors including the proximity of other neurons which may compete for space. The initial growth of primary dendrites from the cell body appears to be under epigenetic control (p. 113), i.e. it is determined by interactions between the genome of the cell and its immediate environment, in a manner not well understood; there is much evidence that subsequently the branching pattern reflects the formation of contacts between the dendrite and the growth cones of axons it is destined to form synapses with, dendrites branching upon meeting a growth cone and continuing until the next contact (Berry 1980). The frequency of branching therefore reflects the frequency of synaptic interactions. Once established, dendritic trees may be continually remodelled (Sadler & Berry 1988), as noted in observations on living cells in vivo, labelled with intravital tracers and examined at intervals over a period of months (Purves et al 1986), providing for detailed adjustment of neuronal behaviour.

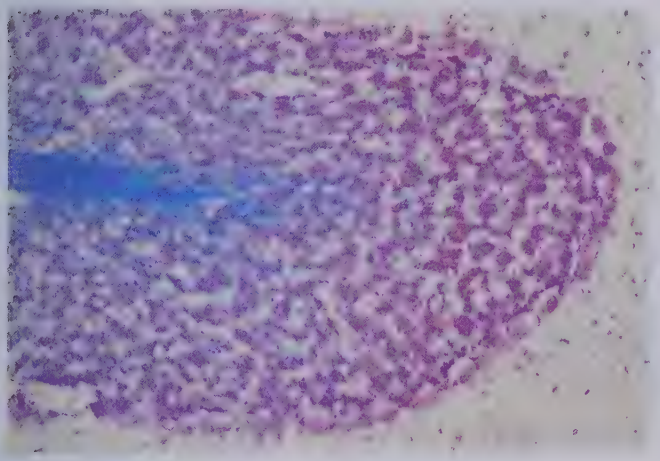


Counts of *dendritic spines* (an indication of synapses, p. 882) show that in some neurons many thousands are spaced over much of the dendritic tree (Gelfan & Rapisarda 1964, Gelfan et al 1970). Such data indicate that different populations of neurons, with the same general mode, have their own ratios between somatic and dendritic surface volumes, spine counts, etc. (Lindsay & Scheibel 1974). The import of these parameters is in numbers of afferent synapses, their positions and patterns of electrical disturbance at cell membranes following their activation (Rall 1977). A basic feature is the relative distribution of excitatory and inhibitory synapses; this can only be estimated by electron microscopy, with limited statistical validity (p. 886). Microelectrode studies are a possible means of analysis but dendrites are too small for ease of intracellular recording and only elaborate mathematics can extract any meaning from the records. However, it has long been known that dendritic defects can be correlated with behavioural deficits, e.g. neonatal mice, made thyroid hormone-deficient to simulate human cretinism, show behavioural retardation; the dendritic trees of their cerebral cortical neurons are smaller, with fewer branches (Eayrs 1955).

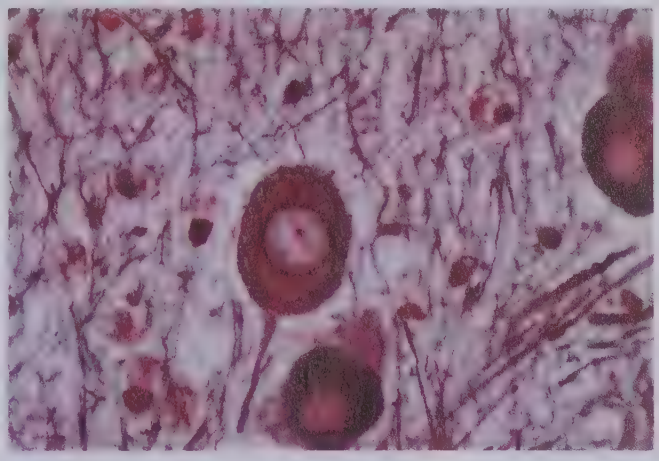
PHYSIOLOGICAL PROPERTIES OF NEURONS

Neurons typically receive, conduct and transmit *information* (p. 860), coded in transient electrochemical changes in their membranes (Katz 1966, Kuffler & Nicholls 1977). These changes consist of rapid fluxes of ions across the plasma membrane, against a background of steady, transmembrane electrical potential difference.

The resting potential (7.19) of a neuron is identical to the transmembrane potential in non-excitable cells. In most neurons it is about 80 mV, inside negative. Such bio-electrical potentials are due to differences in the concentration of anions and cations inside and outside, which depend on the selective permeability of the plasma membrane and the active transport of ions, particularly sodium and potassium, across it. These factors result in a high concentration of potassium and negative, non-diffusible ions (proteins, etc.) and low concentration of sodium and chloride ions *inside* the cell, compared with external concentrations of these ions. Calcium in the cell is also at much lower concentration than in extracellular fluids. The resting potential can change either by *graded potentials* or *action potentials*. Graded potentials occur mainly across the membranes of *dendrites* and *somata*; they are typically transient increases or decreases in resting potential, i.e. the cell is relatively *hyperpolarized* or *depolarized*. Action potentials are transient complete reversals of polarity across the membranes of *axons* (and some large dendrites which are like axons in structure).



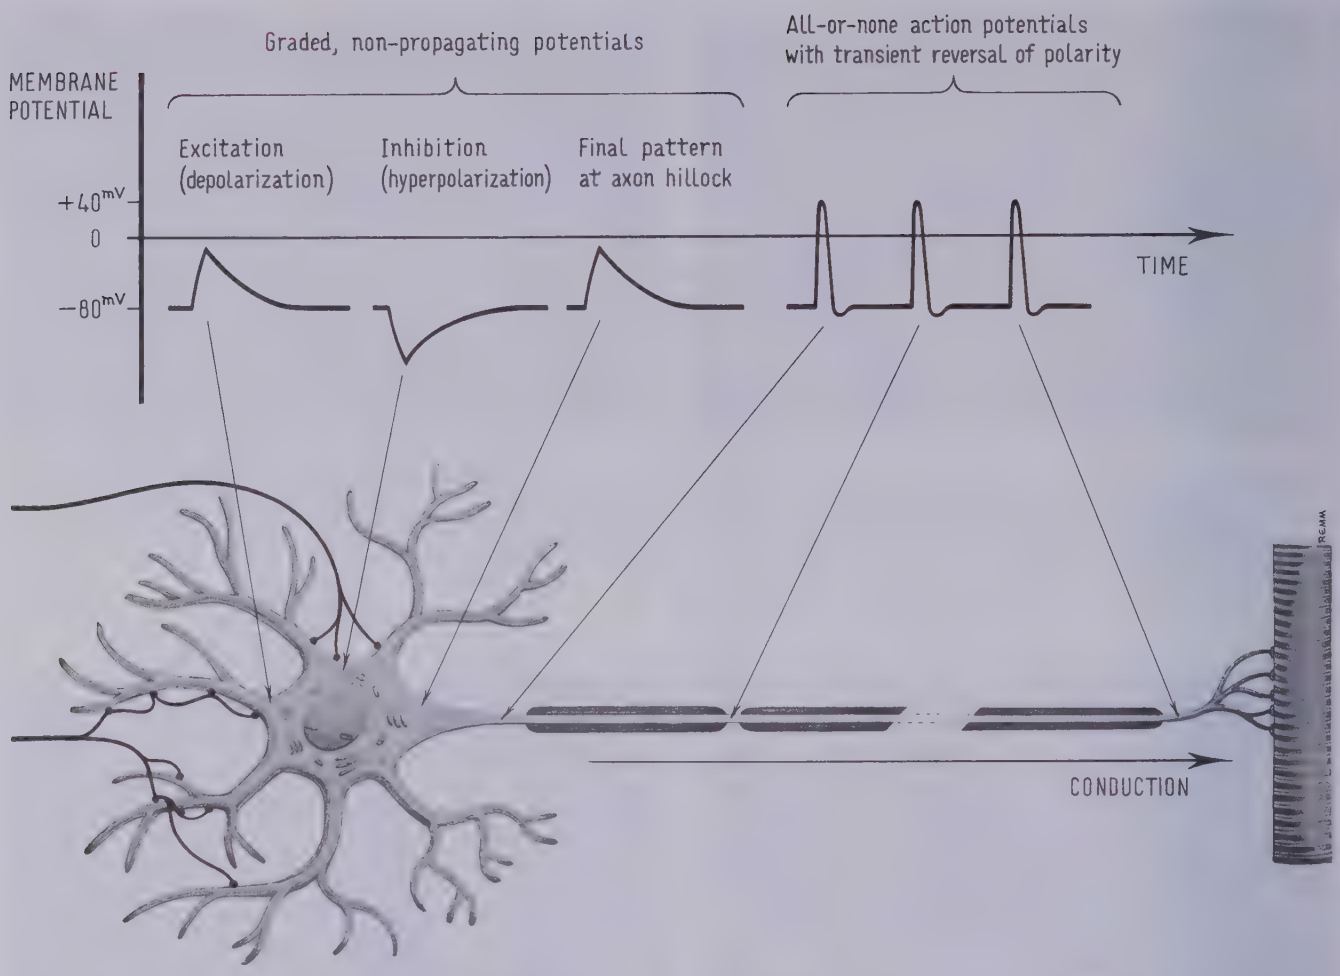
Graded potential variations may be *excitatory* or *inhibitory* to the neuron. When excitatory, they accompany an increased permeability to sodium or calcium ions, which flow down their concentration gradient into the cell, progressively *depolarizing* the membrane towards zero potential. This influx results from the transient opening of ionic channels within certain proteins (sodium or calcium gates). The scale and timing of depolarization at a particular locus is related mathematically to the stimulus



7.18 Different neurohistological methods. A. A high-power light micrograph showing part of a pyramidal neuron from the cerebral cortex of a rat, prepared by the rapid method of Golgi. The bases of several dendrites covered with dendritic spines and a thin axon (left) are visible. Preparation supplied by A. R. Lieberman of University College, London.

B. A low-power light micrograph of groups of interweaving axons from the medulla oblongata of a cat, stained by the Holmes' silver method. Preparations B–D supplied by E L Rees of the Anatomy Dept., UMDS, Guy's Campus, London.

C. A group of neuronal perikarya (purple) amongst bundles of myelinated fibres (blue), from the cerebellum of a rat. Stained by the cresyl fast violet-Luxol fast blue method.



D. A section through the mesencephalic nucleus of the trigeminal nerve (rat), stained with the Holmes' silver nitrate method to show large unipolar neurons from one of which a dendro-axonal process is emerging.

strength. Adjacent regions of membrane are also depolarized, but with decreasing amplitude at increasing distances from the locus. The larger the initial depolarization, the greater is the spread of its effect to the adjacent areas of membrane. This allows a *summation* of the effects of multiple excitatory stimuli applied at different loci of the receiving surface. Inhibitory stimuli, believed to act mainly by an increasing inflow of negatively charged chloride ions, tend to *increase* the membrane potential (*hyperpolarization*), opposing or reducing the *total excitatory state*.

The action potential, nerve impulse or **spike potential**, as seen in peripheral nerves, is in contrast a brief complete, *reversal* of polarity, due to the influx of sodium ions, followed by a rapid return to the resting potential as potassium ions flow out, the whole process being completed in about 5 milliseconds (Hodgkin & Huxley 1952). For a particular neuron, the *amplitude* and *duration* of successive action potentials are identical; however much a stimulus exceeds the *threshold value*, the actional potential is the same size and is thus said to be an all-or-none response. Once initiated, an action potential spreads rapidly; but, unlike graded potentials, its size and timing do not alter; the wave sweeps rapidly over the membrane at a constant rate and does not diminish with distance. It is therefore a *propagated* and *non-decremental* event. After the action potential, however, there is an irreducible *refractory period*, during which action potentials cannot be elicited; this fixes a maximum frequency possible and varies with the size of the axon diameter. The action potential is the basis of neural conduction and communication within the nervous system which is thus *frequency-coded*. It should be noted that variations may occur in the detail of ionic conductance changes; thus in central axons, the recovery phase of the action potential is not dependent on potassium efflux but on general current leakage.

Graded and action potentials are functionally interrelated at particular regions of neuronal surfaces; e.g. in a motor neuron, the *graded* potentials of the dendrites and soma depolarize the axon hillock to initiate *action* potentials in the initial axonal segment. The greater the graded somatic depolarization becomes, the more frequent are the action potentials; thus, the *state of excitation* of the soma is directly related to the *frequency of the action potentials* in the axon. When an action potential reaches the axonal terminals, it causes a graded depolarization of the presynaptic membrane and as a result discrete amounts of a *neurotransmitter substance* are released to change the degree of excitation of the next neuron, myocyte or glandular cell. Closely grouped action potentials (*trains* or *volleys*) are naturally more effective than single 'spikes' in releasing neurotransmitter; extracellular enzymes often limit the action of neurotransmitters.

Though a change from a graded to an action potential usually occurs in the initial axonal segment, in many peripheral receptors with an axon-like dendrite (e.g. cutaneous sensory neurons) it occurs close to the sensory endings, often at the most peripheral

7.19 The types of change in electrical potential which can be recorded across the cell membrane of a motor neuron at the points indicated by the arrows. Excitatory and inhibitory synapses on the surfaces of the dendrites and soma cause local graded changes of potential which summate at the axon hillock and may initiate a series of all-or-none action potentials, which in their turn are conducted along the axon to the effector terminals.

node in myelinated fibres. In such cases, the graded potential itself occurs at the sensory ending (a sensory potential, p. 907) where the sensory stimulus is received.

In amacrine neurons (p. 1202) and other microneurons lacking true axons, *all* electrical activities may be graded; such neurons are able to conduct electrical changes in any direction from the locus of stimulation. In neurons with axons conduction is naturally unidirectional, from dendrites and soma to axon terminals (*orthodromic conduction*); when artificially stimulated in their periphery, axons can conduct centripetally (*antidromic conduction*), such electrical changes invading the soma where they can be detected with a microelectrode.

Due to their mode of synaptic excitation and decremental conduction of dendrites and cell bodies, neuronal shape and the distribution of their excitatory and inhibitory synapses must be related to the neuronal input and output. A full analysis of these parameters may be expected to shed light on the functions of neurons and their interactions, and much attention has been paid to this area of research.

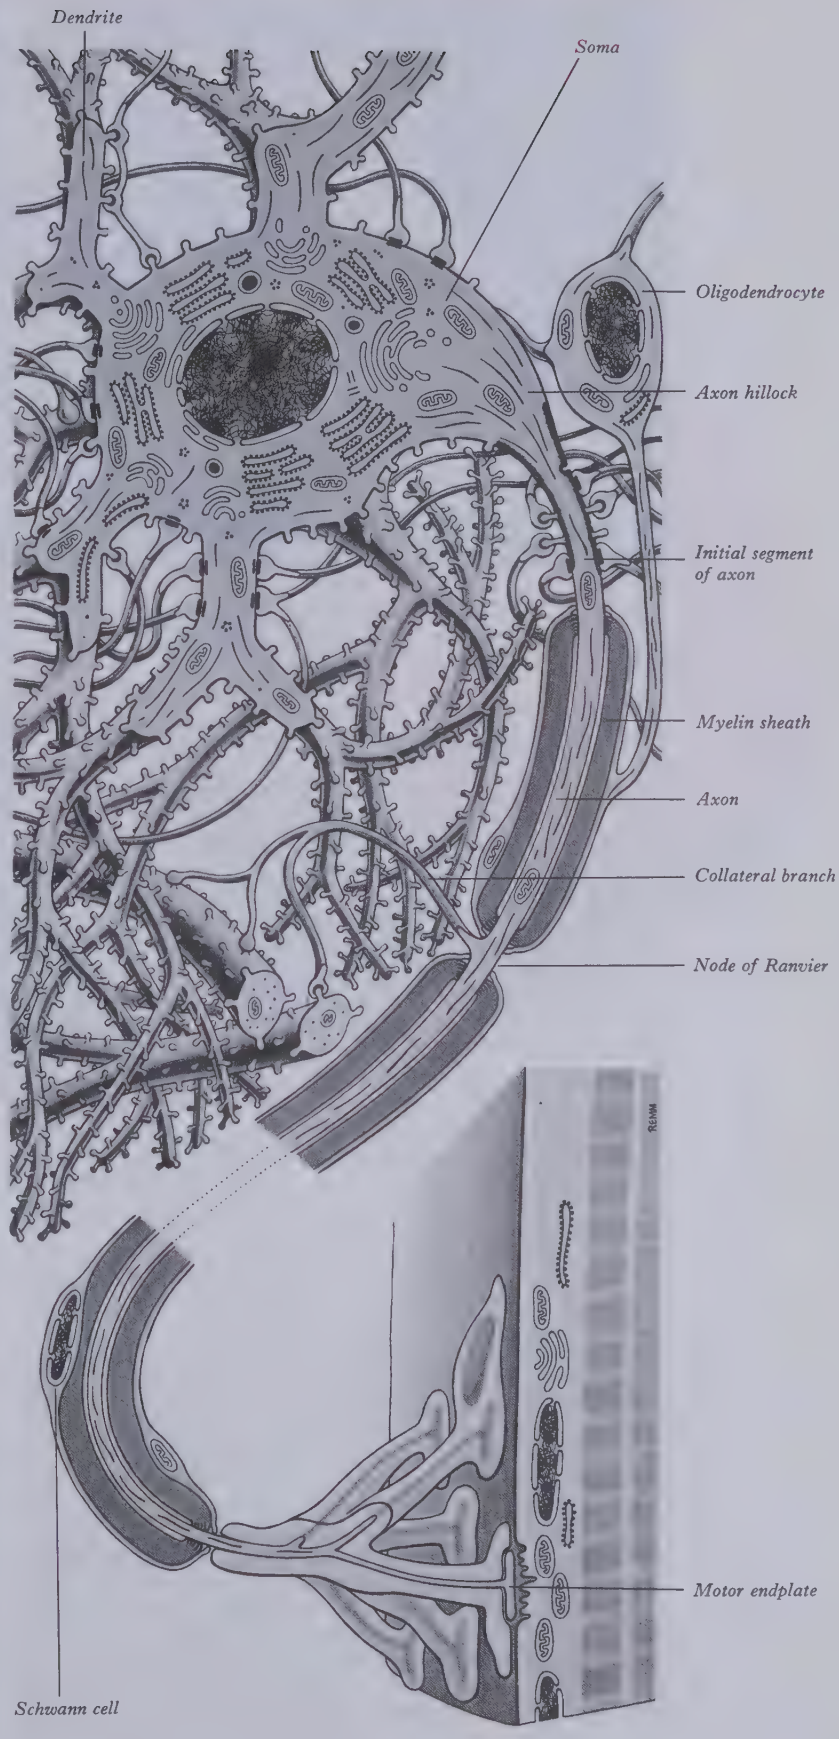
NEURONAL ULTRASTRUCTURE

Since the early studies by Palay & Palade (1955), Robertis & Bennett (1955) and others, our information on neuronal ultrastructure has increased greatly (Peters et al 1976, Palay & Chan-Palay 1977). As in light microscopy it is useful to distinguish between regions consisting mainly of neuronal somata and dendrites ('grey matter') and those dominated by regular arrays of axons constituting tracts ('white matter'). Within the grey matter, the neuronal somata are surrounded by complex regions of axon terminals, dendrites and neuroglial processes, forming the *neuropil* (e.g. Peters et al 1970).

The cytoplasm of a typical soma is rich in granular and agranular endoplasmic reticulum (7.20,21) and free polyribosome, the latter often congregated in large groups associated with granular endoplasmic reticulum; these aggregates are visible by light microscopy, because of their constituent RNA, as basophilic *Nissl* or *chromatin bodies* or *granules*; these are more obvious in large, highly active cells, such as spinal motor neurons, where *stacks* of granular endoplasmic reticulum occur (7.21). The *nucleus* is characteristically large, round and euchromatic, with one or more prominent *nucleoli*, as in all cells engaged in a marked degree of protein synthesis. Numerous mitochondria act as sources of energy for cellular activities. Lysosomes occur in moderate numbers and Golgi complexes form distinct groups, particularly near the bases of main dendrites and opposite the axon hillock. *Neurofilaments* and *microtubules* are abundant, bundles of the former being the 'neurofibrils' of light microscopy; both occur in the soma and extend along *dendrites* and *axons*, in proportions varying with the type of neuron and cell process. Dendrites are usually richer in microtubules than axons, which may be almost filled by neurofilaments. Though their bundles diverge at neuritic branching, tubules and filaments do not themselves branch. Actin microfilaments have also been described in neurons, as in most cells (Lasek & Hoffman 1976).

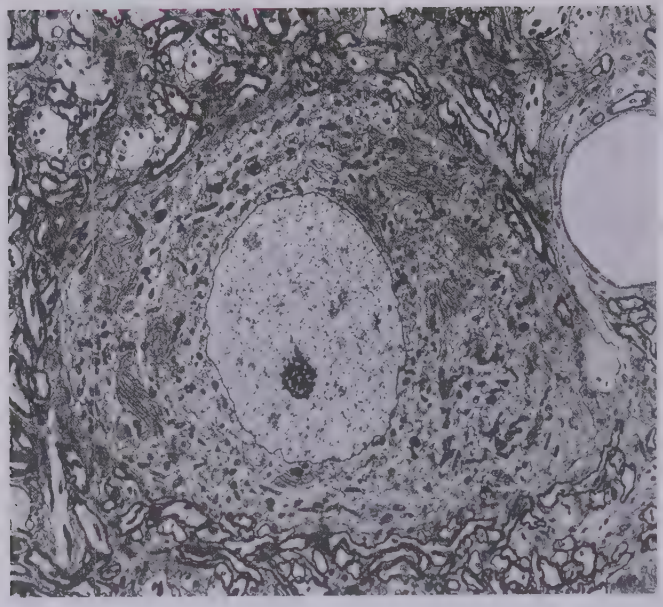
Centrioles, formerly believed absent from mature neurons, have been seen in every type examined, perhaps concerned in the generation or maintenance of the microtubular apparatus during development and subsequent life, rather than in cell division. (Neurons cannot undergo mitosis, once they are formed in the

prenatal period, see p. 917.) In some neurons centrioles associated with ciliary projections have been reported; though such structures are common on the surfaces of developing neuroblasts, cilia also occur in mature cells; their significance, except at some sensory terminals, is obscure.



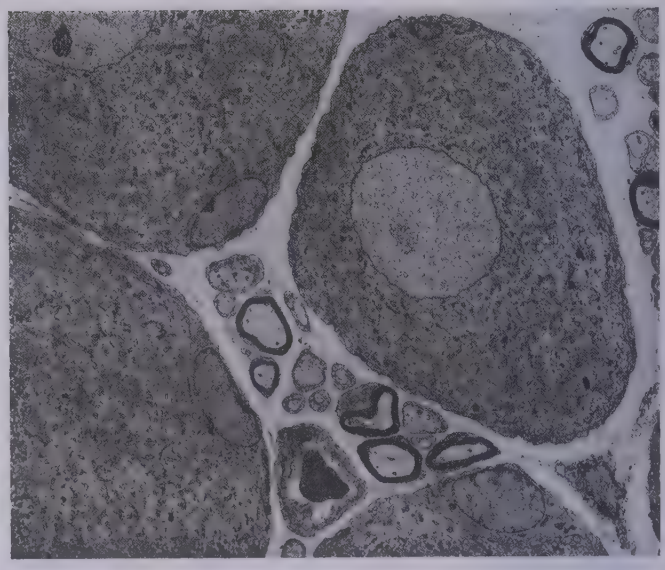
Other inclusions are also common in the neuronal cytoplasm; *pigment granules* appear in certain regions (Barden 1969); e.g. the substantia nigra (p. 894) has a *neuromelanin*, probably a waste product of catecholamine synthesis in these neurons. In the locus coeruleus a similar pigment, rich in copper, gives a bluish colour to the neurons. Some neurons are unusually rich in certain metals, e.g. zinc in the hippocampus, iron in the oculomotor nucleus. These metals may form part of special enzyme systems. Ageing neurons accumulate granules of *lipofuscin* (senility pigment), especially in spinal ganglia, a breakdown product of lysosomal action.

Dendrites share some features of the somata, containing: microtubules, neurofilaments, mitochondria, a few lysosomes, ribosomes, agranular and sometimes granular endoplasmic reticulum (7.20, 25). Axons are similar in these respects, except that they contain no ribosomes. The agranular endoplasmic reticulum in neurites often forms perforated transverse septa or longitudinal tubules and spherical vesicles. Various types of vesicle cluster near the points of neurotransmission (vide infra, p. 884).

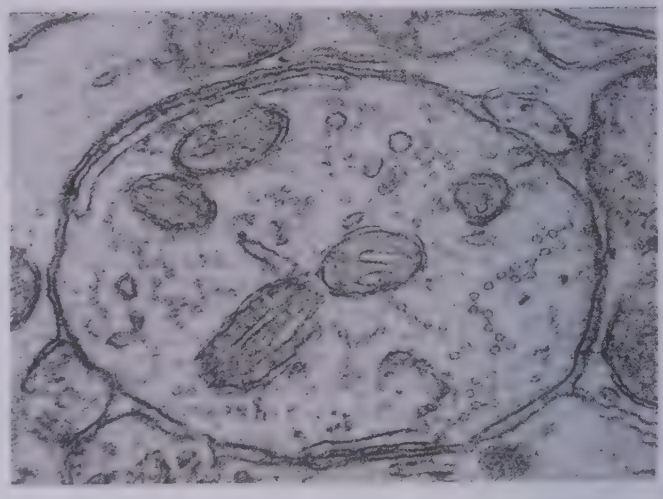


As stated previously, various features of neurons indicate high levels of protein synthesis. The significance of this is probably manifold. Maintenance and repair of cytoplasm are necessary in all cells and the huge total volume of cytoplasm within the soma and neurites of many neurons must demand a high protein synthesis simply for these routine activities. Other proteins (enzyme systems, etc.) are involved in the elaboration of neurotransmitters and in the reception of stimuli. Various enzymes occur at the surfaces of neurons where they are associated with ionic transport, e.g. sodium and potassium stimulate ATP-ase and the 'second messenger' systems mediated by the adenylcyclase and phosphoinositol pathways. Although the apparatus for protein synthesis (including RNA and ribosomes) occurs throughout the soma and dendrites, it is usually absent from axons, leading to the question of how transmitter substances and other materials are transported to neuronal terminals.

AXOPLASMIC FLOW



Neuronal cytoplasm, as in other cells, is in continual motion; in tissue culture bidirectional streaming of vesicles along axons is clearly visible and there is indisputable evidence that similar movements occur in vivo, resulting in a net transport of materials from the soma to the terminals, with a lesser movement in the opposite direction (Weiss 1970). Experiments with radioactive substances (e.g. from the retina along the visual pathway) and investigations involving the ligature and subsequent examination of central tracts and peripheral nerves (Kapeller & Mayor 1967) show that *two major types of transport* occur: one slow, the other relatively fast. The first is a *bulk flow of axoplasm* which occurs only in the anterograde direction, transporting cytoskeletal proteins and soluble, non-membrane bound proteins. This moves at about 0·1–2 mm a day, the *slow transport*. In contrast, *rapid transport* carries vesicular material at about 100–400 mm a day and in the hypothalamohypophyseal tract (p. 1010) at a maximum of 2800 mm a day; it is bi-directional along the axon. This rapid flow is abolished by local treatment with colchicine, indicating that microtubules are involved in their process (p. 29). Ultrastructurally, (and most clearly demonstrated in lampreys) vesicles with side projections can be seen to line up along the outside of microtubules and may be transported by the shearing forces generated between their side-arms and microtubules. Since ligature experiments show a build-up of vesicles on *both* sides, the mechanism must allow *bi-directional movement* of organelles. Recently, a class of proteins (kinesins) have been shown to move along the external surfaces of microtubules in either direction and appear to correspond to the vesicle–microtubule links seen in electron micrographs. Such proteins may be analogous to the dynein arms of ciliary microtubules (p. 32) and act to cause



7.20 Schematic drawing of the ultrastructure of a motor neuron, showing part of its dendritic field (above left); the dendrites are studded with spines which are contacted by different types of synaptic terminal. The cytoplasm of the neuronal soma contains stacks of rough endoplasmic reticulum and other organelles. See text for full description.

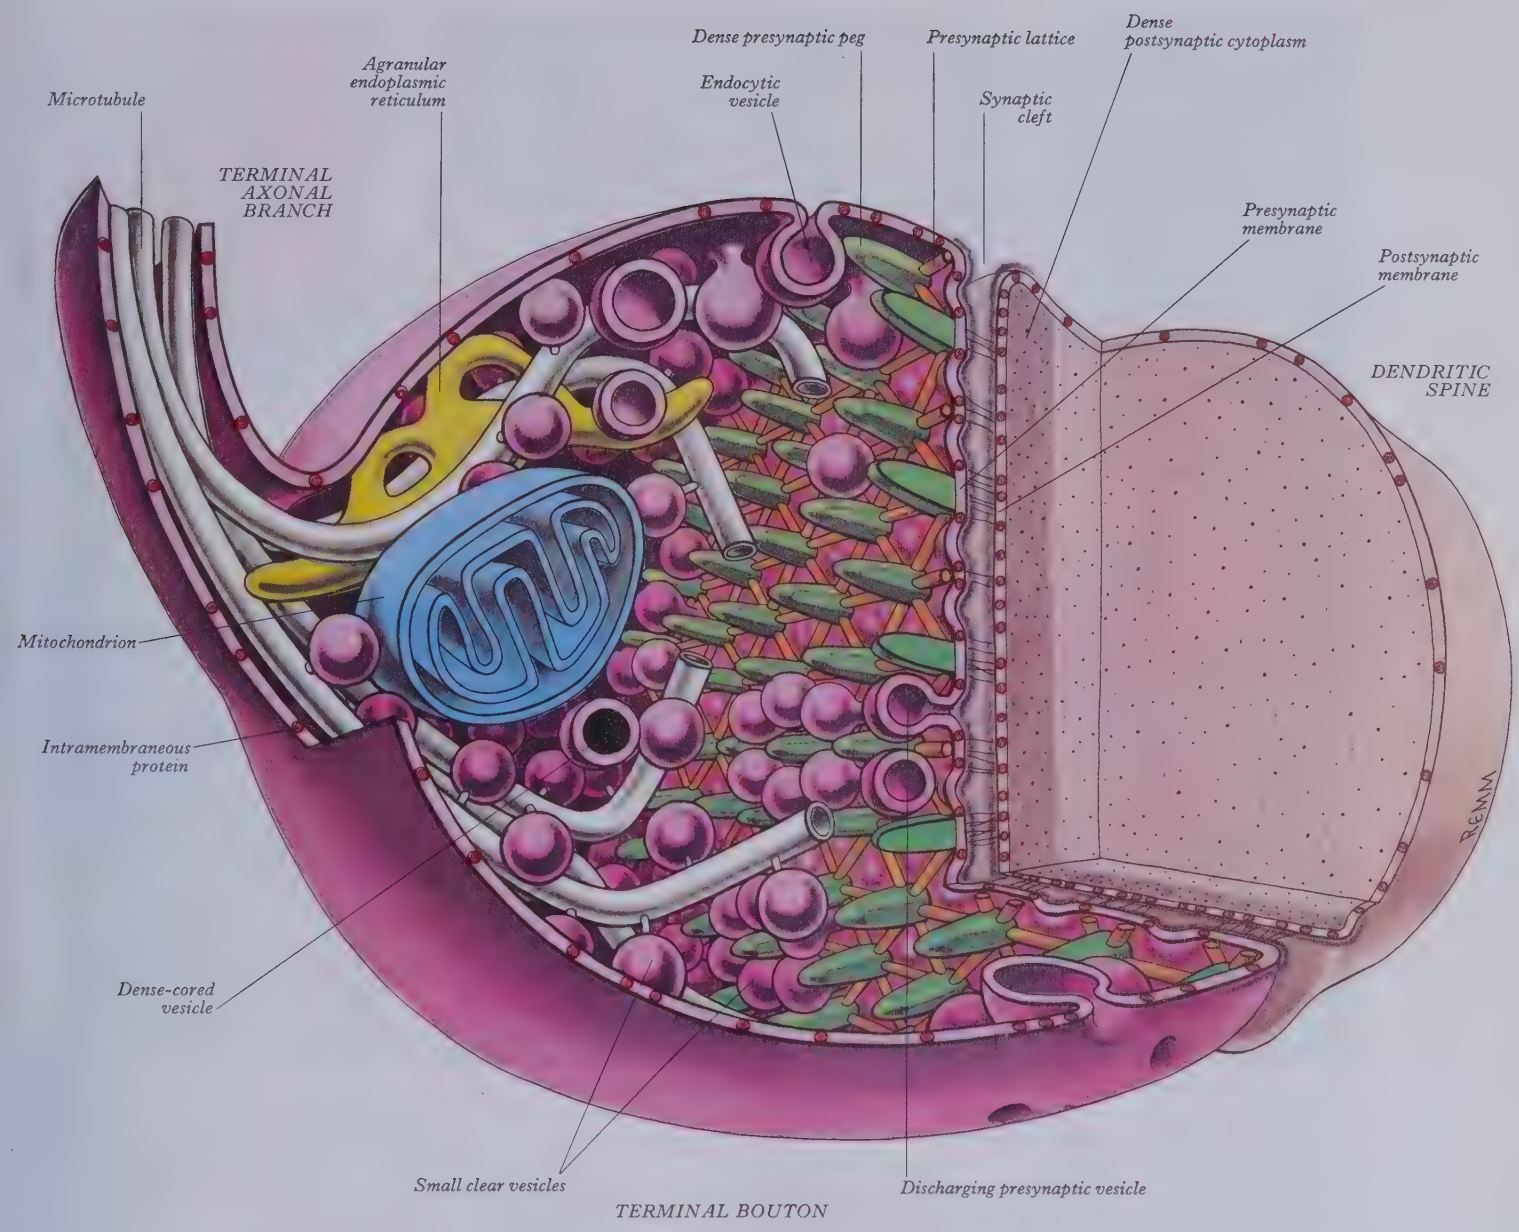
streaming movements of various kinds within axons, dendrites and neuronal somata. For further details, see e.g. Tytell et al 1981, Lasek 1982, Schnapp & Reese (1986).

Morphology of Synapses



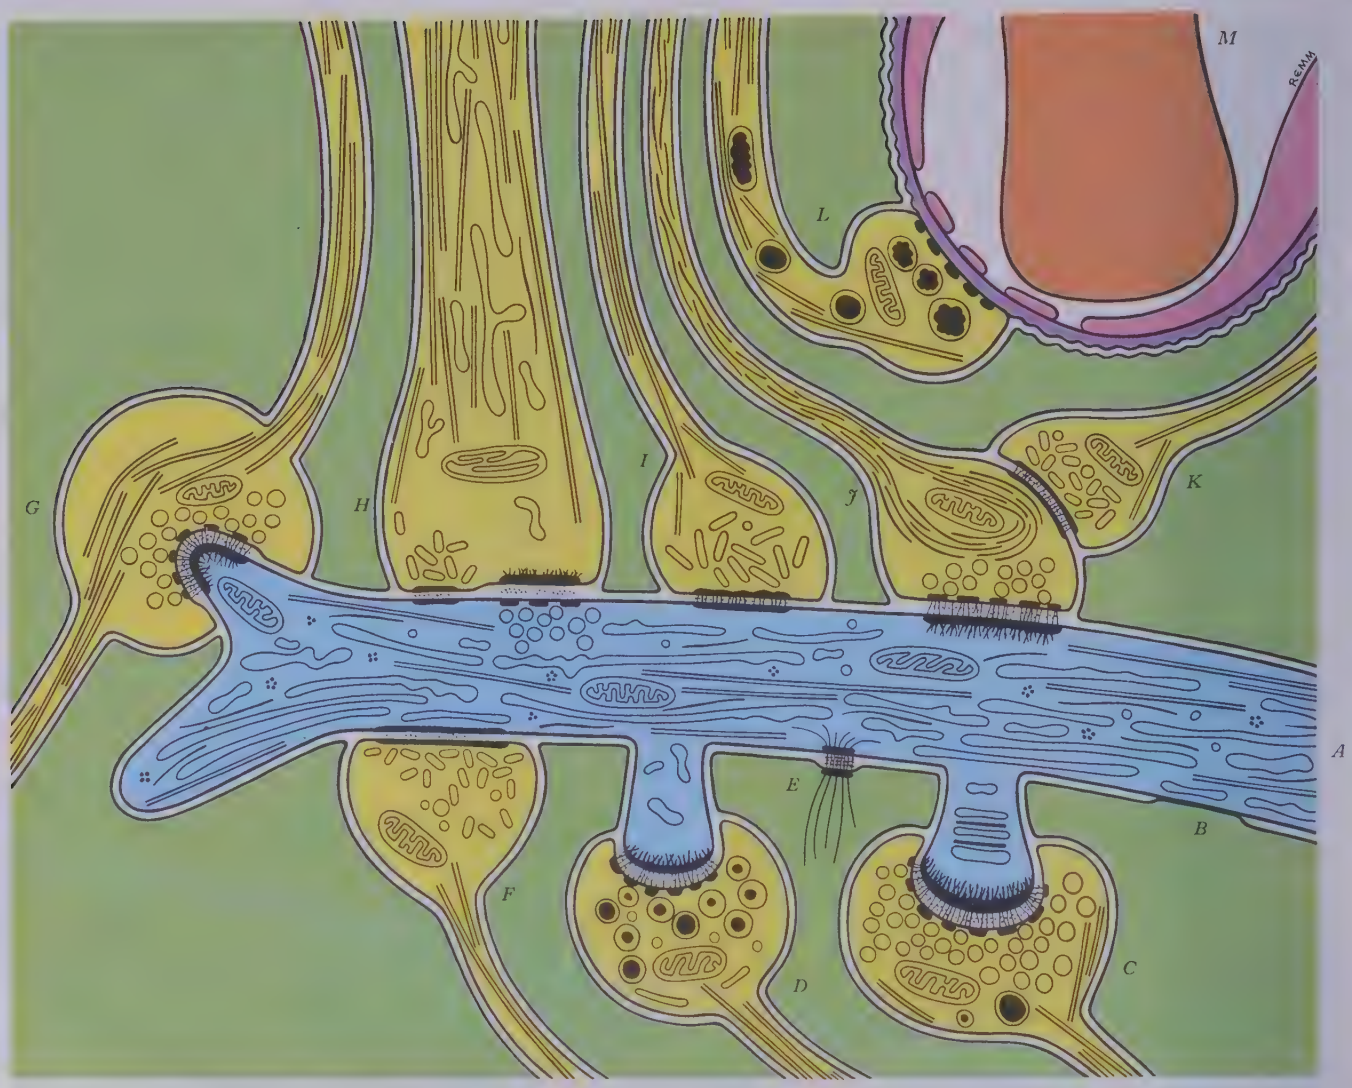
The concept of an interruption in conduction at specific junctions (*synapses*) arose from the observations that there is always an irreducible delay in reflex responses to sensory stimuli and that conduction normally occurs only in one direction, along a multineuronal pathway (Sherrington 1947, Eccles 1964). With the general acceptance of the neuron doctrine, attention focussed on the localization of synapses. Studies by the Golgi technique (p. 876) demonstrated structural specializations at axonal terminals, while other methods showed similar endings in muscles. More recently, electron microscopy, correlated with physiological, pharmacological and biochemical studies have established the major features of synaptic structure (7.22–27) and molecular organization, although there are still many unsolved questions. Since chemical synapses are unidirectional, there should be some structural asymmetry at such junctions. Synapses can be formed between almost any surface region of two neurons. The most common type (7.22, 23, 25) occurs between an axon and a dendrite or a soma, the axon being expanded as a small bulb or *bouton*, either a terminal of an axonal branch (*bouton terminal*) or one of a row of bead-like endings, the axon making contact at several points, often with more than one neuron (*boutons de passage*). Boutons may synapse with: (1) *dendritic spines* or the *flat surface* of a *dendrite*; (2) *spines* or the *flat surface* of a *soma*; (3) the *axonal initial segment* or (4) *boutons of other axons*. The patterns of axonal termination vary considerably; a single axon may synapse with one neuron, e.g. climbing fibres ending on cerebellar Purkinje neurons (p. 971), or more often, with several, e.g. cerebellar parallel fibres, an extreme instance of this phenomenon (p. 971). An axon may synapse primarily with a dendritic tree or arborize around a soma. Afferent axons of different origins may synapse with specific parts of a neuron, e.g. pyramidal neurons of the visual cortex, where optic afferents synapse chiefly with the basal segments of apical dendrites. (See also afferent terminals in the cornu ammonis p. 1037.) In *synaptic glomeruli* and *synaptic cartridges* groups of axons contact dendrites of one or more neurons in regions encapsulated by neuroglia (7.27); their complex interactions are described below (p. 888).

SYNAPTIC SPINES

The spinous extensions of dendrites and soma (7.18, 20, 22–24), *spines* or *gemmules*, form receptive contacts with many afferent boutons, taking several forms. Spines usually have slender stalks and expanded distal ends; most spines are not more than 2 μm long, with one or more terminal expansions; but they can also be short and stubby, branched and bulbous (vide infra). Various experimental and theoretical studies have so far failed to demonstrate unequivocally what role the spines have in dendritic function. It has been proposed that they may limit the impact of individual synapses on the electrical state of the postsynaptic cell so that no single synapse dominates the total input. However, it has been calculated that a change in the width of a spine's stalk could change its effect markedly and it has been suggested that spines may be contractile (Crick 1982), providing a possible means of modulating neuronal excitability, e.g. in memory formation (see Koch & Poggio 1983).

ULTRASTRUCTURE OF SYNAPSES

Ultrastructurally, chemical synapses are specialized appositions between two or more neurons, with some form of asymmetrical



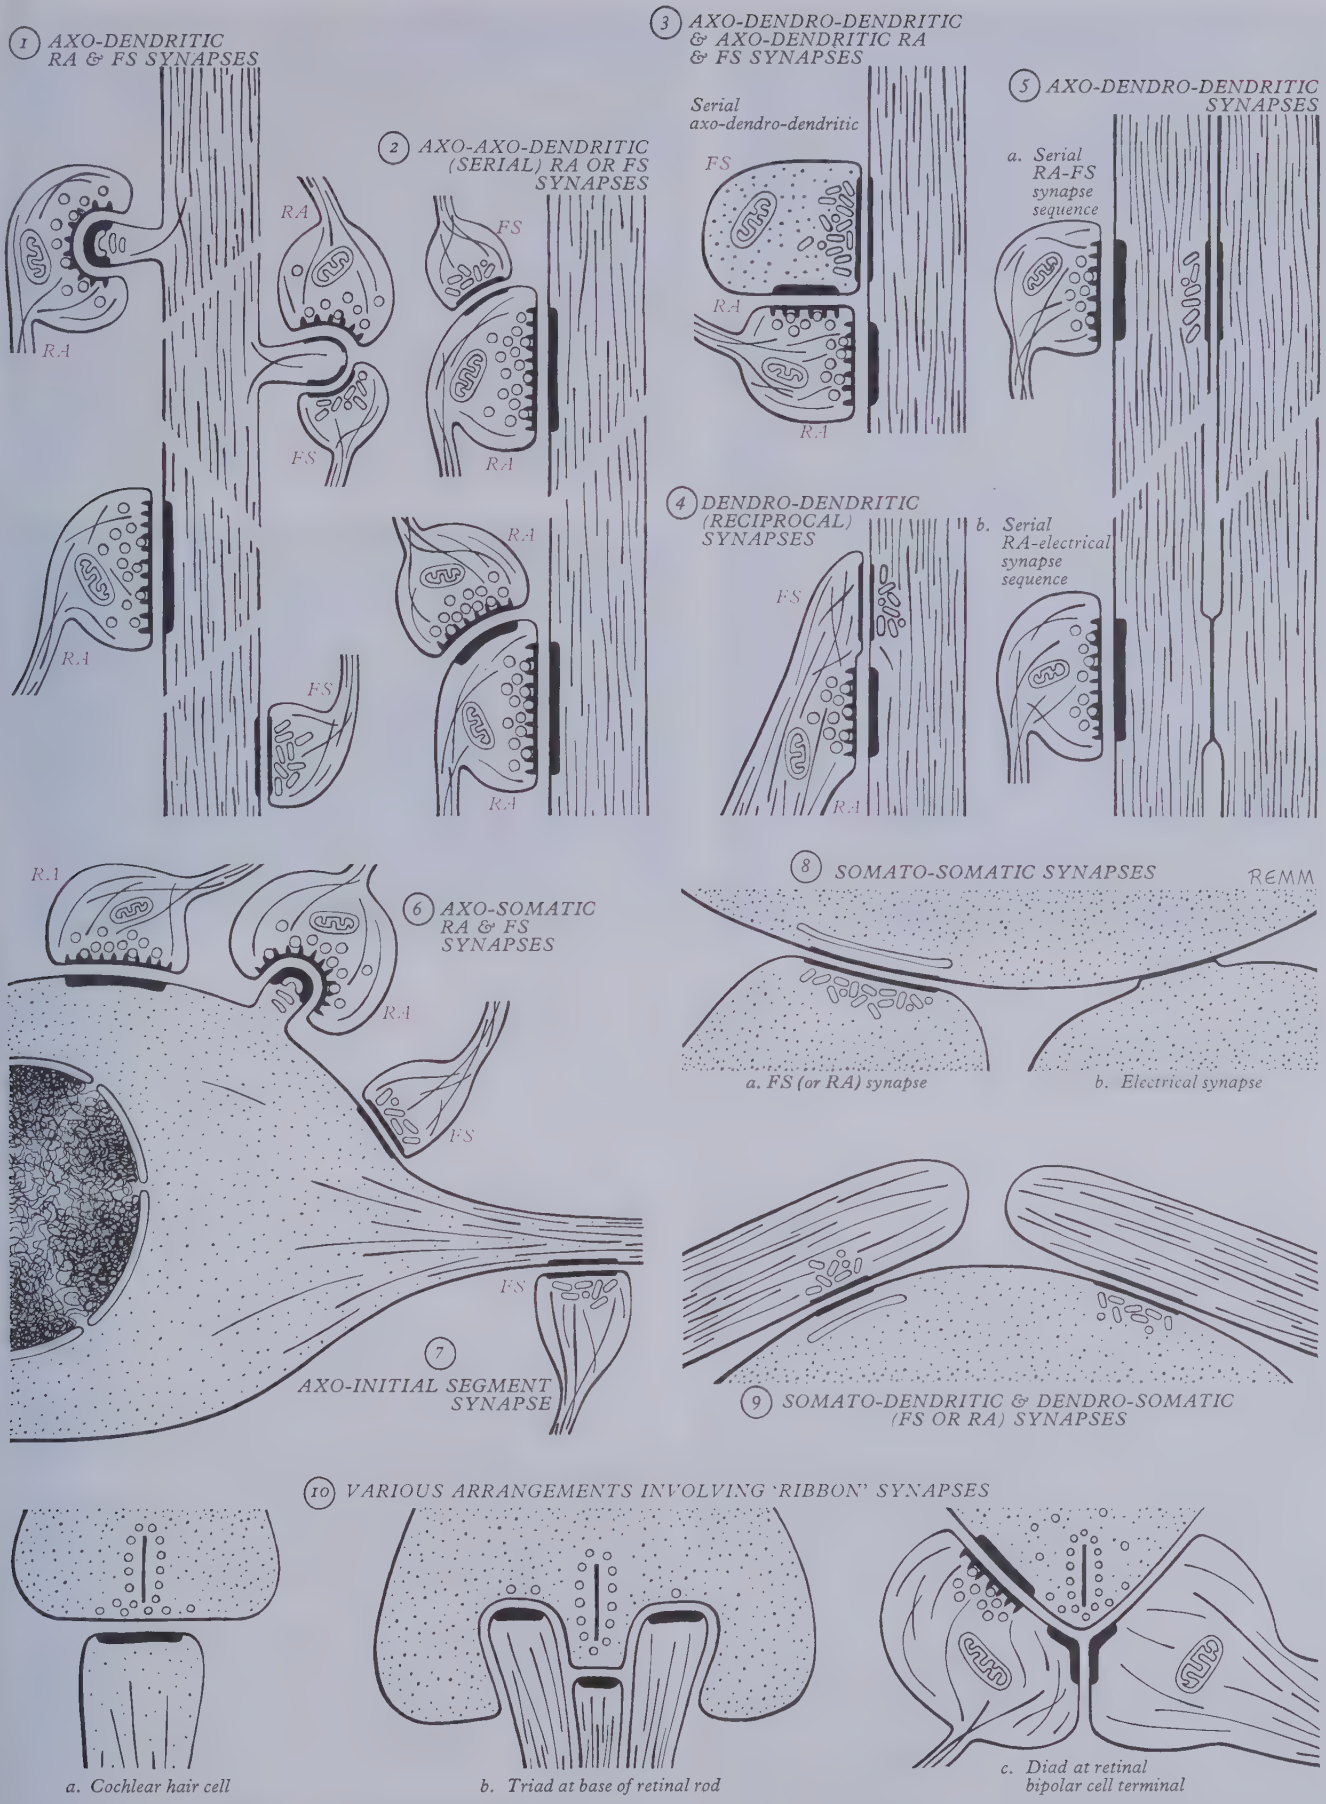
7.22 The general organization of an excitatory synapse (asymmetrical, Gray type I) showing a synaptic bouton (left), cut away to show presynaptic structures, and an associated dendritic spine (right).

organization (7.22–25). They can be variously classified, e.g. by the type of neuronal process participating and the direction of transmission; thus synapses may be *axodendritic* (most common), *axosomatic* (also common), or less frequently *axoaxonic*, *dendroaxonic*, *dendrodendritic*, *somatodendritic* or *somatosomatic* (Shepherd 1974, Gray 1974). Axodendritic and axosomatic synapses occur in all regions of the central nervous system and in autonomic ganglia. Axoaxonic synapses occur between boutons of two axonal terminals (p. 888) or terminals and initial segments of other axons (7.23–25). The other types appear restricted to regions of complex interaction between larger sensory neurons and microneurons, e.g. in the thalamus.

For clarity, **axodendritic synapses** will first be detailed (7.22, 23), since they have been subjected to much research, e.g. by Gray (1959, 1961, 1969, 1974), Uchizono (1965), Pappas & Purpura (1972), Shepherd (1974), Rakic (1975) and Jones (1978). Each is an apposition of a *presynaptic bouton* (*synaptic bag*) with a postsynaptic process, separated by a *synaptic cleft*. On both sides are zones of dense cytoplasm, usually broken on the presynaptic side into several groups, and postsynaptically often extended into a filamentous *subsynaptic web*. The cleft shows fine transverse filaments. The presynaptic bulb has numerous small *synaptic vesicles* clustered against the synaptic cleft, often filling almost the whole bouton; mitochondria, membranous sacs and occasional lysosomes also occur. When fixed in the presence of albumen, boutons show numerous axonal microtubules close to the presynaptic membrane or attached to presynaptic dendrites (Gray 1975), each microtubule surrounded by synaptic vesicles connected to it by short filaments. How these details are revealed by this unusual preparation is uncertain but the complex may be a means of conveying transmitter-containing vesicles close to the presynaptic membrane, to which they may attach and fuse, releasing their contents at specific sites ('*synaptopores*') into the synaptic cleft when the bouton is depolarized. Membrane added by vesicular fusion with the presynaptic surface is re-absorbed for recycling, as endocytic vesicles around the periphery of the bouton (Heuser & Reese 1975).

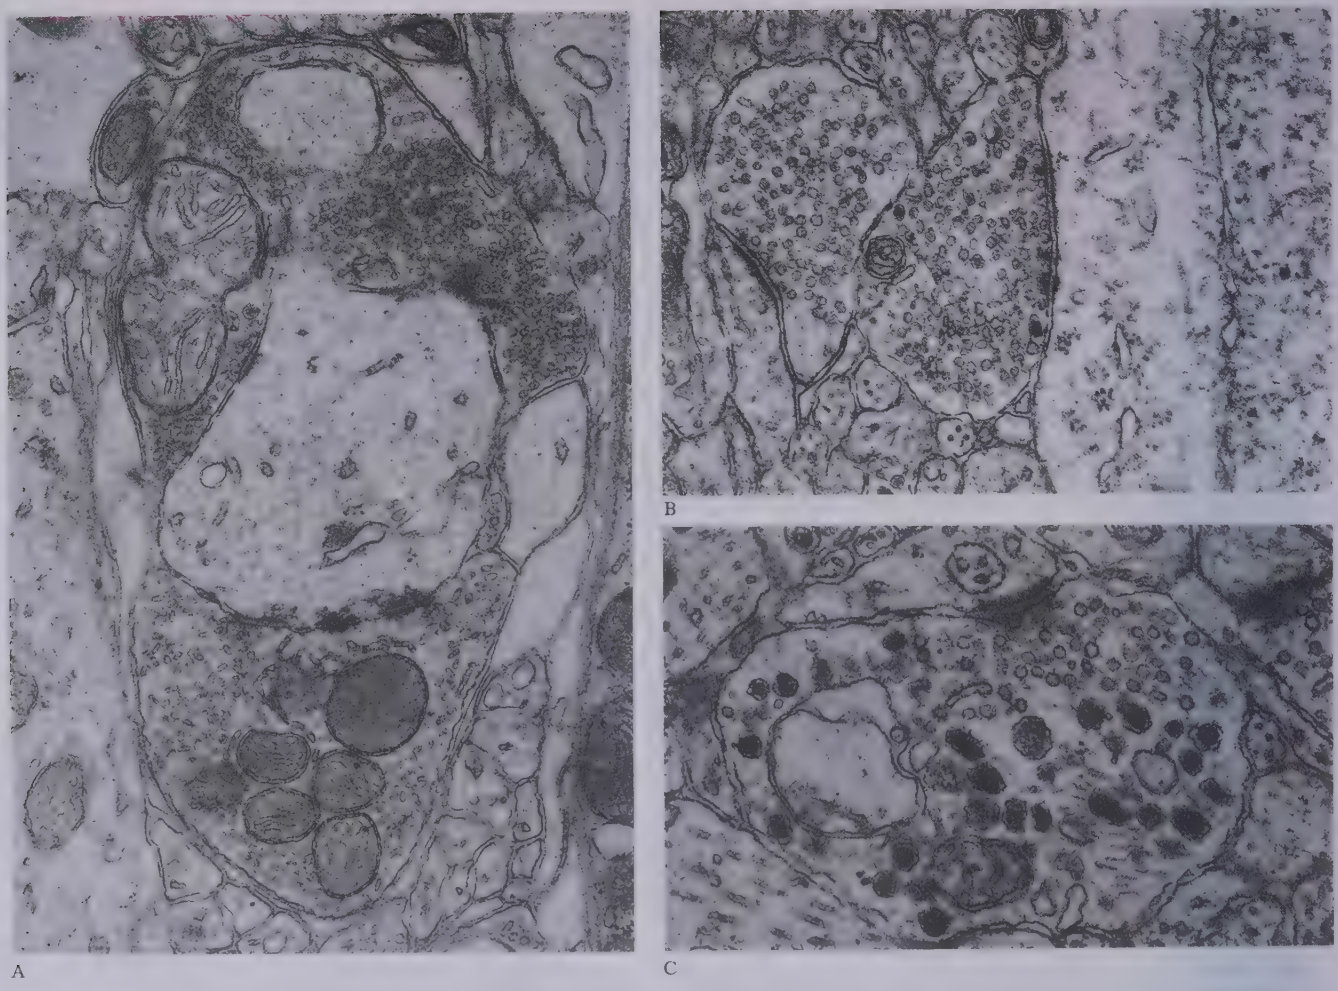
Cytochemical investigation has also revealed other details of presynaptic organization (Pfenninger & Rees 1976), mainly of the 'type I' class of synapse (vide infra). Staining with ethanolic phosphotungstic acid shows a hexagonal pattern on the cytoplasmic side of the presynaptic membrane, probably consisting of

7.23 A scheme of the ultrastructure of chemical synapses, showing various junctional structures, grouped around a dendrite (A). The gap junction (B) and the desmosome (E) are without synaptic significance. Excitatory synaptic boutons are shown (C, G) containing small spherical translucent vesicles. D: a bouton with dense-cored, catecholamine-containing vesicles; F: an inhibitory synapse containing small flattened vesicles; H: a reciprocal synaptic structure between two dendritic profiles, inhibitory towards dendrite A and excitatory in the opposite direction; I: an inhibitory synapse containing large flattened vesicles. J and K: two serial synapses; J is excitatory to the dendrite; K is inhibitory to J; L: a neurosecretory ending adjacent to a vascular channel (M), surrounded by a fenestrated endothelium. All the boutons in this diagram are of the terminal type, except G which is a *bouton de passage*.



proteinaceous pillars guiding vesicles to the membranous attachment (7.22). Other methods, such as bismuth iodide staining with enzymic digestion, also demonstrate glycoproteins in the synaptic clefts and postsynaptic proteins in the membranes of adjacent dendrites. Freeze-fracture techniques show rings of particles in presynaptic membranes, at vesicular attachments, and numerous particles in postsynaptic membrane, perhaps representing receptors for neurotransmitter substances (Akert et al 1972) or ionic channels affected by such neurotransmitters.

Another internal constituent recently discovered is the protein synapsin I, a filamentous substance which in its non-phosphorylated state binds strongly to synaptic vesicles and other structures within the bouton. On excitation of the bouton, synapsin I becomes phosphorylated, due to calcium influx, and binds less strongly to the vesicles, perhaps allowing them to reach the presynaptic membrane and fuse with it to release transmitter substances (see Linstedt & Kelly 1987).



In some sites the neurofilaments of an afferent axon enter the bouton to form a variable loop, visible by light microscopy with silver stains. On the postsynaptic side there are often membranous structures in the cytoplasm, such as parallel cisterns forming the *spine apparatus* of some mammalian dendrites. Glial processes commonly surround the synaptic structures but do not normally enter the synaptic clefts. The presynaptic surface is flat where it adjoins the smooth surface of a dendrite or soma but at endings on postsynaptic spines it may be highly curved round one or more of these projections (7.23, 24, 25). In some sites the dendritic surface forms a large spike, interdigitating with the presynaptic surface. Conversely, dendritic expansions may be deeply invaginated by axonal terminals.

FUNCTIONAL CLASSIFICATION OF SYNAPSES

Since synapses are inhibitory, excitatory or may affect neurons in other ways and different transmitters are released at them, it is to be expected that various structural varieties exist. Such indeed is the case, although it is as yet far from clear how many or, often, what neurotransmitters they release. However, for practical purposes they may be classed by the shape of their synaptic vesicles and the arrangement of the pre- and postsynaptic cytoplasmic densities into several types. Synapses rich in *catecholamines* (noradrenalin, adrenalin, dopamine) contain large (40–60 nm) *dense-cored vesicles* (7.23) like those of adrenal chromaffin cells; at some sites they are inhibitory and at others excitatory, depending on the nature of the receptor molecules in the postsynaptic membrane. *Neurosecretory endings*, like those in posterior pituitary, contain huge (50–200 nm), irregular dense-cored vesicles (7.25). Among other central synapses Gray (1961) recognized, in

7.24 Various types of simple and multiple arrangements of synapse involving 'asymmetrical' synapses with rounded vesicles (RA), 'symmetrical' synapses with flattened vesicles (FS) and electrical synapses. For further details, see text.

7.25 Electron micrographs demonstrating various types of synapse. A. This shows a pale cross-section of a dendrite upon which end two synaptic boutons. One of them (above) contains round vesicles, and the other (below) contains flattened vesicles of the small type. A number of pre- and postsynaptic thickenings mark the specialized zones of contact. B. Two types of synaptic structures; one of them (left) is a type I synapse between an axon terminal containing round vesicles and a dendritic spine; the other (right) is a type II synapse between an axon terminal containing pleomorphic vesicles, and the surface of a neuronal soma. C. A type I synapse containing both small, round, clear vesicles and also large dense-cored vesicles of the neurosecretory type. A and B provided by A R Lieberman, Department of Anatomy, University College, London.

osmium-fixed material, two classes: *type I* in which the subsynaptic zone of dense cytoplasm is thicker than on the presynaptic side; and a *type II* in which the two zones are more symmetrical but thinner (7.23, 24). The widths of synaptic clefts also differ, being about 30 nm in type I and 20 nm in type II. With aldehyde perfusion for fixation, these two types appeared to contain distinct kinds of synaptic vesicles, type I having small spherical vesicles about 50 nm in diameter and type II showing a variety of flat forms (7.25A). Where electrophysiological data were available, as in the cerebellum, *type I synapses* could be linked with *excitation* and *type II* with *inhibition* (Uchizono 1965). Other reports indicate a more complex classification; it is possible to distinguish between large (25 × 60 nm) and small (15 × 40 nm) flat vesicles (Pinching & Powell 1971), and also between discoidal, fusiform and irregular types (Dennison 1971). Other studies show that in fresh specimens all vesicles may be spherical, some flattening on exposure to the buffers used in preparative procedures (Bodian 1970). Synaptic endings also show *mixed populations* of flat and spherical vesicles in varying proportions, depending on the osmotic strength of the fixative. Though such appearances are partly artificial, they indicate real chemical differences. Classification of synaptic boutons has been attempted in different regions by criteria such as vesicular shape and size, distribution of pre- and postsynaptic cytoplasmic thickenings, size of bouton, presence of mitochondria, etc. A common scheme (Guillery 1969, Partlow et al 1977) designates the type I synapse of Gray as a round 'vesicle-asymmetrical thickening' (R.A.) and Gray's type II as a flat 'vesicle-symmetrical thickening' (F.S.); various subdivisions of these two categories have also been suggested (Robson & Hall 1977). While such schemes may have descriptive value, the state of knowledge of transmitters at various synapses and their functional status is generally too slight to justify more than crude classification. Mixed populations of small, clear vesicles and large, dense-cored ones commonly occur, sometimes correlated with peptide transmitter substance P, serotonin, or enkephalins (Beaudet & Descarries 1979, Pickel et al 1979) (vide infra).

Some synapses may lack specialized contact zones, being areas of transmitter release from the varicosities of non-myelinated axons, such effects sometimes being diffuse (paracrine, see p. 887) as in the aminergic pathways of basal nuclei (p. 1076).

The freeze-fracture appearances of type II synapses lack the pre- and postsynaptic intramembrane particles typical of type I, suggesting basic differences in mechanisms of release and action of the transmitter at the postsynaptic membrane (Landis et al 1974).

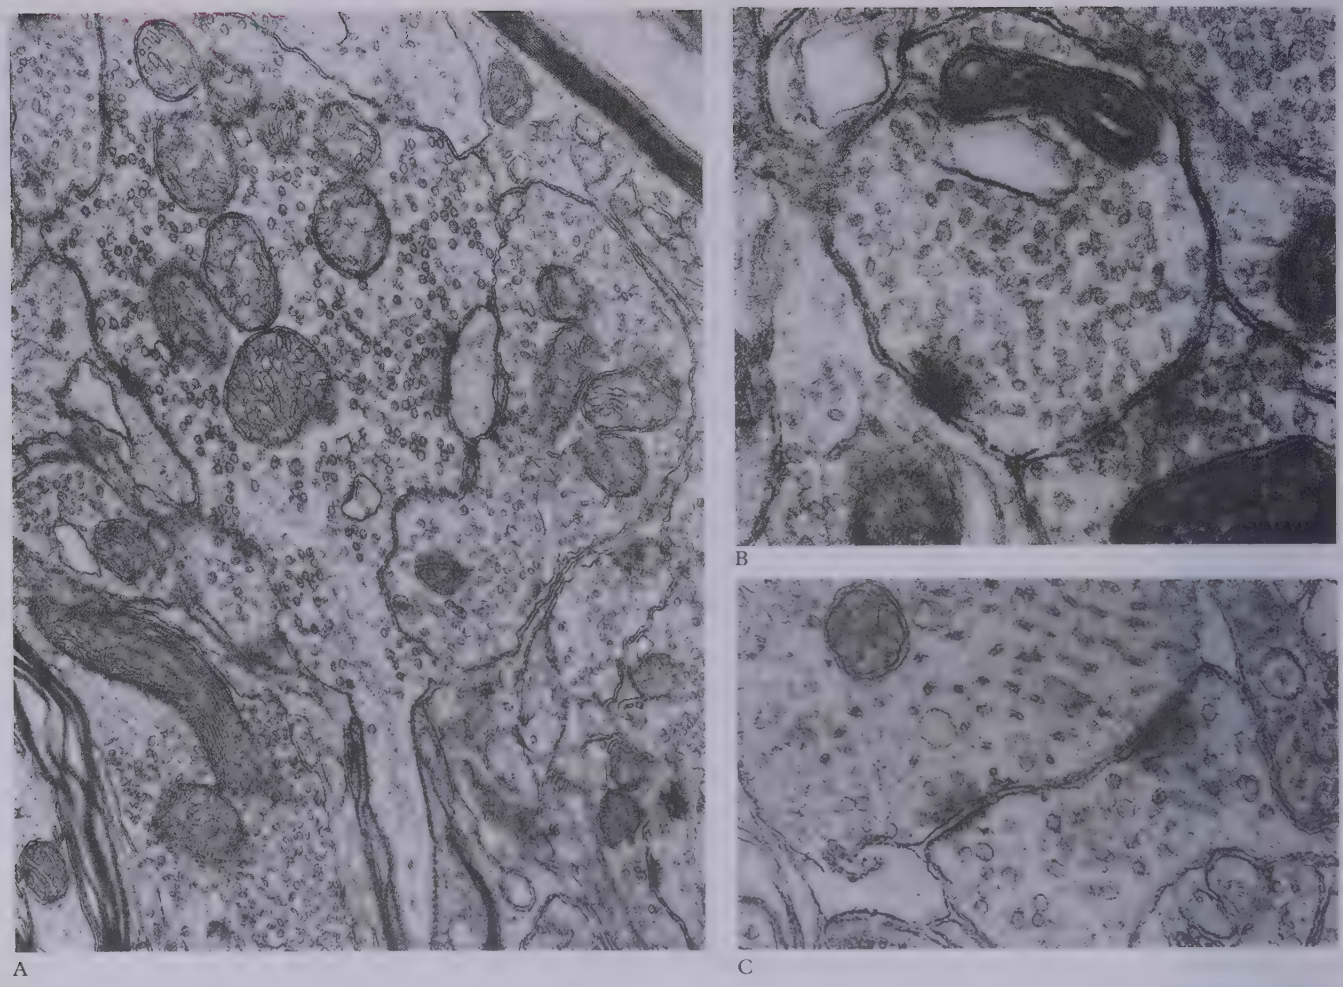
The junctions between the retinal receptors and bipolar neurons, and between cochlear hair or the vestibular sensory cells and their afferent endings, are both synapse-like structures, differing from the usual pattern in that vesicles are clustered around an internal cytoplasmic rodlet (Flock 1971, Boycott & Kolb 1973).

NEUROCHEMICAL TRANSMISSION

Neurotransmission at all the synapses so far described in this account is chemical, involving the release of neurotransmitters

from synaptic vesicles into a synaptic cleft to cause a change in the permeability and therefore the electrical polarization of the postsynaptic membrane. Such alterations may be excitatory (depolarizing) or inhibitory (hyperpolarizing), and are generally rapid and short-lived, as the transmitter is quickly inactivated either by an extracellular enzyme (e.g. acetylcholinesterase) or by uptake into the presynaptic process. The presynaptic ending may also have more complex actions on the target cell, causing much more prolonged or even permanent changes in cell behaviour. Indeed it is becoming increasingly clear that classic, rapid neurotransmission, measured in milliseconds, represents one extreme of a broad spectrum of neural effects which also include slower electrical changes lasting for seconds or minutes, or long-lasting, even permanent cellular changes due to alterations in gene expression, e.g. resulting in the synthesis of more receptor molecules for the postsynaptic surface or altering the numbers of synapses, the extent of the dendritic tree, the growth of axons and the overall metabolism of the cell. Permanent or semi-permanent changes of these types provide a physical basis for memory processes in the nervous system; they are also reflected in the trophic interactions between neurons which occur not only during development (where they are most obvious, see e.g. growth factors, p. 919) but form the constantly fluctuating background to the day-to-day activities of the mature nervous system, seen most dramatically when neurons alter their behaviour and morphology after damage has deprived them of their normal synaptic input. *Neurohormones* must also be included in this range; these are synthesized in neurons and released into the blood circulation by exocytosis at synaptic terminal-like structures and, of course, may act at great distances from their site of secretion. Similarly, neurons may also secrete into the cerebrospinal fluid or into the intercellular spaces of the nervous system (vide infra) to affect many other neurons, diffusely and at a distance. To encompass this wide range of phenomena the general term *neuromediation* has been used, the chemicals involved being *neuromediators*.

Typically, there are two major events during synaptic activity: firstly the release of a neurochemical substance contained within synaptic vesicles by exocytosis (p. 29). This occurs when an action potential (or in some cells, a graded depolarization) reaches the presynaptic terminal, causing an influx of calcium and initiating a series of chemical events which cause synaptic vesicles to fuse with the presynaptic membrane, thus ejecting their contents into the synaptic cleft. Secondly, the chemical diffuses across the narrow gap, binds to receptor molecules embedded in the postsynaptic membrane and alters the permeability of this membrane to various ions (calcium, sodium, potassium or chloride). In some cases (e.g. the 'nicotinic' receptor for acetylcholine), the receptor molecule is also itself a transmembrane ion channel so that, when the neurotransmitter binds to it, there is a rapid, transient opening of the channel, which causes an electrical change lasting only a few milliseconds. In other cases, e.g. in the activation of the 'muscarinic' acetylcholine receptor, the changes take much longer to develop and often last for seconds or even minutes; where they have been examined in detail, all such slow responses operate by means of a receptor molecule in the postsynaptic membrane which activates a 'second messenger' system within the postsynaptic cytoplasm, e.g. involving the activation of the adenyl cyclase-cyclic AMP pathway, leading indirectly to the opening (or closing) of ionic channels at its surface. Therefore the action of a neuromediator depends not only on its chemical structure, but also on the type of receptor system present; different receptors may be linked to particular ion channels, e.g. enkephalin μ receptors to potassium channels and enkephalin κ receptors to calcium channels. A number of classic transmitters have actions both of the fast, direct type and of the slow indirect, e.g. acetylcholine, γ-aminobutyric acid and glutamate.



Second messenger systems are also thought to be responsible for the much wider and long-lasting effects on the postsynaptic cell; after repeated synaptic activity, they may alter the activity of enzymes in the postsynaptic cytoplasm to cause changes in the arrangement of the cytoskeleton in this region and thus the size, shape, stability and electrical properties of the postsynaptic structure may alter semi-permanently. In some glands, the intercellular 'gap' junctions (p. 24) become non-conducting, so uncoupling adjacent cells from metabolic intercommunication. The numbers of receptor molecules in a postsynaptic membrane may also alter as a delayed response to repetitive activity (or to inactivity), to enhance or diminish the effectiveness of the synapse. Second messengers may reach the nucleus of the cell to activate or suppress DNA transcription and so cause major alterations in the overall metabolism, including the synthesis of structural molecules, neurotransmitters and the enzymes of energy production. All such changes affect the electrical behaviour of individual cells and, if multiplied by similar responses in large neuronal populations, enable neural networks to modulate their behaviour according to the types and magnitudes of the influences reaching them.

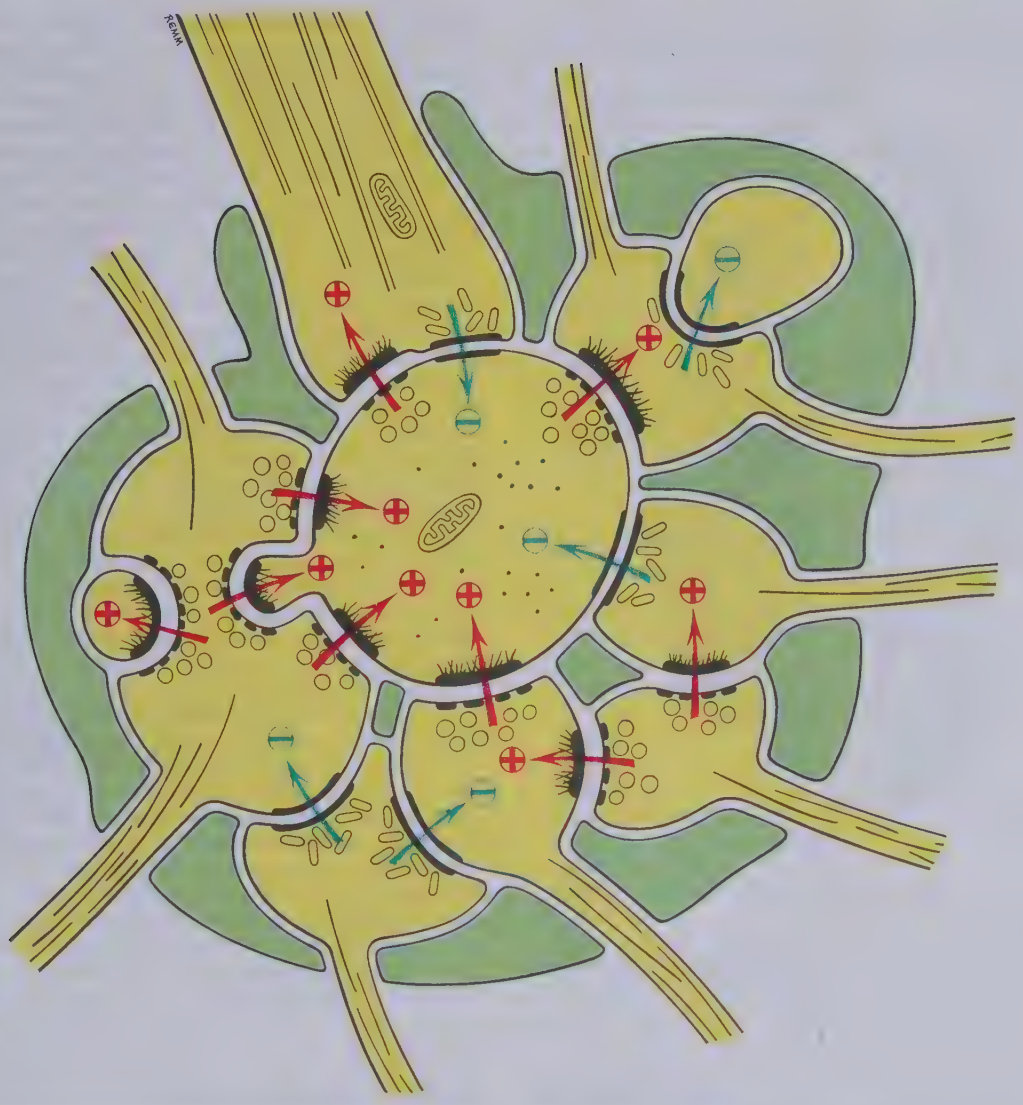
Neuromodulators. A further twist in the story is that some neuromediators do not themselves have noticeable effects on the postsynaptic membrane but affect its responses to other neuromediators, either enhancing their activity (increasing the immediate response in size, or causing a prolongation) or perhaps limiting or inhibiting their action. Such substances have been called *neuromodulators*: a single synaptic terminal may contain one or more neuromodulators in company with a neurotransmitter, usually (though not always) in separate vesicles; the mode of action of neuromodulators is still not entirely clear but may involve either a direct binding to, and alteration in the response of, the receptor for the *neurotransmitter* or it may cause a second messenger-mediated change in the postsynaptic membrane which would then alter its response to the neurotransmitter. In some cases there may be a difference in the number of nerve impulses needed for the release, the neuromodulator only being secreted after more sustained stimulation of the ending.

Neuropeptides, which are extremely numerous (see pp. 891–892), are apparently nearly all modulators, at least in some of their actions. They are stored within dense granular synaptic vesicles of various sizes and appearances. Although they are distributed widely through the nervous system, certain areas have high concentrations and large numbers of different types. This finding has been analysed in detail by Nieuwenhuys (1986) in an extensive review and theoretical discussion of neuromediators in relation to classic neuroanatomy (see also p. 992). It is well known that in many parts of the nervous system, both central and peripheral, axon terminals have zones of transmitter release which are not closely apposed to a postsynaptic membrane but separated from it by a variable intercellular gap, perhaps as much as 0·2 μm ('synapses á distance', see e.g. Chan-Palay 1983). Chemicals released from such axons may diffuse quite widely through the intercellular spaces to arrive at receptor sites on the surfaces of several neighbouring cells. Such effects are analogous to those of neuro-endocrine endings, although the chemicals released are of course restricted to a limited volume and are said to be *paracrine*. In a given area of grey matter (or of non-striated muscle), several different neurotransmitters and neuromodulators from different sources may impinge on the mixed population of receptor molecules on a particular target cell, giving a great variety of possible responses, so that the level of excitation and therefore of action potential generation in a neuronal population fluctuates constantly as information from different sources converges on its dendrites and somata. Such areas of multiple interaction are frequently associated with neural activities directed towards homeostasis (e.g. ionic regulation, cardiovascular control), the survival of the individual in more extreme circumstances and the continuance of its genes, i.e. reproduction.

Synaptosomes

The term *synaptosomes* (synaptic 'bags') is the name given to an experimental preparation consisting of axon terminals, separable by fractionation techniques from brain homogenates. Where acetylcholine is the transmitter, enzymes (e.g. choline acetyltransferase) able to synthesize it from choline exist in synaptosomes, the transmitter being stored in or near the synaptic vesicles. Catecholamines and other possible transmitters have also been demonstrated thus in synaptosomes (vide infra).

7.26 Electron micrographs of complex arrangements of synapses. A. This shows a large terminal bouton of an optic nerve afferent fibre, which is making contact with a number of postsynaptic processes, in the dorsal lateral geniculate nucleus of the rat. One of the postsynaptic processes (right) also receives a synaptic contact from a bouton containing flattened vesicles. B. Three neuronal processes in serial contact. On the lower right, a process containing round vesicles synapses with a second process (centre) containing flattened vesicles; in turn the latter makes contact with a third process (lower left): specimen from the dorsal lateral geniculate nucleus of the rat. C. This demonstrates reciprocal synapses between two neuronal processes in the olfactory bulb. A and B provided by A R Lieberman of University College, London.



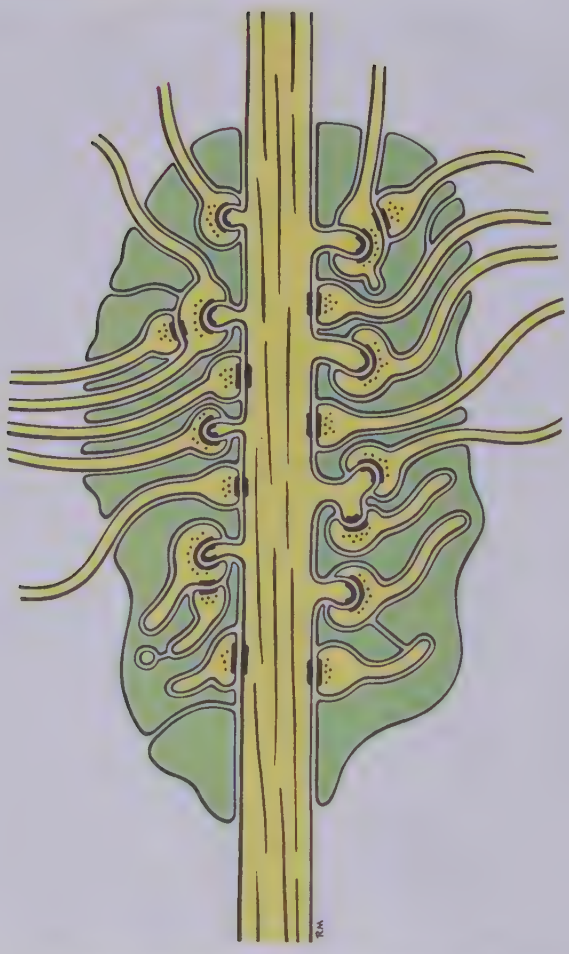
ELECTRICAL SYNAPSES

In mammals chemical transmission at synapses is by far the most common but in lower vertebrates and some invertebrates electrical synapses are abundant where speed or synchrony of neural response is a requisite. Examples are 'spoon' endings in the chick ciliary ganglion, 'club' endings on giant Mauthner cells in the medulla in many fishes, the electromotor synapses in electrogenic fishes and the giant nerve fibre systems of crayfish and earthworm. Such synapses are like 'gap' or electrical junctions in cardiac (pp. 24, 557) and non-striated muscle (p. 562) and are much faster than chemical synapses. Some invertebrate synapses of this kind are bi-directional. Similar junctions occur in mammals, e.g. in the superior olivary and vestibular nuclei, cerebellar and cerebral cortices; but the corroboration of their transmissive properties is not yet available (Gwyn et al 1977).

ORGANIZATION OF SYNAPTIC GROUPS

The effects of synaptic endings on other neurons partly depend on their arrangement and relation to other synapses. In *serial synapses* (7.23, 24, 26B) some terminal bulbs end on others to modify their response to afferent volleys, a possible basis of *presynaptic inhibition* (e.g. in the spinal cord) and of *presynaptic facilitation*, depending on the type of synapse. *Reciprocal synapses* (7.24, 26C), first found in the olfactory bulb and lateral geniculate body and later in many other sites, transmit both ways by staggered synaptic zones on opposite sides of the synaptic cleft; they are usually excitatory in one direction and inhibitory in the other. They may be the basis of lateral inhibition (Rall et al 1966, Shepherd 1974, 1978). Other varieties of serial synapses between different axonal, dendritic and somal structures have been described, some of them depicted in 7.24 (Gray 1974, Colonnier 1974, Shepherd 1974, 1978).

In **synaptic glomeruli** (7.27A) several boutons synapse with dendrites and sometimes with each other in localized regions of neuropil, usually within layers of gliocytes (Szentágothai 1970). Where microneurons are involved, synaptic patterns may become exceedingly complex, including various excitatory and inhibitory relations between neurites; these may occupy extensive zones as **synaptic clusters**. In **synaptic** or **neuropil cartridges** part of a dendrite is enclosed by a glial sheath to isolate a cylindrical zone of synaptic endings on the spines and dendritic surface between them (7.27B). Astrocytes (p. 893) may also isolate or juxtapose groups of interacting neurons. Though such arrangements of synapses in circumscribed areas is well established, the disposition of different types of synapse on neuronal surfaces is less certain. Inhibitory synapses can reduce the excitability of a neuron by their actions on dendrites and the soma, or may exert a total inhibitory blockade at some strategically-placed sites such as the initial segment of the axon (7.19), or the terminals of basket neuron axons synapsing with the 'pre-axons' of Purkinje neurons (p. 971).



7.27A A synaptic glomerulus, showing various arrangements of synapses grouped around a centrally placed terminal dendritic expansion, seen in cross-section. Both excitatory (+) and inhibitory (−) synapses are shown; the direction of transmission is indicated by arrows (red for excitation, blue for inhibition). A glial capsule surrounds the whole complex.

DEVELOPMENT AND PLASTICITY OF SYNAPSES

Embryonic synapses first appear as inconspicuous dense zones flanking synaptic clefts (Bodian 1970, Pfenninger & Rees 1976). Immature synapses often appear after birth, suggesting that they may be labile, recruitable for transmission and dispensable when redundant. This is implicit in some theories of memory, which postulate that synapses are modifiable by frequency of use, to establish *preferential conduction pathways*. Recording from hippocampal neurons suggests that in some locations, even a brief synaptic activity (e.g. 1 second) can increase the strength of the synapse for some hours or longer (long-term potentiation). The mechanism of this appears to involve cytoskeletal changes modulated by calcium activation of protein kinases within the postsynaptic process (see e.g. Smith 1987). However, such dramatic changes may be limited to regions of the nervous system involved in memory storage; in other areas smaller adjustments may occur with the use or disuse of synapses, e.g. in the number of postsynaptic receptor sites. During early postnatal life it is well-established that a normal increase in numbers and sizes of synapses and dendritic spines depends on the degree of neural activity, as shown in the visual cortex of young animals temporarily blinded in one eye, where dendritic spines of cortical neurons show a greatly impaired development (Rothblat & Schwarz 1979).

NEUROMEDIATORS

Until recently the classes of chemicals known to be involved in chemical synapses were limited to a fairly small group of 'classic' neurotransmitters: acetylcholine, noradrenalin, adrenalin, dopamine and histamine, all with quite well defined 'fast' effects on other neurons, muscle cells or glands and satisfying the criteria laid down by the classic pharmacologists such as Henry Dale. With increasing research into the chemistry of the brain and more detailed electrophysiological and pharmacological studies, it became increasingly obvious that within the nervous system there are many synaptic interactions that cannot be explained in terms of these neurotransmitters and that other substances, particularly some amino acids such as glutamate, glycine, aspartate, gamma-aminobutyric acid and the monoamine, serotonin, were good transmitter candidates. With the development of monoclonal antibody technology it was found that many substances which hitherto had been observed only in relation to the hormonal secretions of the hypophysis, or of the entero-endocrine system of the alimentary tract, can be detected widely and often systematically throughout the central and peripheral parts of the nervous system (see e.g. Björklund et al 1984, Nieuwenhuys 1986). Many of these are peptides, some of them closely related to each other chemically or even derived from a single large 'parent' molecule by its fragmentation. When isolated and tested by

7.27B A synaptic cartridge, with synapses grouped around a segment of a dendrite and enclosed within a glial capsule (green).

neuropharmacological methods, these substances have been shown to have a great range of effects on neurons, non-striated muscle and glands, frequently as neuromodulators (vide supra). There are in excess of 60 known neuropeptides at the time of writing and their numbers are likely to increase as the techniques of molecular genetics are applied to the nervous system. However, it is highly problematical as to which of these substances actually represent functional neuromediators; some of them may be intermediate metabolites, or even the breakdown products of other neuromediators. Because more than one may be present at a single synapse, it has proved difficult to apply the rigorous criteria of classic neuropharmacology and many of these chemicals are therefore often referred to as only *putative* neuromediators. Nevertheless, various of these chemicals have been localized within synaptic vesicles of specific terminals and it has been possible to relate their presence to the physiological properties of known cells. Some of the postsynaptic receptor molecules which bind these substances have also been characterized, giving the corresponding neuromediator a measure of pharmacological respectability.

A comprehensive view of this field, were it indeed possible, is clearly outside the scope of the present account. It must be noted, though, that these substances, their neurobiology and distributions within the nervous system are of major importance in the functional organization of the brain, spinal cord and peripheral nerves and of neural interactions with the rest of the body. Before discussing these topics in the context of neuroanatomical pathways and centres (see e.g. p. 992), we will consider some of the better known neuromediators (see Table, p. 891).

Acetylcholine is perhaps the most extensively studied neurotransmitter of the classic type; its precursor, choline, is synthesized in the neuronal cell body and transported to the axons terminals where it is acetylated and stored in 'clear' spherical vesicles about 50 nm in diameter. This neurotransmitter is synthesized by motor neurons and released at all their motor terminals on skeletal muscle and at synapses in parasympathetic and sympathetic ganglia. Many parasympathetic and some sympathetic ganglionic neurons are also cholinergic, as are some of the terminals of the efferent olivo-cochlear tract ending on cochlear hair cells. Acetylcholine has been demonstrated in many major non-motor systems of the brain and spinal cord, using immunohistochemical methods, by labelling neurons with antibodies directed against the enzyme choline acetyl transferase which is involved in its synthesis; in some sites acetylcholine is also associated with the degradative extracellular enzyme acetyl cholinesterase (e.g. at neuromuscular junctions, p. 904), an association that has been used extensively to indicate the presence of the transmitter. There has been much recent clinical interest in the central cholinergic pathways, since there is evidence that damage to this neurochemical system, particularly in the basal forebrain, may be a causative agent in some degenerative conditions such as Alzheimer's disease.

The effects of acetylcholine on nicotinic receptors (i.e. those in which nicotine is an agonist) are rapid and excitatory; in the peripheral autonomic system, the slower, more sustained excitatory effects of cholinergic autonomic endings are mediated by different (muscarinic, m_1) receptors via a second messenger system (vide supra) which results in the closure of a potassium channel.

Monoamines

These substances, often termed *biogenic amines* because of their importance to nervous function, consist of: the *catecholamines* noradrenalin, adrenalin and dopamine; the *indoleamine* serotonin (5-hydroxytryptamine); and histamine. Before suitable monoclonal antibody labels were available, catecholamines were localized by the formaldehyde-induced fluorescence (Falck et al 1962) or the glyoxylic acid methods (e.g. Axelsson et al 1973, Lindvall & Björklund 1974) but now it is possible to detect specifically the synthetic enzymes associated with each substance, using immunohistochemistry. Neurons which synthesize the monoamines include sympathetic ganglia and their homologues, the chromaffin cells of the adrenal medulla and paraganglia; within the central nervous system, their cell bodies lie chiefly in the brain stem, although their axons spread and ramify exceedingly widely into all parts of the central nervous system. Monoamine cells are also present in the retina (p. 1202).

Noradrenalin is the chief transmitter present in sympathetic ganglionic neurons and is released at their endings in various tissues, notably non-striated muscle and glands but also in other sites including adipose and haemolymphopoietic tissue (p. 836) and the corneal epithelium. This neuromediator is also present at synaptic endings widely distributed within the central nervous system; many of them are terminals of neuronal somata situated in the locus coeruleus in the medullary floor. The actions of noradrenalin depend on its site of action, varying with the type of postsynaptic receptor. In some cases, e.g. the neurons of the submucosal plexus of the intestine and of the locus coeruleus, it is strongly inhibitory due to its actions in closing a potassium channel via the $\alpha 2$ adrenergic receptor, whereas the β receptors, e.g. of vascular non-striated muscle, mediate depolarization and therefore vasoconstriction.

Adrenalin is also present in central and peripheral nervous pathways and occurs alongside noradrenalin in the adrenal medulla. Both of these monoamines are found in dense-cored synaptic vesicles about 50 nm across. Dopamine is a neuromediator of considerable neurobiological and clinical importance, present mainly in the central nervous system, where it occurs in neurons with cell bodies in the telencephalon, diencephalon and mesencephalon. A major dopaminergic neuronal population in the midbrain constitutes the *substantia nigra*, so called because its cells contain neuromelanin, a black granular by-product of dopamine synthesis (p. 982). Dopaminergic endings are particularly numerous in the corpus striatum, limbic system and cerebral cortex and pathological reductions of dopaminergic activity have widespread effects on motor control, affective behaviour and other neural activities, as seen in Parkinson's syndrome. Structurally, dopaminergic

synapses contain numerous dense-cored vesicles resembling those of noradrenalin.

Serotonin and *histamine* occur in neurons mainly in the central nervous system; serotonin is synthesized chiefly in small median neuronal clusters of the brain stem (mainly in the raphe nuclei), but their axons spread and branch extensively throughout the entire brain and spinal cord. Synaptic terminals contain rounded, clear vesicles about 50 nm across and are of the asymmetrical type. Histaminergic neurons appear to be relatively few and are restricted largely to the hypothalamus.

The amino acids. The best understood of these is γ-amino butyric acid (GABA) which is a major inhibitory transmitter released at the terminals of local circuit neurons within the brain stem and spinal cord (e.g. the recurrent inhibitory Renshaw loop, p. 865), within the cerebellum (as the main transmitter of Purkinje neurons) and elsewhere. It is located in flattened or pleiomorphic vesicles within symmetrical synapses, at which it may be inhibitory to the postsynaptic neuron or may give either presynaptic inhibition or facilitation, depending on the synaptic arrangement (p. 888). A major synthetic enzyme is glutamic acid decarboxylase (GAD) which can be used as an immunochemical marker for its neuroanatomical study.

Glutamate and *aspartate* are considered to be major excitatory transmitters present within widely distributed cell bodies and fibres of the central nervous system, including the major projection pathways from the cortex to the thalamus, tectum, substantia nigra, pontine nuclei, as well as many other parts of the brain and spinal cord. They have been located in the central terminals of the auditory and trigeminal nerves, and glutamate is present in the terminals of parallel fibres ending on Purkinje cells in the cerebellum, amongst other locations. Structurally, they are associated with asymmetrical synapses containing small (30 nm) round, clear synaptic vesicles. *Glycine* is another important, well established inhibitory transmitter of the central nervous system, particularly the lower brain stem and spinal cord, where it is mainly located in local circuit neurons. *Taurine*, another inhibitory neuromediator, is present widely in the central nervous system including the cerebral cortex and cerebellum; there is evidence, however, that it may act as a neuromodulator rather than a transmitter at these sites.

Neuropeptides

As already mentioned, the number of peptide neuromediators, either established or putative, is extremely large (see Table). Many of them co-exist with other neuromediators in the same synaptic terminals, from one to three types often sharing a particular ending with a well-established neurotransmitter; in some cases they have been shown to be present within the same synaptic vesicles. Some of them occur both centrally and peripherally in the nervous system and are particularly represented in the ganglion cells and peripheral terminals of the autonomic system (see Burnstock 1986), where their physiological actions are more accessible to study; others are entirely restricted to the central nervous system. In view of the vast scope of this subject, only a few examples will be considered; for further details the reader is referred to some recent reviews of this subject (e.g. Emson 1983, Martin & Barches 1986, Nieuwenhuys 1986).

For convenience of description, most of the neuropeptides are classified according to the site where they were first discovered. Thus there are the 'gastrointestinal' peptides found initially in the gut wall (p. 1376), then a group first associated with the hypophysis cerebri (including releasing hormones, adenohypophyseal and neurohypophyseal hormones) and finally peptides discovered first in the nervous system. Some of these peptides are closely related to each other in their chemistry because they are derived from the same gene products (e.g. the pro-opiomelanocortin group) which are cleaved in various ways to provide smaller peptides. The significance of the presence of these substances in both neural and non-neural tissue can at present only be guessed at: perhaps it represents a genetic economy in that the same molecule can be used for quite different purposes in different biological situations; alternatively it has been suggested that at least in certain instances the same peptide is present in regions with related biological functions.

A summary of the main classes of neuromediators or putative neuromediators found in the nervous system

Non-peptidergic neuromediators

Acetylcholine

Monoamines

Noradrenalin
Adrenalin
Dopamine
Serotonin
Histamine

Amino acids

Glutamate
Aspartate
Glycine
Gamma aminobutyric acid (GABA)
Taurine

Purines

Adenosine triphosphate (ATP)

Peptides

Peptides first found in the gastrointestinal tract

Bombesin
Cholecystokinins (CCK)
Gastrin
Glucagon
Insulin
Motilin
Neurotensin (NT)
Pancreatic polypeptide (PP)
Substance P (SP)
Vasoactive intestinal polypeptide (VIP)

Peptides first associated with the hypothamalo-hypophyseal complex

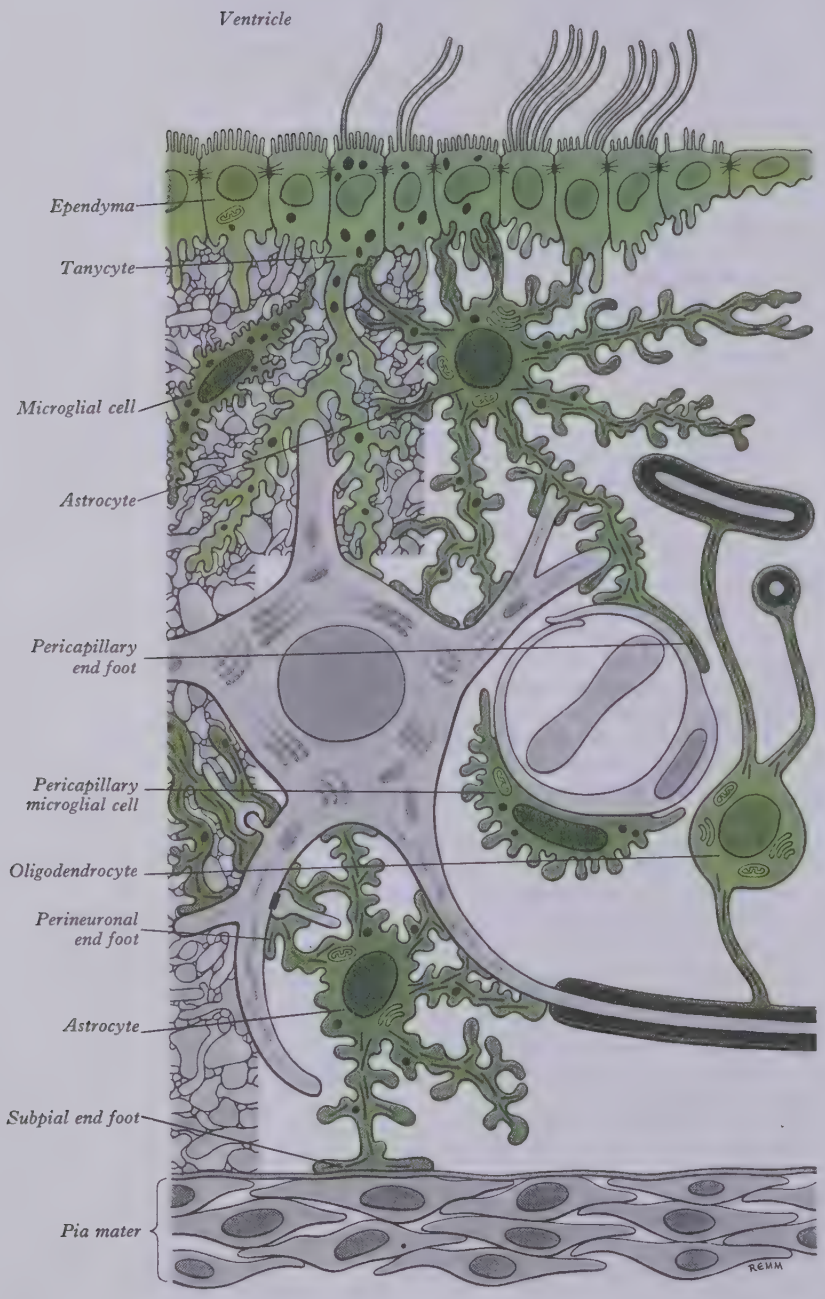
Hypothalamic releasing hormones:
Corticotropin-releasing factor (CRF)
Growth hormone releasing hormone (GHRH)
Luteinizing hormone releasing hormone (LHRH)
Somatostatin (SST)
Thyrotropin-releasing hormone (TRH)
Neurohypophyseal peptides:
Vasopressin (arginine vasopressin; AVP)
Oxytocin (OXT)
Pro-opiomelanocortin (POMC) derivatives:
Corticotropin (ACTH)
Corticotropin-like intermediate lobe peptide (CLIP)
β-endorphins (β-END)
β-lipotropin (β-LPH)
γ-lipotropin (γ-LPH)
Met-enkephalin (M-ENK)
Leu-enkephalin (L-ENK)
α-melanocyte stimulating hormone (α-MSH)
γ-melanocyte stimulating hormone (γ-MSH)
Prodynorphin derivatives:
Neodynorphins α and β (α, β-NE)
Dynorphins (DYN) A and B

Other peptides

Angiotensin II (ANG-II)
Bradykinin
Calcitonin-related gene peptide (CGRP)
Carnosine
Gallinine
Natriuretic peptide
Neuropeptide Y
Sleep peptide(s)

Growth factors

Nerve growth factor (NGF)
Platelet derived growth factor (PDGF)



Substance P (*SP*) was the first of the peptides to be characterized as a 'gastrointestinal' neuromediator. It consists of 11 amino-acid residues and is a major neuromediator in the brain and spinal cord. It occurs in about 20% of spinal and trigeminal ganglion cells, in particular those small neurons giving off narrow unmyelinated (class C) or myelinated (Aδ) axons, nociceptive in function. It is also present in some fibres of the facial, glossopharyngeal and vagal nerves. Within the central nervous system, SP is present in several apparently unrelated major central nervous pathways. It is contained within large granular synaptic vesicles in multi-neuromediator synapses; its known action on neurons is prolonged postsynaptic excitation.

Vasoactive intestinal polypeptide (*VIP*), another gastrointestinal peptide, is also widely present in the central nervous system, where it is probably an excitatory neurotransmitter or neuromodulator. Its distribution includes, among many other areas, distinctive bipolar neurons of the cerebral cortex, small spinal ganglion cells, particularly of the sacral region, and the median eminence of the hypothalamus where it may be involved in endocrine regulation. It is also present in intramural ganglion cells of the gut wall and sympathetic ganglia.

Somatostatin (ST, somatotropin release inhibiting factor) has a broad distribution within the nervous system and may be a central neurotransmitter or neuromodulator. It has also been detected in small spinal ganglion cells.

β-*endorphin, leu-enkephalin and met-enkephalin and the dynorphins* belong to a group of peptides ('naturally-occurring opiates') which have aroused much interest because of their pharmacological properties in relation to analgesia. They bind to opiate receptors in the brain and can induce analgesia if infused into appropriate areas of the brain stem. Although their distribution in the brain is complex, they coincide frequently with the opiate receptor sites, as determined by biochemical and radioactive labelling methods. In general their action seems to be inhibitory. The enkephalins have been localized in many areas of the brain, particularly the septal nuclei, amygdaloid complex, basal ganglia and hypothalamus; they therefore appear to be important mediators in the limbic system and in the control of endocrine function. They are also strongly implicated in the central control of pain pathways, including the peri-aqueductal grey matter of the midbrain, a number of reticular raphe nuclei (e.g. nucleus raphe magnus, the medial reticular formation of the rhombencephalon) and the spinal nucleus of the trigeminal with its spinal continuation into the substantia gelatinosa. Among other means of modulating the nociceptive channels, the enkephalinergic pathways appear to exert an important presynaptic inhibitory action on the nociceptive afferents in the spinal cord and brain stem (see p. 942). Like many other neuromediators, the enkephalins also occur widely in other parts of the brain, though in lower concentrations, being present throughout the neocortex, the olivo-cochlear bundle and many other sites in the nervous system.

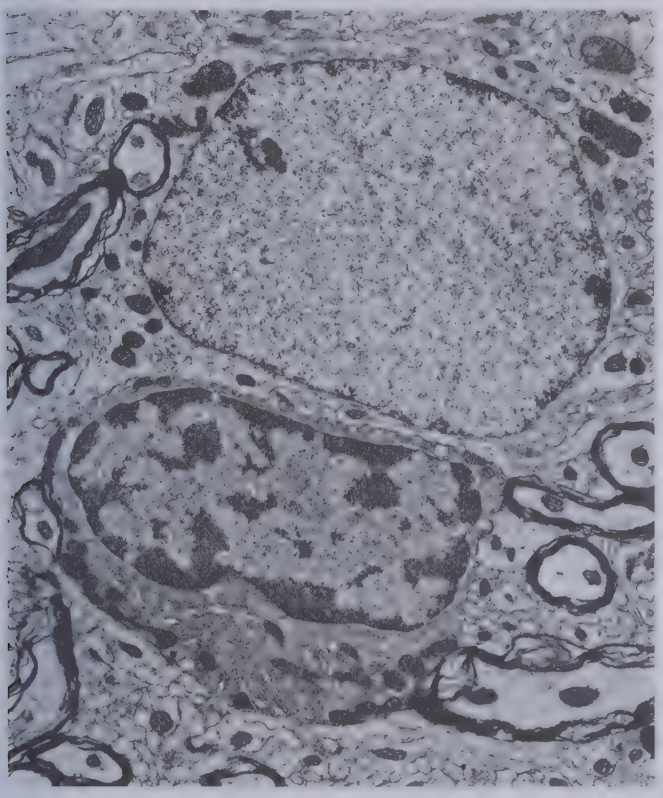
Cholecystokinin is present throughout the brain but is particularly concentrated in the cerebral cortex, amygdaloid complex, hippocampus, peri-aqueductal grey and the dorsal grey columns of the spinal cord. Its precise functions in these sites are as yet uncertain.

7.28 Schema showing the types of non-neuronal cells in the central nervous system. The ependymal and glial cells are shown in green. The ependyma includes examples of ciliated and non-ciliated cells and one tanycyte, with a centrally directed basal process. Two astrocytes are shown apposed to a neuronal soma and dendrites; one (above) also contacts a capillary, the other (below) expands on the pial surface. An oligodendrocyte (middle right) provides myelin sheaths for two axons. Two flattened microglial cells, one adjacent to a capillary (middle right), and the other within the neuropil at the top left, are also illustrated.

Neuroglia

Non-excitable cells constitute a major component of nervous tissue (7.28, 29, 30, 31) with many important functions in the operation of the nervous system as a whole. In the **peripheral nervous system** they include a number of different classes, among which the Schwann cell (lemmocyte) is most prominent (p. 901); but in the peripheral ganglia of spinal and autonomic pathways *capsular gliocytes* (*satellite cells*) ensheath ganglion cells, terminal *lemmal cells* occur around encapsulated sensory terminals and *teloglial cells* ensheath motor terminals; various types of supporting cells (*sustentaculocytes*) are present in sensory epithelia. These various types of cell will be considered later in this section (p. 901, 911).

In the **central nervous system** the non-excitable cells include various classes of *neuroglial cells* and also cells which line the internal cavities of the brain and spinal cord (*ependymal cells*, *choroidal cells*, etc.).



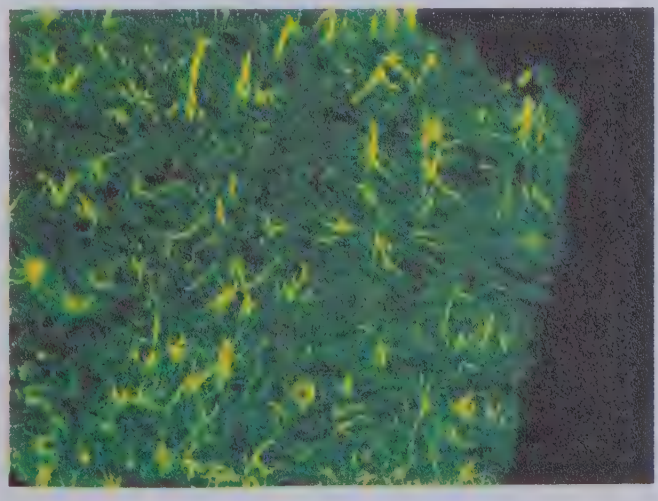
NEUROGLIAL CELL TYPES

Neuroglial cells vary considerably in abundance and types in different regions of the central nervous system. In earlier times, their small size and variable reactions to the special staining methods needed to demonstrate them made them less accessible than neurons to histologists. It was only with the application of electron microscopy, biochemistry and, more recently, immunohistochemistry and cell culture methods that any great

advances on the classic descriptions (e.g. by del Rio Hortega 1924) have been made. Even now there are many uncertainties about the number of classes of neuroglial cells and of their origins and functions in the nervous system. However, they are divisible into two major groups according to their origins: *macroglia* which arise within the neural plate in parallel with neurons and which constitute the great majority of neuroglial cells; and *microglia*, smaller cells derived from mesodermal tissues around the nervous system, which enter relatively late in development (and may continue to do so in postnatal life in small numbers). Microglial cells are generally considered to be a type of mononuclear phagocyte (p. 668).

Macroglia

The cells of this division consist of *astrocytes* and *oligodendrocytes*; this term may also be extended to include specialized types such as *retinal glyocytes* (*Müller cells*), *Bergmann glia* of the cerebellum, *pituicytes* of the neurohypophysis, *ependymal cells* and *choroidal cells*. In addition to these there are the stem cells from which macroglial cells originate during development and throughout postnatal life.



7.29 An electron micrograph of two neuroglial cells situated amongst myelinated and non-myelinated nerve fibres, in the rat thalamus. An oligodendrocyte containing numerous mitochondria, a well-developed endoplasmic reticulum and an indented nucleus is shown below; a larger astrocyte with a vesicular nucleus and scanty cytoplasm is demonstrated above. Provided by A R Lieberman of University College, London.

Astrocytes (7.28) have small somata (in humans about 8 µm across) with many dendritic extensions. Traditionally they have been subdivided into star-like *protoplasmic astrocytes*, with broad symmetrically spread processes confined to the grey matter and *fibrous astrocytes* located chiefly in the white matter, their processes spread asymmetrically, often in a radial direction among the fasciculi of nerve fibres. A third type, the *perinodal astrocyte* has recently been proposed as occurring in relation to the node of Ranvier in central myelinated fibres, constituting a cell type intermediate between an astrocyte and an oligodendrocyte. Fourthly, immature *stem astrocytes* capable of mitosis are present in certain areas such as the subventricular zones of the nervous system (see p. 195). Astrocytic processes have fine, foliate extensions which partly surround and separate neurons and neurites, often ending in plate-like expansions on blood vessels, ependyma (vide infra) and the pia mater limiting the surface of the central nervous system (the *glia limitans externa*). Ultrastructurally they are typified by a pale nucleus with a narrow rim of heterochromatin (7.29), pale cytoplasm rich in glycogen, lysosomes (*granules* or *gliosomes* of light microscopy), Golgi complexes and (in fibrous astrocytes) bundles of intermediate (10 nm) filaments throughout their processes (Mori & Leblond 1970, Ling et al 1973). Glial filaments contribute much to the total protein content of brain. Characteristically, these intermediate filaments are composed of *glial fibrillary acidic protein* (GFAP) which can be readily detected by immunocytochemistry (7.30). These filaments are probably skeletal in function (Schacher et al 1977). Desmosomes and gap junctions (pp. 18–19) form contacts between astrocytes and sometimes between astrocytes and neurons. Such cells show several forms; isotopic labelling suggests that astrocytes which can divide in mature animals undergo structural transformations before disintegration. In injured brain they proliferate (gliosis) and can then also act as phagocytes and later form scar tissue.

Oligodendrocytes (7.28, 29), as the name implies, have fewer processes than astrocytes. They occur as *intrafascicular* cells in myelinated tracts and as *perineuronal* oligodendrocytes where their processes adjoin neuronal somata. Their major role is to lay down myelin around central nervous axons and thus they are the central counterpart of peripheral myelinating Schwann cells. However, the composition and detailed form of central and peripheral myelin differ (Gregson 1975) and the relation between the axon and the myelinating cell is also dissimilar: an oligodendrocyte may enclose several axons in separate myelin sheaths, whereas Schwann cells ensheath only one axon. Ultrastructurally oligodendrocytes have a round nucleus and a cytoplasm rich in mitochondria, microtubules and glycogen. Like astrocytes, they vary from cells with large euchromatic nuclei and pale cytoplasm to those with heterochromatic nuclei and dense cytoplasm. Tritium labelling shows that they can proliferate in *mature* animals and thus show stages of maturation and degeneration.

Glioblasts are pre- or postnatal stem cells differentiating into macroglia. They have a pale nucleus and cytoplasm, free ribosomes and are usually rotund. They are numerous, even in adults, in a diffuse subependymal zone. It is not known whether they are multipotent in adults, i.e. able to form astrocytes or oligodendrocytes, or if individual gliocytes for each line may exist. They appear to be the main source of macroglial cells by mitotic division in fetal and postnatal periods (Mori & Leblond 1970, Ling et al 1973, Kaplan & Hinds 1980, Sturrock 1982, Reyners et al 1986, Berry 1986).

7.30 Section of the brain stem (rat) stained by immunfluorescence to show astrocytes containing glial fibrillary acidic protein (GFAP). Preparation by Martin Sadler, Anatomy Department, UMDS, Guy's Campus, London. Magnification × 150.

7.31 Astrocyte in tissue culture, demonstrating the presence of glial fibrillary acidic protein (GFAP), shown by rhodamine immunofluorescence. Provided by Caroline Wigley, Anatomy Department, UMDS, Guy's Campus, London. Magnification × 600.

Pituicytes of the neurohypophysis resemble astrocytes but their processes end mostly on vascular endothelial cells. **Müller** cells of the retina (p. 1199), or *radial gliocytes*, have much in common with astrocytes and have a similar origin. Cerebellar **Bergmann glial cells** have somata arranged in a row some distance below the pial surface. A single apical process branches to end in pial expansions (end-feet).

Ependymal cells (ependymocytes) form a unicellular epithelium lining the ventricles and central canal (7.28). They vary from squamous to columnar in form according to their locality. At the ventricular surface they are in contact by means of gap junctions and occasional desmosomes; their surfaces have numerous microvilli and cilia, the latter often motile and contributing to the flow of cerebrospinal fluid. Ultrastructurally (Brightman & Palay 1963, Bleier 1977) the nucleus is heterochromatic and indented; their cytoplasm abounds in mitochondria, lysosomes, microtubules and microfilaments. There is much regional variation in the ependymal lining of the ventricles but four major varieties have been distinguished in mammals (see Scott et al 1974, Page et al 1979, Page & Leure-duPre 1983).

These consist of: (1) general ependyma overlying areas of grey matter; (2) general ependyma lining white matter; (3) specialized areas of ependyma in the third and fourth ventricles; (4) choroidal epithelium.

Firstly, the ependyma overlying areas of grey matter are cuboidal, each cell bearing about 20 cilia in its apical centre, surrounded by short microvilli. The cell margins are not extensively folded, and cells are joined by gap junctions and desmosomes; their contents are as stated above. They do not have a basal lamina, but beneath them is a subependymal zone from two to three cells deep, consisting of cells resembling ependymal cells in their organelles and nuclei; the blood vessels beneath them have no fenestrations and few transcytotic vesicles, i.e. they are typical of the central nervous system (p. 691). Where the ependyma lines myelinated tracts, cells are much flattened and even squamous and fewer of them are ciliated; again there are gap junctions and desmosomes but the lateral margins of cells are highly folded and interdigitating. No subependymal zone is present but blood vessels are as described for the previous type. It has been suggested that these differences may be related to a greater role in the exchange of metabolites between grey matter and cerebrospinal fluid than occurs for white matter, the former being metabolically more demanding than the latter.

Specialized areas of ependymal cells are found in four areas around the margins of the third ventricle (the circumventricular organs) including the lining of the median eminence of the hypothalamus and forming the subcommissural organ, the subfornical organ and the organum vasculosum of the lamina terminalis and other related areas (see p. 1005). At the inferoposterior limit of the fourth ventricle is the area postrema, which has a similar structure. In these sites the ependymal cells are only rarely ciliated and their ventricular surfaces have many microvilli and apical blebs. They have many mitochondria and well-formed golgi complexes lying apical to a rather flattened, basal nucleus. The cells are joined laterally by tight junctions, forming a barrier to the passage of materials across the ependyma, and desmosomes. Many of these cells are *tanycytes*, with basal processes projecting into the perivascular spaces surrounding underlying capillaries, which are fenestrated and therefore do not form a blood–brain barrier. It is thought probable that these areas constitute special zones by which substances can pass from the nervous tissue and vascular supply into the cerebrospinal fluid within the ventricle by active transport through the ependymal cells; many of the neurons in the vicinity of such areas liberate neuropeptides and other biogenic substances, which may therefore pass into the ventricles to gain access to a much wider population of neurons via the permeable ependymal lining of the rest of the ventricle; a reverse process is also likely by this route (see also p. 1453). High concentrations of receptor sites for certain neuropeptides are present at these surfaces.

Finally, the ependyma is highly modified where it lies adjacent to the vascular layer of the *choroid plexuses* (p. 1080). Here the cells resemble those of the circumventricular organs, except that they do not have basal processes but constitute a cuboidal epithelium resting on a basal lamina adjacent to the externally applied pia and capillary layer (with fenestrated endothelium). Cells have numerous long microvilli with a few cilia interspersed; they have many mitochondria and large golgi complexes and their nuclei are basally placed. Tight junctions forming a transepithelial barrier and desmosomes occur between cells and the lateral margins of cells are highly folded. All of these structural features accord with the secretory activity of these cells, which are responsible for the formation of most of the cerebrospinal fluid.

Tanycytes (*ependymoglial cells*, *ependymal astrocytes*) have already been mentioned in connection with the possible transport of substances between the vascular system, neurons and the ventricular contents. This form of cell, often with a highly elongated basal process which in some cases reaches the pial surface, is encountered during early development of the central nervous system, where it appears to play a vital part in guiding the migration of neurons (pp. 195, 918). Such cells also occur widely in the nervous systems of lower vertebrates and may be regarded as perhaps the most primitive type of glial cell, phylogenetically. They also persist in mammals in the form of retinal Müller cells and somewhat modified Bergmann glia (vide supra), which may also be involved in guiding neuronal migration; it is interesting that these cells share certain immunochemically demonstrable antigens not present in other astrocytes (see e.g. Schachner 1982).

The functions of glial cells may be numerous, though not yet fully explored (Kuffler & Nicholls 1976): (1) They are a supporting component in nervous tissue; glial filaments, microtubules and surface contacts suit them to this role. (2) They are insulators, separating neurons and their processes, grouping synaptically interacting regions and limiting the ionic spread from neurons. Electrical studies in leeches, where gliocytes are large, confirm this, showing their inability to conduct surface depolarization (Nicholls & Kuffler 1964). (3) They are phagocytes of foreign material or cellular debris and provide limited repair as glial scar tissue or fill gaps left by degenerated neurons. (4) They absorb and store neurotransmitters from nearby synapses and may metabolize them; thus transmitters are removed from the sites of action, as shown by autoradiographic studies of e.g. gamma aminobutyric acid uptake by gliocytes (Schon & Kelly 1974). Transmitters may sometimes be released from them, though this has not yet been demonstrated as a normal activity; changes in external potassium, occurring when nearby axons are active, cause GABA release (Iversen & Kelly 1975), which may modify local synaptic processes (Kuffler & Nicholls 1976). (5) Oligodendrocytes form and maintain myelin sheaths of the larger central axons like Schwann cells in the periphery. (6) Ependymocytes are associated with secretion into and uptake and transport from the

cerebrospinal fluid, e.g. in regions associated with hypophysis cerebri, where they may transport hormone-controlling factors in the median eminence and hypophysial stalk (Bleier 1977). (7) Macrogliocytes may help in the control of physiological activity in the neuronal groups which they infiltrate, by regulating their metabolic and ionic environment. Astrocytes (and Schwann cells) have both cation and anion channels at their surfaces and can take up potassium and chloride readily (see Gray & Ritchie 1985); metabolic alterations in glial cells may also affect the ionic environment of neurons and hence their patterns of excitability (Kuffler & Nicholls 1976). Such alterations may occur when anions such as chloride, applied experimentally to the brain surface, cause the *spreading depression of Leao*; various cerebral metabolic changes may also affect electrical behaviour in this way, either normally or pathologically. (8) Golgi first suggested that macrogliocytes, by contacts with blood vessels and ventricular surfaces and neurons, could be an intracellular route for nutrient diffusion from blood and cerebrospinal fluid to neurons, but there is little firm evidence of this; consistent evidence of a neuroglial connection between the nutrient supply and the neuronal surface is lacking and other routes are available, intercellular diffusion and intracellular transport being adequate for this. While glial nutrient routes cannot be excluded, they need not be invoked to explain neuronal nutrition. (9) An important function of glial cells may be to prevent other cell types (e.g. fibroblasts) from growing into the central nervous system; this may be brought about by passive exclusion or, as seems more likely, by active inhibition; this may be related to the failure of axons to regenerate within the central nervous system (see p. 918).

Microglia

Microgliocytes (7.28), the smallest glial cells, have flattened profiles and give off numerous fine, short, dendritic processes insinuated between neurons or applied to capillaries. Ultrastructurally, they show heterochromatic, flat or indented nuclei and many lysosomes, features identical with those of extra-neural macrophages. Experiments with labelled medullary or circulating monocytes show that such blood cells can migrate as macrophages into damaged or degenerating central nervous tissues to phagocytose cellular debris; they are indistinguishable from indigenous microgliocytes activated to perform a similar role. Indeed, macrophages may remain as sedentary microglia, though most apparently migrate into the brain and spinal cord in late fetal and early postnatal life (Imamoto & Leblond 1977, 1978, Ling 1978). See also Hayes et al (1988).

ORIGINS OF NEUROGLIA AND EPENDYMA

As stated elsewhere (pp. 178, 917), ideas about the origins of the different cell types of the nervous system have undergone a number of major changes over the last century and are still not worked out in detail. However, it is now generally agreed that cells of the neural plate begin to differentiate early in the development of the nervous system into neuronal and glial cell lines and that the first recognizable type of the latter is probably the radial glial cell (also termed an ependymal astrocyte or early tanycyte). The perinuclear cytoplasm of this cell forms part of the ventricular lining but it also has a highly attenuated process which stretches away from the ventricle as far as the outer, pial surface of the central nervous system, so bridging the entire wall. Radial glial cells are considered to be of major importance in directing neuroblast migration (see p. 195 for further details); they also appear to give rise to astrocytes which migrate into the nervous tissue and also, by losing their basal processes, they form the ependymal cell layer lining the ventricle. (In some cases the basal process is retained, as in the mature tanycytes of the endocrine hypothalamus, p. 1453.) Immunohistochemical and electron microscopic methods have also shown that the periventricular zone of cell proliferation found in the early neural tube includes cells with glial characteristics (e.g. they are positive for glial fibrillary acidic protein, GFAP), so it is likely that glial cells begin to be formed at the same time as neuroblasts but, unlike neuroblasts, they are able to continue proliferating albeit at a reduced rate in postnatal life. The subependymal layer of the periventricular region is a major source of such cells, new astrocytes migrating out into the neural tissue to their final destinations.

The further differentiation of the classes of macroglial cells is even less clear. Recently, several immunohistochemical markers of the different glial cells have been developed and in particular have been applied to cells in tissue culture as well as in the intact nervous system. Although the most detailed analysis applies only to the cell lineages of the optic nerve, the results may also apply to other parts of the nervous system (Miller & Raff 1984). Astrocytes of the optic nerve are divisible into two classes on the basis of their antigens reactive to monoclonal antibodies. Type I astrocytes probably correspond to the classic protoplasmic and fibrous astrocytes, while Type II is thought to be a perinodal cell. Type I and II cells are formed from separate stem cells but Type II cells share the same stem cell as oligodendrocytes, differentiating along one or other of the latter pathways depending on environmental factors.

It appears that new astrocytes can be formed throughout life, particularly in early postnatal growth and in response to injury; likewise oligodendrocytes have a limited ability to proliferate. Whether mature cells retain this ability, or if persistent stem cells are the source of these new cells is at present unknown. This ability has one unfortunate aspect in that the great majority of brain tumours are of glial origin. Schwann cells and various other accessory cells of the peripheral nervous system (ganglionic capsular cells, etc.) are derived from the neural crest and migrate into position in advance of growing neurites. Schwann cells are also able to multiply throughout life; they do this in early postnatal growth of the body but later only divide as a response to injury.

THE BLOOD–BRAIN BARRIER

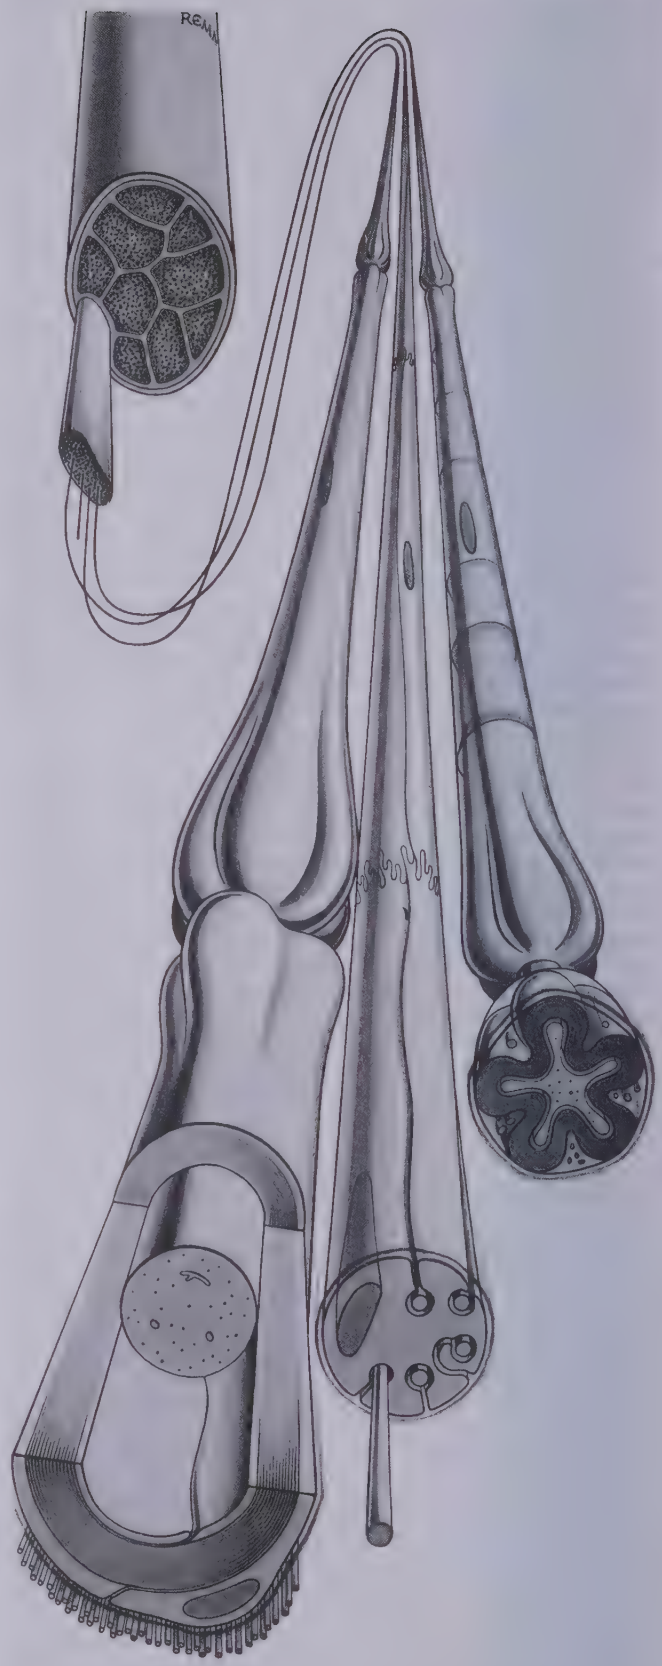
In early experiments it was discovered that certain dyes, when injected into the blood, failed to stain the parenchyma of the brain and spinal cord, though they passed easily into non-nervous tissues. Subsequently observations confirmed that access of various substances from the bloodstream to the extracellular space of the central nervous system is restricted as if by a physiological barrier. The structural nature of this '*blood–brain barrier*' has been much discussed in relation to the chemotherapy of nervous disorders and anaesthesia (Davson 1970). However, many materials injected directly into the *ventricles* of the brain do enter brain tissue, indicating that the barrier exists at capillary level. Experiments with peroxidase as a colloidal tracer (Brightman & Reese 1969, Brightman et al 1970) show that diffusion occurs freely *within* the extracellular spaces of the central nervous system and that, when injected into the central cavities, the tracer passes freely through the ependymal intercellular junctions (which are punctate and of the communicating or 'gap' variety), traversing the nervous tissues to reach the pial surface. Such diffusion stops at the capillary endothelium; the capillaries are unusually impermeable to *large molecules*, due to non-leaky tight junctions, a lack of fenestration and only small numbers of membrane vesicles (p. 691). Diffusion from the choroid plexus is also restricted by the combined impermeability to macromolecules of the vascular endothelium *and* the choroidal epithelium; cerebrospinal fluid therefore contains only materials secreted selectively by the choroidal epithelium (Cserr 1971).

EXTRACELLULAR SPACE IN THE BRAIN

The amount of extracellular space in the central nervous system is of much interest because of its relevance to the diffusion of substances through nervous tissue, including the dissemination of neurotransmitters and neuromodulators, the passage of substances to and from the blood and many other factors determining the local environment of neurons and glial cells. Central nervous tissue totally lacks lymphatic drainage but cerebrospinal fluid draining to the dural vessels may be regarded as analogous to lymph in some respects. Electron microscopy has shown that in

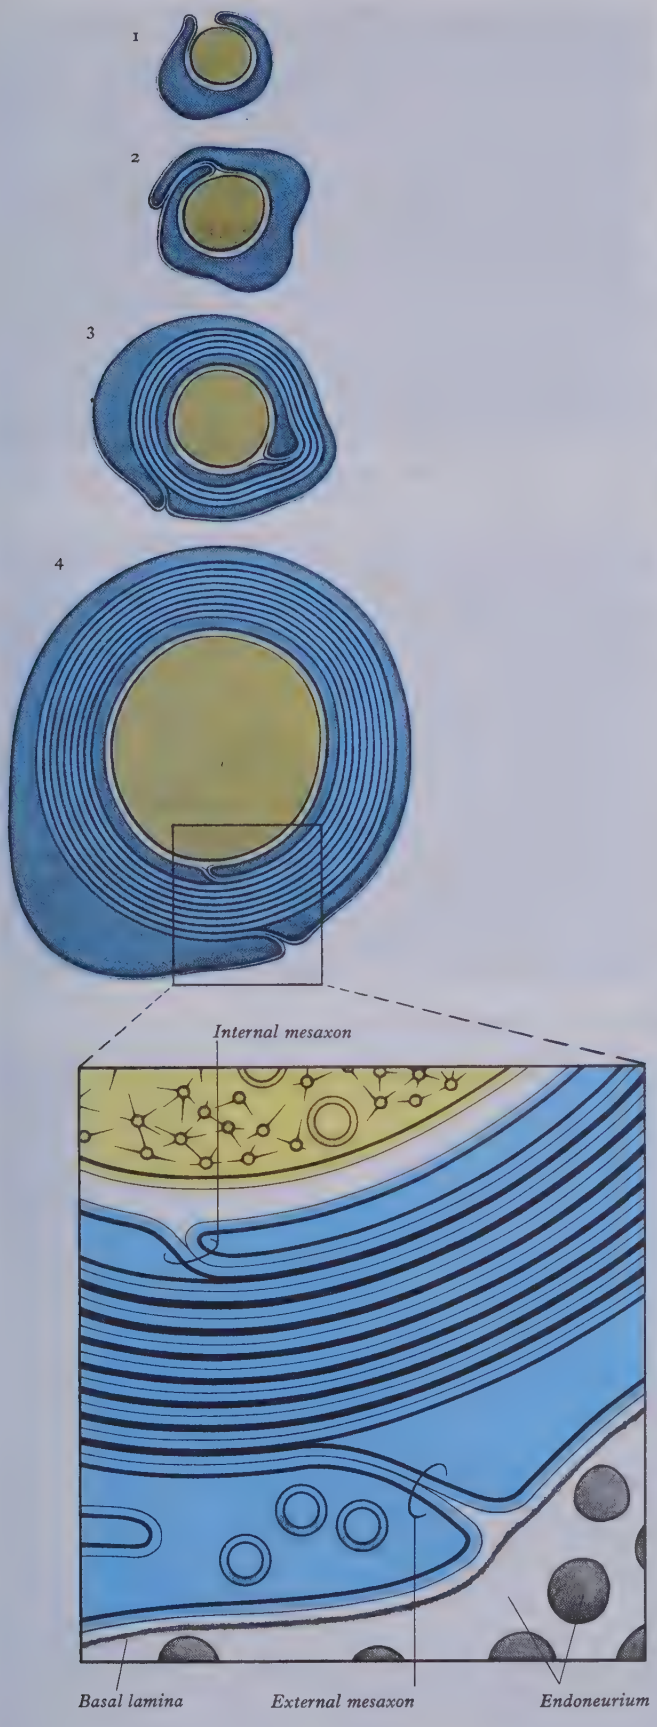
general there is relatively little extracellular space (apart from that within the vascular system), cells being separated by only a 20 nm gap. This has been confirmed by freeze-fracture studies where rapidly frozen tissue is thought to preserve its structure more faithfully than with chemical fixation. However, it appears that some areas of the brain have larger intercellular spaces.

The lack of large diffusion channels through neural tissue is perhaps not a metabolically limiting factor, given the rich capillary beds which are found in the central nervous system; the restriction of extracellular movements is likely to be important in maintaining a tight control on the movements of chemicals and cells in nervous tissue, providing a highly stable environment and a mechanically coherent framework for neural activity.



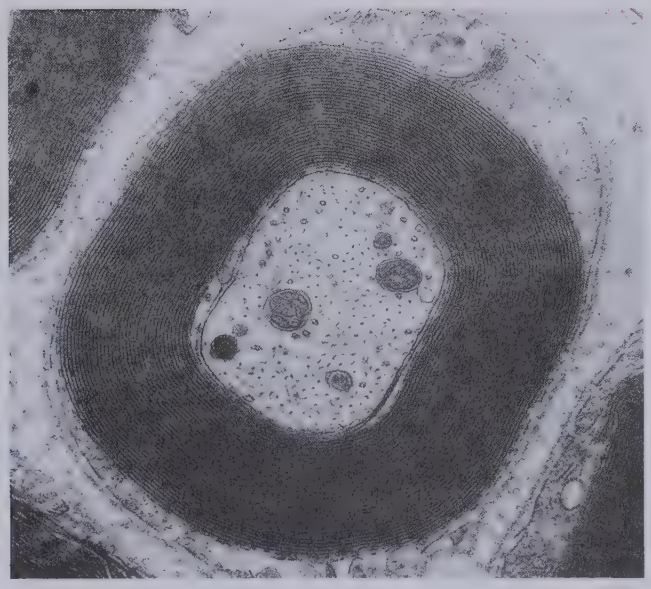
Peripheral Nerve Fibres

As in the tracts of the central nervous system, both myelinated and non-myelinated fibres occur peripherally but they are ensheathed by *Schwann cells* (*lemmocytes, peripheral glia*) in place of oligodendrocytes. Both central and peripheral fibres present some difficulties to the light microscopist, because of the small size of the non-myelinated fibres and the disruption of the sheaths of myelinated fibres caused by treatment with lipid solvents prior to sectioning. Various methods have been devised to overcome these problems. For myelin sheaths these depend on fixing and staining myelin in teased material for individual fibres or in processed and sectioned blocks. Methods using osmium are valuable, because osmium tetroxide in aqueous solution or chromate and haematoxylin solutions fix and stain simultaneously. Frozen sections may be stained with lipid-soluble dyes. Polarized light, phase or interference microscopy are useful for freshly teased or living nerves. Time-lapse cinemicrography and videotape recording techniques with closed-circuit television have aided the analysis of living nerve fibres (Williams & Hall 1970, 1971a, b). The methods used for demonstrating central neurons (p. 870) have also proved valuable and electron microscopy has added to our knowledge perhaps more than any method.



Structure of the Peripheral Nervous System

The peripheral nervous system includes the craniospinal and autonomic nerves and their associated ganglia, together with their connective tissue sheaths. All lie peripheral to the pial covering of the central nervous system, through which the central and peripheral nerve fibres are continuous, although with contrasting detailed structure and behaviour (7.32–46).



The **sensory ganglia** of dorsal spinal roots (7.36) and the ganglia of the trigeminal, facial, glossopharyngeal and vagal cranial nerves are enclosed in periganglionic connective tissue, resembling perineurium (p. 897). Their neurons are *unipolar*, with spherical or ovoid somata of varying size, aggregated in groups interspersed with fasciculi of myelinated and non-myelinated nerve fibres. Their structure is described elsewhere (p. 1093); a single non-myelinated neurite (a 'dendro-axonal' process) leaves each soma, highly convoluted at its origin before bifurcating at a T-junction into the central and peripheral processes of a sensory nerve fibre. In myelinated fibres the junction occurs at a node of Ranvier (p. 903). The peripheral neurite reaches a sensory ending; since it conducts towards the soma it is functionally an *elongated dendrite* but has the structural and functional properties of a *peripheral axon* and, following common usage, it will be so termed here. Each unipolar soma has a *nucleated capsule* of flat, epithelioid *capsular cells*, variously termed ganglionic gliocytes or *satellite cells*. (The term *satellite* is applied in different ways; some use it for small round extracapsular ganglionic cells, others include ganglionic capsular cells and Schwann cells or include all non-neuronal cells, central and peripheral, which are perineuronal. The name is also applied to cells associated with striated myocytes, p. 562.) The cytoplasm of capsular cells resembles that of Schwann cells (vide infra); their deep surfaces interdigitate with reciprocal irregularities in the

7.32 Some structural features of peripheral nerve fibres. A nerve trunk (top left) is cut away to expose a single fasciculus, from which three fibres are indicated in detail. These include two myelinated axons, one on each side of a group of non-myelinated axons enclosed within a Schwann cell sheath. The myelinated fibre on the left has been cut away at various points to demonstrate the relationship between the axon, the Schwann cell and its sheath of myelin.

7.33 The development and organization of the myelin sheath of a peripheral nerve fibre. In stages 1–4 myelin formed by a Schwann cell (blue) progressively envelops the growing axon (yellow), to form the final pattern of spirally disposed myelin lamellae: see enlarged detail at the base of the diagram.

7.34 An electron micrograph of a myelinated peripheral nerve fibre, showing an axon containing neurofilaments, microtubules and mitochondria, surrounded by a myelin sheath, enclosed in turn by Schwann cell cytoplasm and endoneurial spaces. Provided by S Standring, Department of Anatomy, UMDS, Guy's Campus, London. Magnification ×25 000.

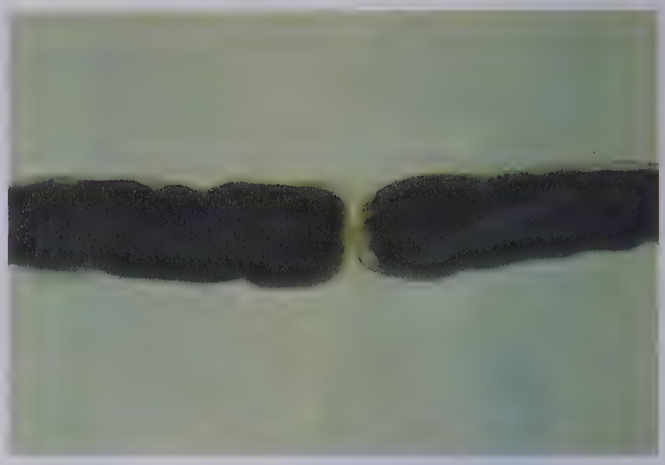
exteriors of the subjacent nerve cells. The capsular layer is continuous with similar cells enclosing the convoluted part (*initial glomerulus*) of the dendro-axonal process and then with the Schwann cells of the peripheral and central processes. Outside these layers lies a delicate vascular connective tissue continuous with the endoneurium of the peripheral nerve and nerve root.

Sensory ganglionic neurons are not entirely confined to the discrete craniospinal ganglia; singly or in small groups they often occupy '*heterotopic*' positions distal or proximal to their ganglia.

Autonomic ganglia have a different structure; their neurons are multipolar, with dendritic trees receiving synapses from preganglionic autonomic motor fibres, and are surrounded by a mixed neuropil of afferent and efferent fibres, dendrites, synapses and non-neural cells (p. 1157).

Nerve trunks and their principal branches consist of parallel bundles of efferent and afferent axons and are ensheathed by Schwann cells which in some cases elaborate *myelin sheaths*; these are surrounded by connective tissue sheaths at different levels of organization. Nerve fibres (i.e. axons with their ensheathing Schwann cells) are grouped into *fasciculi* of widely variable numbers. The size, number and pattern of fasciculi vary in different nerves and at different levels along their paths; their number increases and their size decreases some distance proximal to a point of branching. Similarly, where nerves are subjected to pressure, e.g. deep to a retinaculum, fasciculi are increased in number but reduced in size and the associated connective tissue and vascularity also increase; such a nerve shows a pink, fusiform dilatation, sometimes termed a *pseudoganglion* or *gangliform enlargement*.

A dense, irregular, connective tissue sheath, the *epineurium*, surrounds the trunk and a similar though thinner *perineurium* encloses each fasciculus, in which the spaces between nerve fibres contain a loose delicate connective tissue *endoneurium*. These connective tissue planes provide routes for vessels, capillary beds and associated lymphatics, most of which run largely parallel to the nerve fibres, within endoneurial spaces, with cross-connections passing between them.



The epineurium is a collagenous adventitial coat with little regularity of organization (Thomas 1963); the perineurium in contrast has regular laminae of fibroblasts alternating with collagenous sheets. Mast cells and macrophages are relatively frequent in this sheath. Fibroblasts form junctional complexes, which from some tracer experiments appear to impede to some

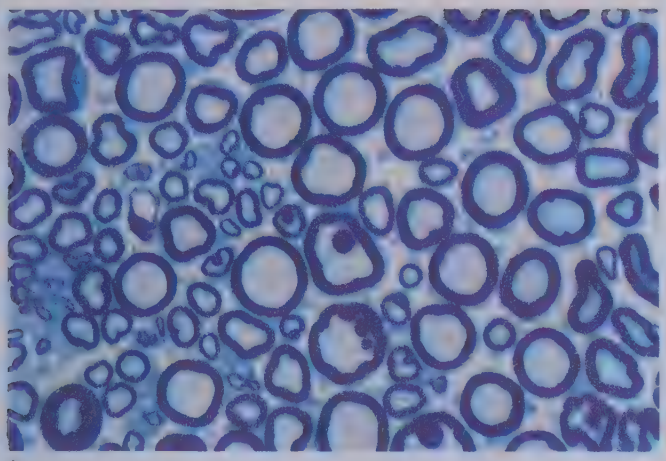
extent the diffusion of large molecules across the sheath (Waggener & Beggs 1967); however, more recently this has been denied. The fibroblasts also have numerous pinocytotic vesicles, an indication of active transport across the perineurium.

CLASSIFICATION OF PERIPHERAL NERVE FIBRES

Several schemes of classification of peripheral nerve fibres have been used, based on various parameters including conduction velocities, functional nature, fibre diameters and other attributes. Of two in common use (see accompanying table), the first, devised by Erlanger & Gasser (1937) from conduction speeds in amphibian axons, divides fibres into three major classes, designated A, B and C, corresponding to peaks in the distribution of their conduction velocities. Group A fibres are subdivided into α, β and γ subgroups; B group fibres are preganglionic autonomic efferents, and C fibres non-myelinated. Since diameter and conduction velocity are in most fibres proportional (in myelinated fibres conduction in metres per second is approximately six times the fibre diameter expressed in micrometers), the group Aα fibres are widest and most rapid and C fibres the narrowest and slowest. In mammals Aβ fibres were found to be negligible but a subclass of non-autonomic fibres similar in conduction speeds to B fibres, termed Aδ fibres, was discovered.

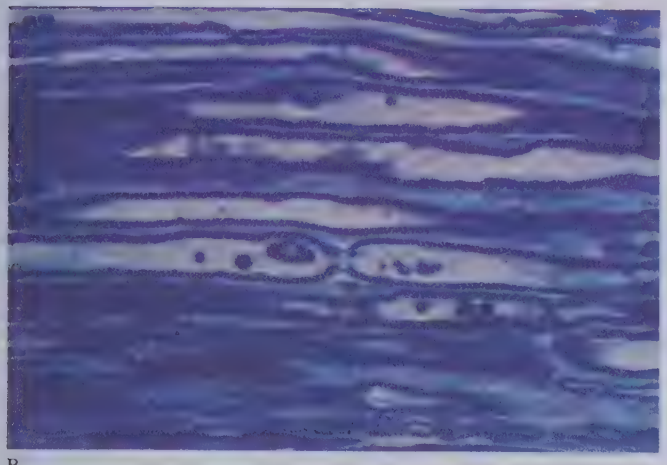
In Erlanger & Gasser's scheme *afferent fibres* are confined to Aα, Aδ and C groups, the largest (Aα fibres) including the axons of the encapsulated cutaneous, joint and muscle receptors and some large alimentary enteroceptors. Aδ fibres belong to nociceptors, including those in dental pulp, skin and connective tissue; C fibres have thermoreceptive, nociceptive and interoceptive functions. *Somatic efferent fibres* include Aα, Aβ and Aγ axons. Aα fibres innervate only extrafusal muscle, being maximally 22 μm in diameter and conducting at a maximum of 120 m/s. Fibres to 'fast' twitch muscles are larger than those to 'slow' muscle. Aβ fibres are restricted to collaterals of Aα fibres, forming plaque endings on some intrafusal muscle fibres; Aγ fibres are exclusively fusimotor to plate and trail endings on intrafusal muscle fibres (vide infra).

7.35 A myelinated fibre demonstrated by teasing an osmium-fixed peripheral nerve. In this preparation a node of Ranvier is visible. Magnification × 1000.



Autonomic efferents comprise preganglionic B fibres and postganglionic sympathetic and parasympathetic axons of the C (non-myelinated) group. This scheme can be applied to all fibres of spinal and cranial nerves except perhaps those of the olfactory nerve, whose fibres form a uniquely small and slow group.

Another classification, used for afferent fibres of somatic muscles, was introduced by Lloyd in 1943: myelinated fibres are divided into groups I, II and III, non-myelinated fibres forming group IV. *Group I* fibres are large (12–22 μm) and include primary sensory fibres of muscle spindles (Group Ia) and smaller fibres of Golgi tendon organs (Ib). *Group II* comprises fibres of secondary sensory terminals of muscle spindles, with diameters of about 6–12 μm. *Group III* fibres, 1–6 μm in diameter, have free sensory endings in the connective tissue sheaths around and within

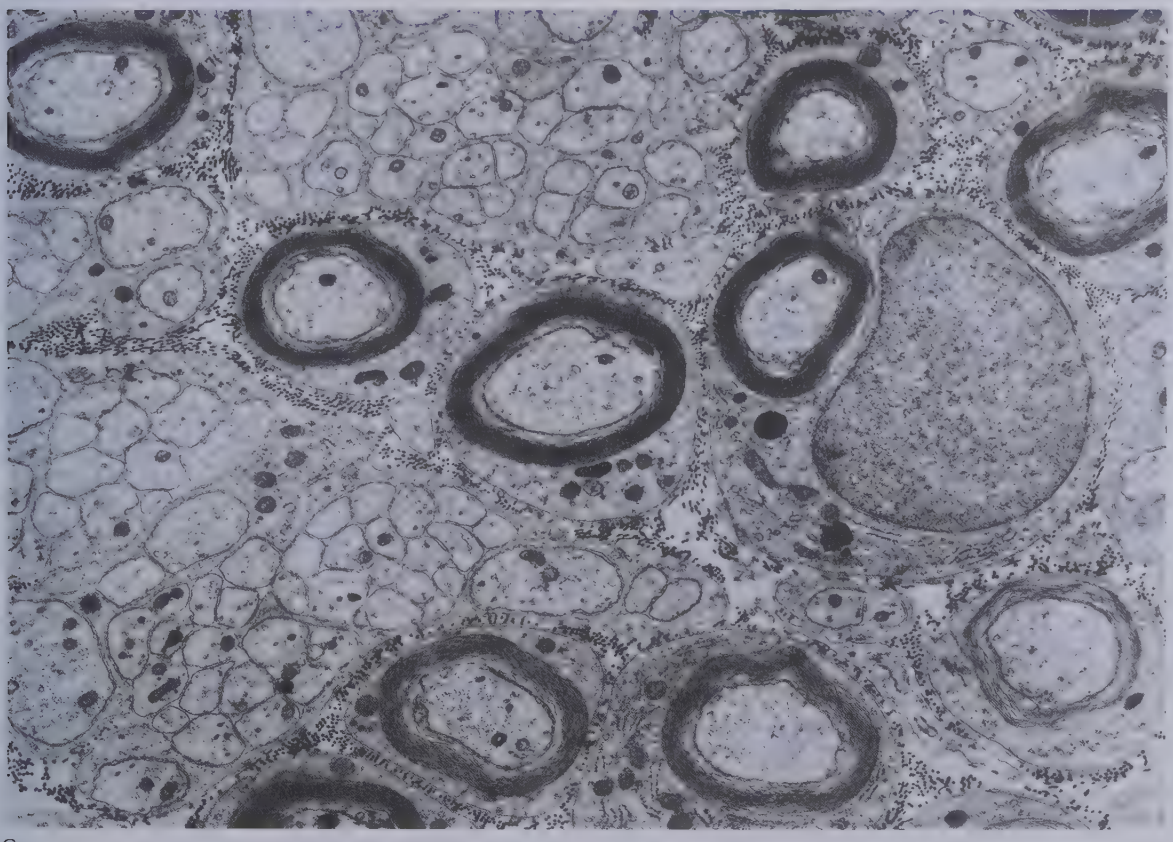


CLASSIFICATION OF PERIPHERAL NERVE FIBRES

CHARACTERISTICS OF FIBRE Type of sheath	Myelinated				Non-myelinated
Fibre diameter	22 μm			1·5 μm	2·0–0·1 μm
Conduction speed (Metres/second)	120	60	50	30 ·· 4	0·5
CLASSIFICATION		A		B	C
1. Erlanger & Gasser *All fibres*					
Subclasses: Efferent	Aα Skeletomotor	Aβ Fusimotor collaterals of A fibres	Aγ Fusimotor	B Preganglionic autonomic	C Postganglionic autonomic
Afferent	Aα and smaller Muscle and tendon; cutaneous			Aδ Cutaneous, muscle visceral, etc.	C Cutaneous, muscle visceral, etc.
2. Lloyd Afferent—skeletal muscle and articular	I *a* primary spindle ending *b* tendon ending	II Secondary spindle ending		III Free ending (nociceptor, etc.) paciniform ending?	IV Free ending (nociceptor, etc.)

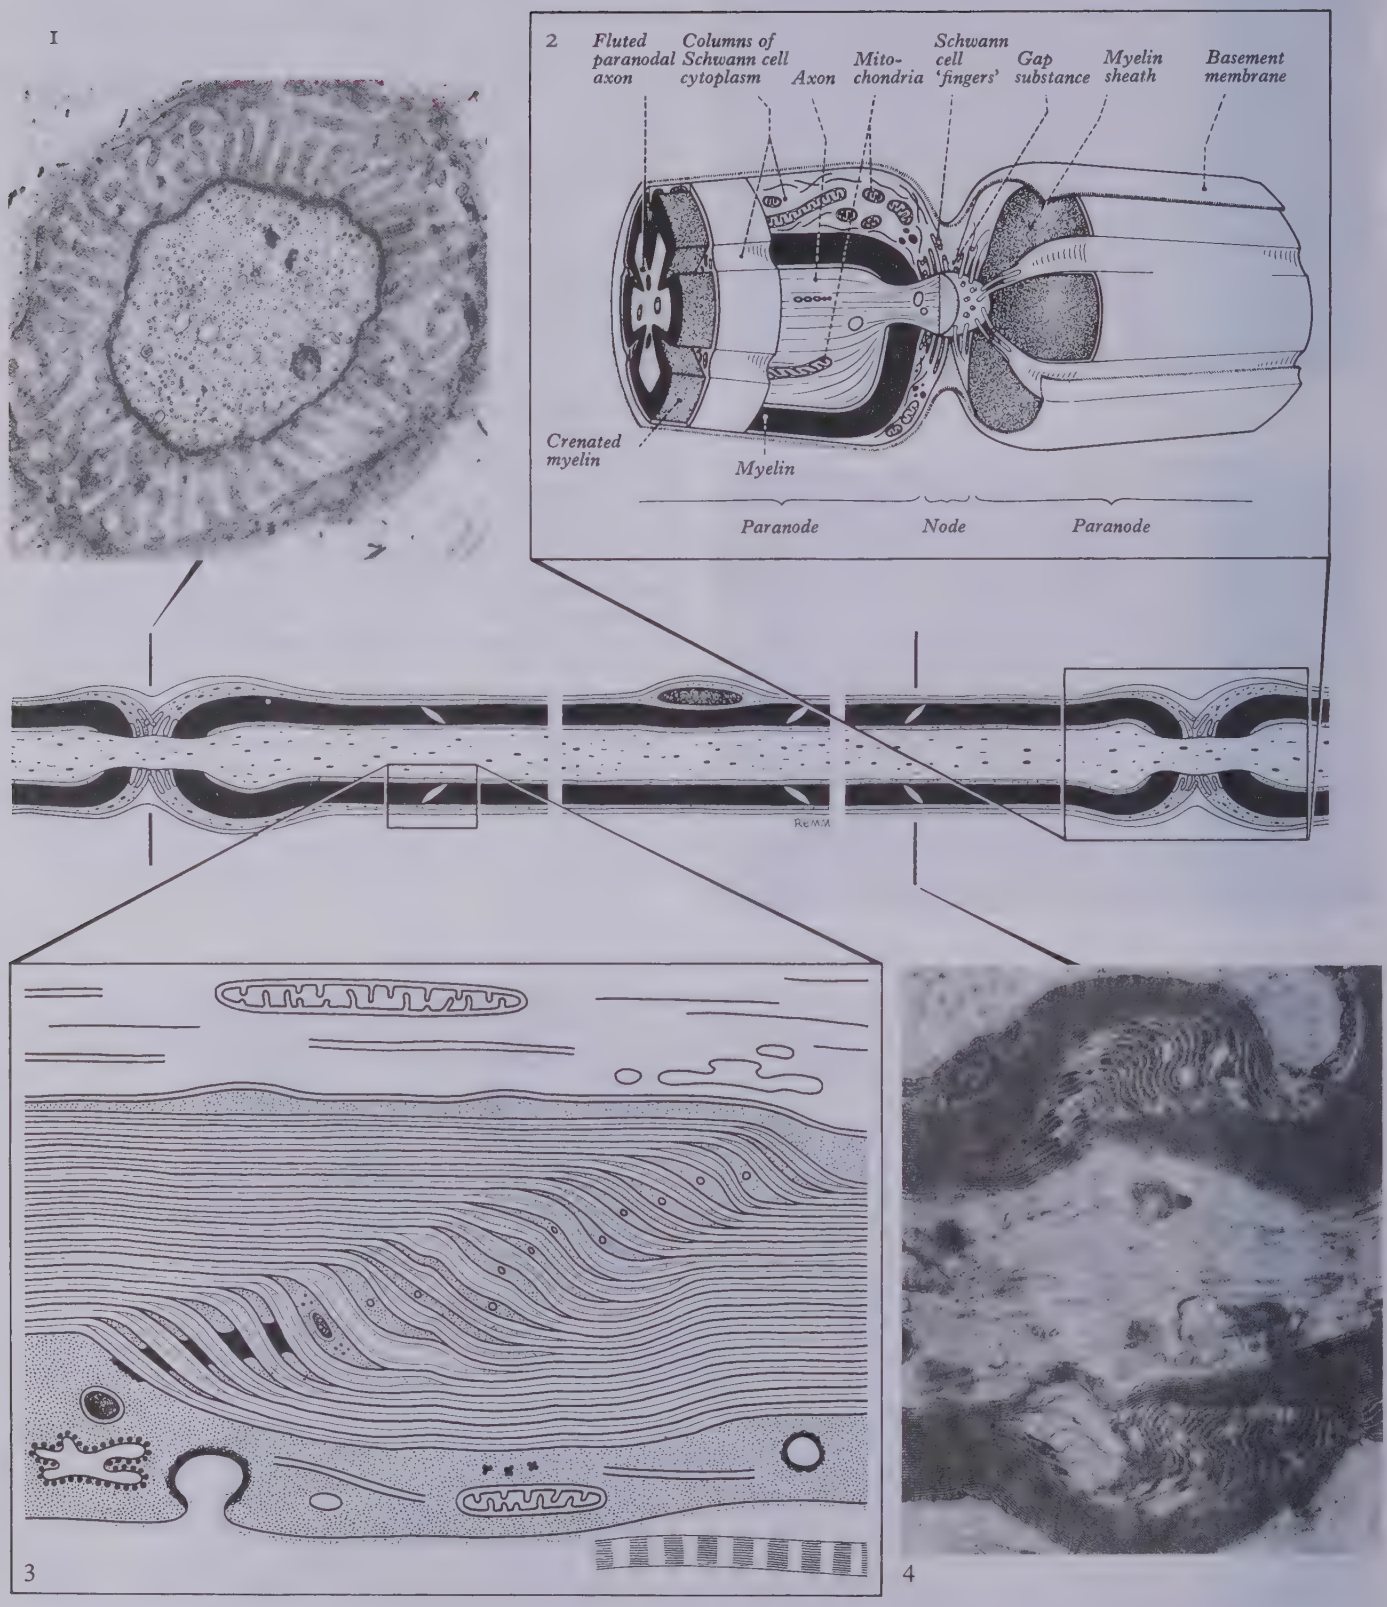
It should be noted that the scale for conduction velocities is not arithmetic.

A



B

7.36 Structure of peripheral nerve fibres.



A. Transverse section of part of a mixed peripheral nerve from a mouse, showing a wide range of diameters of myelinated nerve fibres. Myelin: dark blue; axoplasm: pale blue, embedded in which are slightly darker blue dots, the axonal mitochondria. Note particularly the wide range of *axon* diameters; the smaller axons possess thinner myelin sheaths. The fibre with a particularly thick, double-contoured myelin sheath (bottom left) is sectioned through an incisure of Schmidt-Lanterman. The large fibres with more complex profiles (centre and bottom) are sectioned near the commencement of paranodal bulbs. On the left, between the myelinated fibres, groups of non-myelinated axons, enclosed by Schwann cells (medium blue) are just visible. A 1 μm epoxy resin section, stained with osmium tetroxide solution and toluidine blue, photographed using oil immersion optics.

B. Longitudinal section of material prepared in a manner similar to that in (A). Note particularly the fibre just below the centre of the field which is sectioned through a node of Ranvier. As the internodal myelin sheath approaches the node, its diameter increases to a maximum (the paranodal bulb) and the myelin sheath then curves sharply inwards, to terminate at the limits of the 'nodal gap'. The myelin profiles, apparently lying free within the paranodal bulbs, are demonstrated to be paranodal shelves of myelin, when serial sections are examined (compare with 7.37). Note also the constriction of the nodal axon; long, narrow axonal mitochondria are also visible.

C. Transverse section of an immature peripheral nerve of a rat, taken one week after birth, showing the profiles of numerous axons. Some of the latter are non-myelinated and, either singly or in groups, are invaginated into the surfaces of cytoplasmic processes of adjacent Schwann cells. Other axons are in the process of myelination. Note the Schwann cell nucleus (right) to one side of a myelin sheath and the ultrastructure of the Schwann cell cytoplasm at this stage of development.

C

7.37 General plan of a myelinated nerve fibre in longitudinal section including one complete internodal segment and two adjacent paranodal bulbs, used as a key for the more detailed microarchitecture of specific subregions. 1: a transverse section through the centre of a node of Ranvier, with numerous finger-like processes of adjacent Schwann cells converging towards the nodal axolemma. Many microtubules and microfilaments are visible within the axoplasm. 2: a diagram showing the arrangement of the axon, myelin sheath and Schwann cell cytoplasm at the node of Ranvier in the paranodal bulbs. Supplied by P L Williams and D N Landon. 3: detailed substructure of one-half of an incisure of Schmidt-Lanterman; consult text for further information. Supplied by Susan M Standring and P L Williams. 4: longitudinal section of part of a myelinated nerve fibre (mouse), including an incisure of Schmidt-Lanterman; this appears as oblique zones in the myelin sheath on both sides of the fibre. Consult text for structural details. Nos. 1 and 4 supplied by Susan M Standring, Dept. of Anatomy, Guy's Hospital Medical School, London.

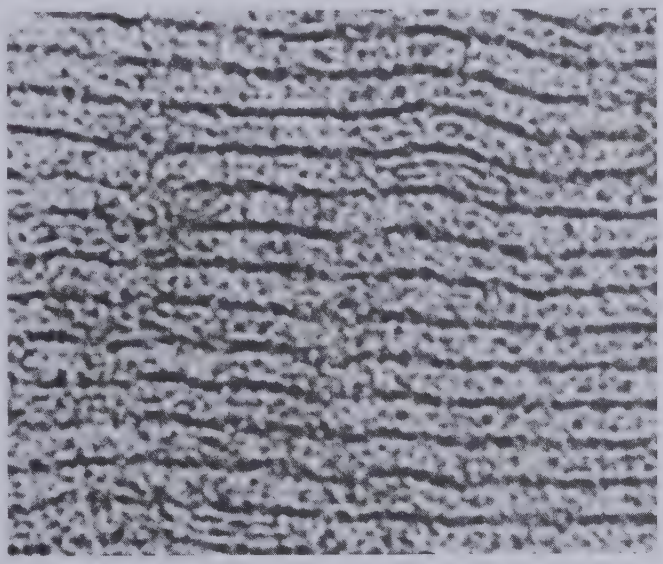
muscles and appear to be nociceptive, related to 'pressure-pain' in externally stimulated muscles. Paciniform (encapsulated) endings of muscle sheaths may also contribute fibres to this class. *Group IV* includes non-myelinated fibres below 1·5 μm with 'free' endings in muscles, being chiefly nociceptive. For a discussion of the sensory nerves of muscle, consult Matthews (1973), Barker (1974) and Hunt (1974).

While these general schemes of classification are valuable in neurophysiology, a single structural parameter such as diameter, measured at one point, cannot adequately categorize nerve fibres throughout the whole course of a nerve. Many values quoted are related only to velocity peaks or sampled diameters. The figures quoted are relative, with some overlap between the functional classes; but these schemes enable us to detect a general pattern of organization in peripheral nerves, which is of considerable interest.

CONDUCTION IN PERIPHERAL NERVES

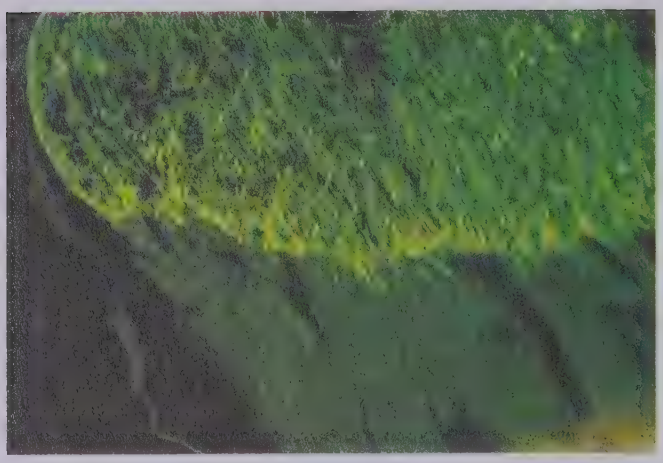
When a nerve is stimulated, the sum of its action potentials, the *compound action potential*, can be recorded with electrodes placed on the surface. Since action potentials travel at different speeds in fibres of different diameters (large fibres creating greater electrochemical fluxes than small fibres), the compound action potential measured at a distance from the point of stimulation is a complex mixture, with at least four sequential waves of different amplitude and velocity, known as α, β, γ and δ waves. As each nerve has its own spectrum of nerve fibres, so is its wave pattern distinctive. In general, fibre types are classified primarily by their conduction velocities, because fibres of different function may have similar velocities (vide supra).

A number of different factors govern conduction velocities of nerve fibres; in non-myelinated fibres, the action potential sweeps continuously over the axolemma as depolarization of one area of membrane triggers depolarization of adjacent areas. The rate of spread is proportional to the axonal cross-sectional area (Hodgkin 1964); but in myelinated fibres the myelin sheath limits propagative excitation to the nodes of Ranvier, from which ionic currents spread to other nodes in sequence. Since the longitudinal flow of ions in the axoplasm and along the outside of the fibre is more rapid than electronic spread along the axonal membrane, much higher velocities are possible by this method, which is termed *saltatory conduction* (Stampfli 1954).



During nodal excitation the permeability of the exposed nodal axolemma to sodium ions increases rapidly and these ions flow in, along their concentration gradient, generating longitudinal ionic currents inside the *internodal axon* to the next node, the electrical circuit being completed by currents in the reverse direction along the outside, in the endoneurial tissue fluid. As the outflow current density at the *next node* reaches *threshold level*, depolarization causes the voltage-sensitive sodium gates in the nodal axolemma to open, repeating the cycle of excitation. Myelin is an imperfect insulator and some radial leakage occurs between the axoplasm of internodes and surrounding tissue fluid, with some loss of efficiency. For a given diameter, maximal efficiency occurs when the axonal diameter and thickness of the myelin sheath are in a ratio of 0·6:1. Only the largest mammalian fibres reach this ratio. Some other dimensions are equally related to conduction in myelinated nerve fibres, including the *internodal distance* and *area*, the molecular *characteristics* and the immediate *micro-environment* of the nodal axolemma. These parameters naturally vary between species, different categories and along individual fibres and branches (Williams & Wendell-Smith 1971).

SCHWANN CELLS (LEMMOCYTES)



Schwann cells are satellite cells of the peripheral nervous system; all peripheral axons are ensheathed by them and are separated from the endoneurium by the Schwann cell plasma membrane. The large volume and surface area of many neurons and the extensive spread of their neurites has, since the early study of these cells, suggested to investigators that there may be some form of functional dependence on the surrounding components such as Schwann cells and there is some experimental evidence to support this concept. Schwann cells participate in the supply of metabolites and trophic factors to axons (Varon & Bunge 1978), in the maintenance of the ionic state of the periaxonal space and possibly to the distribution of neurotransmitters (Villegas 1975); also to the siting of sodium channels along the axolemma (Ritchie & Rogart 1977). Conversely, Schwann cells are profoundly dependent on neurons for many aspects of their biology. Myelin thickness and internodal length (i.e. the size of the Schwann cell territories) are related to axonal calibre and may reflect the axolemmal spacing of antigenic determinants. Tissue culture of neurites and Schwann cells, and the allo- and xeno-grafting of nerve fascicles, have demonstrated that (1) axons are mitogenic for Schwann cells, and (2) Schwann cell differentiation depends in part on neuronal signals (Wood & Bunge 1975, Aguayo et al 1978); Schwann cells can even form myelin around central axons under experimental conditions.

Schwann cell development can be divided into perinatal *migratory* and *proliferative* phases, succeeded by a final *axon-associated* state, in which myelin formation and maintenance may occur. Immature Schwann cells are large and rounded, with an oval nucleus and dense cytoplasm. As they migrate from the neural crest they are first fusiform in appearance and then irregular, insinuating their processes between the outgrowing fascicles of neurites. In mature myelinated fibres, Schwann cell cytoplasm containing metabolic organelles is disposed as thin, apparently discontinuous strips lying external to the myelin sheath; this cytoplasm sometimes lies internally, between the myelin sheath and the periaxonal space. Only at paranodes in nodal gap fingers, spiral incisures and the perinuclear region do any substantial volumes of cytoplasm persist in the mature cell.

The close interrelation of axons and Schwann cells is confirmed by their mutual reactions to injury. Any disturbance of either structure results in cellular alterations. Crushing or cutting of the nerve fibre produces Wallerian degeneration; in this reaction, axons distal to the site of injury degenerate and an intense proliferation of Schwann cells follows in which myelin and axonal debris are phagocytosed. Axonal regrowth into any persistent tubes consisting of Schwann cells and their surrounding basal lamina, which may survive in the distal stump, allows the re-association of axon-Schwann cells and subsequent remyelination. Any metabolic or chemical damage which may occur primarily to Schwann cells results in demyelination or hypomyelination but not always to axonal degeneration.

7.38 High-power electron micrograph of part of a myelin sheath in section, showing dense period lines (the apposition of the cytoplasmic aspects of the cell membranes), alternating with less dense intraperiod lines (the apposition of the external aspects of the Schwann cell membranes). The preparative techniques used have caused the intraperiod line to split into two distinct lines in some places.

7.39 Section through the junction between the central and peripheral nervous system in the sensory root of the trigeminal nerve (rat) demonstrated by immunofluorescence of glial fibrillary acidic protein (GFAP). This is present in the astrocytes of the central nervous system but not in Schwann cells of the peripheral nerve. Provided by Martin Sadler, Anatomy Department, UMDS, Guy's Campus, London.

All larger mammalian axons are *myelinated* (*medullated*). Myelin is responsible for the glistening whiteness of peripheral nerves and central white matter. Axons smaller than 0·5–1·0 μm in diameter are usually *non-myelinated* (*non-medullated*) fibres. Because of important functional differences between these fibre types they will be described separately.

NON-MYELINATED FIBRES

In cutaneous nerves and dorsal spinal roots, about 75% of mammalian axons are non-myelinated; they form about 50% of the fibres of nerves to muscles and 30% in ventral spinal roots. Autonomic postganglionic axons are almost exclusively non-myelinated and preganglionic nerves contain significant numbers of these fibres. A non-myelinated 'fibre' is really a group of small axons (0·15–2 μm in diameter) within a sequential series of Schwann cells. In mature nerves the mode of enclosure of each group of axons shows variation from site to site, and also differs in different species of animals. Axons are usually separated from each other by tongues of Schwann cell cytoplasm but are sometimes further isolated by separate processes of cytoplasm which converge in the perinuclear region (Gamble & Eames 1964). A simpler organization seen in fetal nerves may also persist in some adult nerves, e.g. the olfactory, where bundles of small axons are collectively invaginated into the Schwann cell cytoplasm (see Landon 1985).

A three-dimensional reconstruction from sections of somatic and autonomic nerves reveals that the spatial relations between axons and satellite cells alter continuously within each cell (Aguayo et al 1973). The transfer of axons between one Schwann cell and the next in line usually occurs at their extremities, where their cytoplasmic processes interdigitate (Gamble et al 1978).

Non-myelinated fibres include the smaller of the central nervous axons, peripheral autonomic postganglionic axons and fine sensory fibres, such as those of nociceptors (pp. 909, 912), olfactory axons and others, invaginated into a longitudinal series of Schwann cells (7.36C). The line of invagination during development is marked by a *mesaxon*, a double layer of Schwann cell plasma membrane, its apposed, intucked surfaces lying parallel to each other and separated by about 15–20 nm. These layers separate to enclose the axon, separated from it by a *periaxonal space* of similar dimensions. At the exterior of the Schwann cell the layers separate and are continuous with the plasma membrane. Because of this arrangement, endoneurial tissue fluid reaches the periaxonal space between the mesaxonal membranes. These intercellular spaces allow the movement of ions when action potentials are conducted along the enclosed axon. In the absence of a myelin sheath and nodes, saltatory conduction does not occur, and the uninterrupted passage of impulses is relatively slow, with velocities of about 4·0–0·5 m/s. Non-myelinated fibres are classified as types C or IV (p. 898).

MYELINATED NERVE FIBRES

Myelinated fibres (7.32–38) form most of the somatic nervous system, rapid conduction being an obvious evolutionary advantage. The structure of myelin sheaths is best described in terms of their development which begins during prenatal life in many separate sites but is not completed until a considerable time after birth, different pathways maturing at different rates.

Axons of peripheral nerves grow out from neurons in the central nervous system and ganglia in association with Schwann cells which initially multiply as their associated axons lengthen; later they cease dividing and subsequently only increase in size. At first all axons are non-myelinated; later a flap of Schwann cell cytoplasm spirals round the neurite, most of the cytoplasm and the nucleus of the Schwann cell remaining outside (7.33, 36C). As development proceeds, the number of turns increases, transforming the spirals into compacted layers of cell membrane (Robertson 1955). In ultrastructure, mature myelin sheaths are laminated with dense, regular *period lines* (planes of apposition between the *internal* surfaces of plasma membrane), alternating with less dense *intraperiod lines* (appositions between the *external* surfaces of the plasma membrane) (7.33). Treatment with hypotonic solutions causes the sheath to swell, splitting the intraperiod lines and showing that external surfaces are not fused and are apparently able to move on one another (Napolitano & Scallen 1969). On both internal and external aspects of the myelin sheath there are thin layers of Schwann cell cytoplasm which, in many regions along the internodes of mature fibres, are only about 20–30 nm thick. The internal layer is covered by an inner plasma membrane adjoing the 15–20 nm *periaxonal space*, continuous through an *internal mesaxon* with the deepest myelin lamella. Similarly an *external mesaxon* connects the outermost myelin lamella with the superficial Schwann cell plasma membrane. Larger amounts of cytoplasm occur externally at paranodal grooves (p. 903) around the nucleus where it dimples the myelin sheath and also on the internal and external aspects of the incisures of Schmidt–Lanterman (p. 903). These cytoplasmic regions often contain mitochondria, lysosomes, some endoplasmic reticulum and various vesicles and granules. The internal and external cytoplasmic zones are also connected by helical channels containing granular cytoplasm and microtubules at nodes and incisures (vide infra). The external Schwann cell plasma membrane and adjacent basal lamina correspond to the *neurolemma* of light microscopy.

When lipids are removed from the myelin sheath, as in histological processing without prior fixation of lipid components, a network of proteinaceous *neurokeratin* is visible by light microscopy. This represents the denatured remains of the major protein component of myelin (see p. 903), its reticular appearance being an artefact of processing.

THE CHEMICAL COMPOSITION OF MYELIN

Myelin is composed of the compacted plasma membranes of Schwann cells and oligodendrocytes and its composition resembles that of other plasma membranes in containing lipids, proteins and water (which forms at least 20% of the total wet weight) but the relative proportions and dispositions of these are unique to myelin. Myelin can be isolated by techniques involving centrifuging homogenized tissue suspensions in sucrose solutions, followed by osmotic shock and subsequent sedimentation or isolation on sucrose or other gradient systems. It can be further analysed by immunochemical, electrophoretic and other chromatographic methods. The proportions of cholesterol, total phospholipid and glycolipid in myelin differ from those in other membranes, and also differ between central and peripheral myelin. On a molar basis, cholesterol is the major lipid (approximately 40 moles per cent of total lipid); although it is not synthesized within the sheaths themselves, inhibition of cholesterol synthesis affects myelin formation as a whole. The most abundant of the

glycolipids are galactocerebroside, sulphatide and ganglioside. *Peripheral* myelin has a lower concentration of galactocerebroside but higher ones of choline glycerophosphatide and sphingomyelin compared with central myelin. The choline glycerophosphatides have a higher proportion of unsaturated fatty acids than their central counterparts, although long chain fatty acids (C_{25} and C_{26}) are less than 2% of the total, compared with up to 20% centrally. It is noteworthy that most of the organ-specific complement-fixing or precipitating activity of certain demyelinating antisera appears to be largely antigalactocerebroside. Galactocerebroside has been found to be a cell-surface marker for cultured rat oligodendrocytes (the cell type responsible for central myelinogenesis).

About 30% of adult human central myelin is protein. The myelin proteins have been examined by polyacrylamide gel electrophoresis of isolated myelin, solubilized by phenol or sodium dodecylsulphate. At least three proteins have been identified in central and peripheral myelins and, like myelin lipids, they differ in these two sites. Peripheral myelin contains a low molecular weight glycoprotein, P_0, and two basic proteins, P_1 (*c.* 5%) and P_2 (*c.* 20%). P_1 is considered to be analogous to the encephalitogenic basic protein of central myelin. Analysis of immune responses mounted against the basic proteins has elucidated the position and relations of these proteins within the myelin sheaths of various species. It seems likely that few enzymes accompany myelin; only one, 2:3° cyclic AMP 3′-phosphohydrolase has been examined in any detail and is used as an experimental myelin marker. Its role is unknown.

FORMATION AND GROWTH OF MYELIN

Although the organization of myelin at the molecular level is now understood in some detail, the mechanisms by which it is laid down around nerve fibres is still rather obscure. Early models derived from tissue culture data proposed that Schwann cells first formed a loop of cytoplasm around axons, then migrated around them many times to wrap the axons in a tight spiral of membrane (Geren 1954). In the central nervous system at least this appears unlikely, because a single oligodendrocyte may ensheathe several separate axons (Bunge 1968). Other possibilities for myelin formation include the interstitial deposition of myelin molecular components within the lamellae of the sheath, or an ingrowth of the myelin spiral by a relative sliding of its turns, new myelin being added externally (Webster 1971). The enclosed axon might also rotate to wind the myelin upon itself; however, reports that myelin in adjacent internodes may show a reversed spiralization makes the axonal rotation model improbable. Perhaps excessive ingenuity has been expended on models explaining 'spiralization' with less attention to other dimensional changes. Thus, while the sheath *thickens* from a few lamellae to perhaps 300, the *axon* may also grow from 1 to 15 μm and internodal segments increase from 150 μm to 1500 μm in length (Williams & Wendell-Smith 1971). When myelination begins, multiplication of Schwann cells stops, each elongating in adaptation to the overall growth of the nerve (Vizoso & Young 1948, Williams & Kashef 1966). Clearly, much remains to be learnt about the initiation, mechanisms and cessation of myelination and its continued maintenance in the mature nervous system.

In late fetal and early postnatal development myelination does not occur simultaneously in all parts of the body. Nerves and tracts have their own particular temporal patterns, which can be related to their degree of functional maturity (Ochoa & Mair 1969a, b). Among other factors, which are still largely unknown, the onset of myelination is linked to the growth in diameter of non-myelinated axons; in those animals which have been investigated, the critical point appears to be reached when axons are about 1·0 μm in diameter, although some larger non-myelinated fibres also exist (Matthews 1968) and many myelinated fibres < 1 μm in diameter occur. Once begun, myelination continues in parallel with axonal growth until this stops; the ratio between axonal diameter and thickness of sheath is therefore predictable, its value varying with the function of the fibre and the distance from the parent soma (Williams & Wendell-Smith 1971).

THE NODE OF RANVIER (NEUROFIBRAL NODUS)

In myelinated nerves the axon is exposed to the extracellular fluids at regular intervals or *nodes* (*of Ranvier*) where short gaps exist between adjacent Schwann cells or oligodendrocytes (Hess & Young 1952, Landon 1976, 1985, Ghabriel & Alt 1982), the myelinated segments being *internodes*. The internodal distance varies directly with the diameter of fibre from 150 to 1500 μm (Kashef 1966). When fibres branch, they do so at nodes. In peripheral nerves, the myelin sheaths on both sides of nodes usually expand as *paranodal bulbs* (varicosities) (7.36B, 37), which often show an asymmetry related to growth. The surfaces of these bulbs and the underlying axolemma are fluted as they approach nodes and numerous Schwann cell mitochondria occur in these external cytoplasm-filled grooves (Landon & Williams 1963, Berthold 1968, Landon 1976). Axons also narrow at nodes. Each myelin lamella ends in contact with the paranodal axolemma as an expanded loop containing spiralling microtubules and dense cytoplasm. The external paranodal cytoplasm of the Schwann cells sends a number of digital processes which curve to contact the naked nodal axolemma (7.37); these fingers are numerous, forming a regular hexagonal array in large fibres, but are few and irregular in smaller ones. The depression formed at the node by the axonal narrowing is filled between nodal fingers by an acidic mucosubstance, or *gap substance*, which may be a reservoir of ions or a selective barrier to their flow during conduction (vide supra, p. 902, and Landon & Langley 1971). The narrowing of the axon at the node probably increases the transmembrane current density and hence the efficiency of nodal excitation during saltatory conduction. Sodium channels are concentrated at the nodes, few of them occurring internodally. The structural counterparts of these channels are probably the numerous intramembranous particles shown in the nodal axolemma by freeze-fracturing methods. The dense subaxolemmal coating in this region may represent cytoskeletal structures which stabilize the ion channels and anchor them to the nodal region. Central nodes have been less extensively investigated but they appear to be simpler structures, with few nodal fingers and small or no paranodal bulbs.

MYELIN INCISURES (OF SCHMIDT–LANTERMAN)

Originally described as cytological features, the myelin clefts or incisures of Schmidt–Lanterman were subsequently long regarded as artefacts. Ultrastructural and in vivo observations have reinstated them as characteristic features of central and peripheral myelinated fibres (Hall & Williams 1970, Landon 1976). They are oblique interruptions in the compacted lamellae of myelin (7.37) where funnel-shaped zones of cytoplasm spiral between the internal and external layers of Schwann cell cytoplasm. At an incisure the major dense line (p. 902) separates to enclose a helical band of granular cytoplasm; one or more microtubules follow the spiral with intermediate filaments and occasionally other organelles. The cytoplasm is dense and in places resembles that in a zonula adherens of epithelial and other cells, forming an oblique row or *stack* of *desmosomoid* attachments at one or more points near the incisure's external surface. The intraperiod line also splits at incisures to create an extracellular gap connecting the periaxonal and endoneurial spaces. Incisures possibly conduct metabolites deep into myelin sheath and subjacent axon; they appear to be an early site of cellular change in initial stages of Wallerian degeneration (Williams & Hall 1971) and of focal demyelination.

The *classic view* of Wallerian degeneration was that the first week after crush or section was largely a period of *morphological disruption* of the part distal to the injury, but was *biochemically stable*. The structural changes included the formation of myelin *ovoids* containing 'digestion chambers' with axonal disruption. Only in the second week was there thought to be any biochemical change, principally the degradation of phospholipid in the sheath with the liberation of cholesterol esters. More recently, in vivo examination of degenerating nerves (Williams & Hall 1971) showed that events are more rapid. Initial changes include the retraction of the paranodal myelin sheath, the dilatation of incisures and the collapse and rounding of myelin into ovoids at

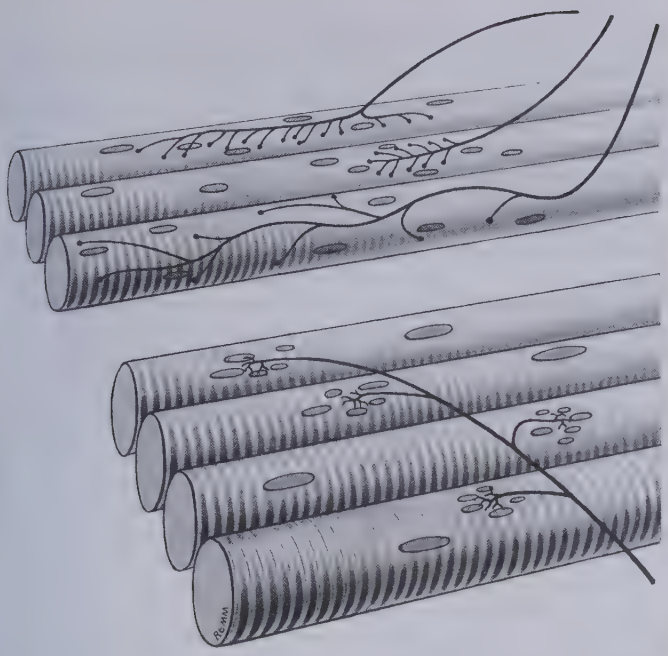
these points, starting within minutes near the lesion and progressing distally during the next 36–48 hours. The concentration of hydrolytic enzymes increases within 12 hours of injury, associated with the loss of trypsin-digestible *basic protein* from the sheath, demonstrable in histological sections as a loss of *trypanophilia*.

With electron microscopy, Wallerian degeneration shows an accumulation of membrane-bound bodies in the axoplasm proximal and distal to the point of injury. Distal degradation of axoplasmic organelles then ensues and at the dilated incisures the previously compact myelin lamellae collapse, with alterations in the repeat periods in their radial structure. Within four days lipid droplets accumulate round degrading myelin within the Schwann cell cytoplasm and are then extruded into the endoneurial space, to be phagocytosed by invading haematogenous macrophages. The early increases in acid phosphatase activity coincides with the appearance of numerous lysosomes in the cytoplasm of Schwann cells. As degradation of myelin proceeds, Schwann cells begin to proliferate. In nerves containing many large myelinated fibres the total of Schwann cell nuclei visible in transverse sections rises to about 16 times the normal levels by the end of the third week. Proliferating Schwann cells line up in parallel longitudinal chains within the persistent basal lamina, where they take part in any subsequent regenerative phenomena which may ensue (p. 918).

THE CENTRAL-PERIPHERAL TRANSITIONAL ZONE

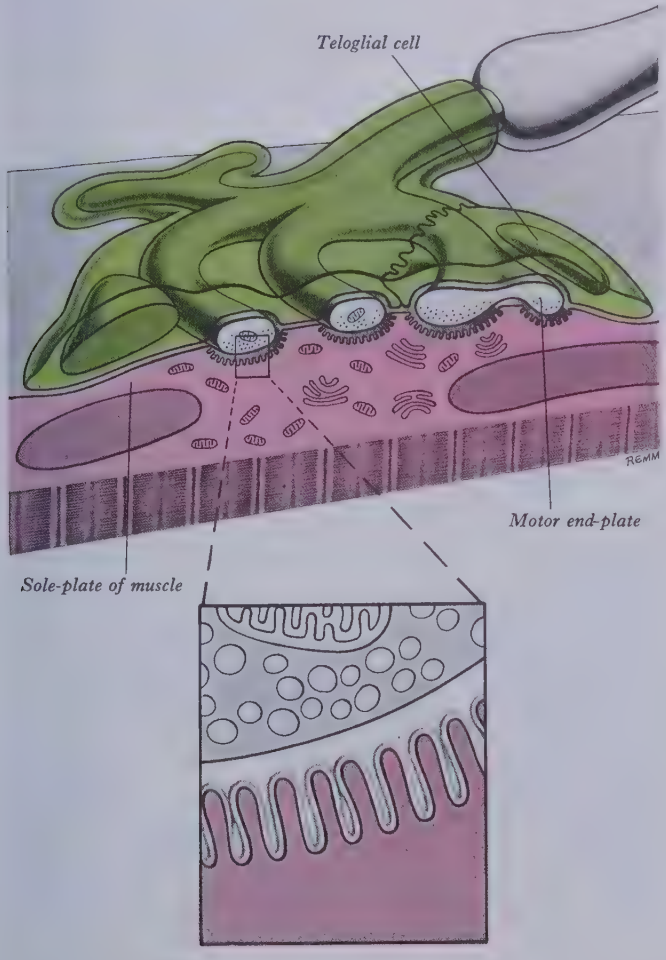
Crossing the transitional zone between the central (CNS) and peripheral (PNS) nervous system, axons are enclosed in a short glial segment generally close to the surface of the spinal cord or brain stem (7.39). In humans this zone lies more peripheral in sensory than in motor nerves; in both of these the apex of the zone is described as the '*glial dome*', its convex surface being directed distally. Electron microscopy shows the dome's centre to consist of fibres with a typical central organization, surrounded by an outer mantle of astrocytes (corresponding to the external glial limiting membrane). From this mantle numerous processes, the '*glial fringe*', project into endoneurial compartments of the peripheral nerve and interdigitate with the Schwann cells. The astrocytes form a loose reticulum through which axons pass. Peripheral myelinated fibres usually cross the transitional zone at a node of Ranvier, termed a *PNS–CNS compound node* (Carlstedt 1977). At such a node distally there is a corona of Schwann cell microvilli and mitochondria-laden paranodal cytoplasm; centrally are a few astrocyte processes, typically making contacts with the axolemma (Berthold 1978). In the first sacral spinal nerve roots (of cats) an average of four or five nodes are associated with the processes of a single astrocyte and these node–astrocyte relations may be specific to such borderline nodes. In some myelinated fibres, however, the central–peripheral transition occurs at an internode, the central myelin being telescoped within an external peripheral myelin sheath. Considerable rearrangement of axons occurs in the rootlets; moreover, many of the largest non-myelinated axons are invested with a thin myelin sheath as they traverse the transitional region.

Peripheral Endings of Effector Neurons



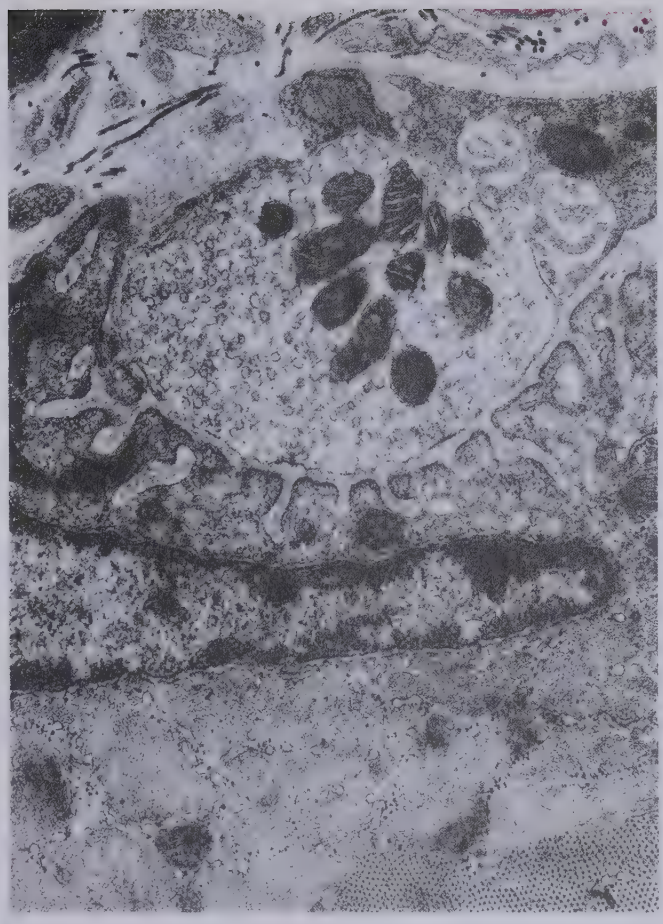
Of the various types of effector endings the most intensively studied are those which innervate muscle, particularly the skeletal variety. All such *neuromuscular* or *myoneural junctions* are regions of neuronal cytoplasm specialized for the release of neurotransmitter on to surfaces of adjacent muscle fibres, causing a change in their electrical state leading to contraction. Because of their similarity to central nervous synapses and the relative ease with which functional studies can be carried out on them, much of our general knowledge of neurotransmission comes from the ultrastructural, physiological, biochemical and pharmacological analysis of neuromuscular junctions rather than central synapses.

In addition to their innervation of muscle, effector neurons also have terminals in or near other cells capable of various types of activity, e.g. glands (secretomotor endings), myoepithelial cells and adipose tissue. It has been proposed on the basis of experimental evidence that nerve fibres may also contribute to the regulation of immune responses (p. 836), by their effects on T-lymphocyte maturation in the thymus, and to many other poorly understood activities of tissues not classically considered to be under nervous control. The hormonal contribution of neuroendocrine cells has, of course, long been known, but more subtle effects elsewhere may play a major role in the maintenance of homeostasis in many other sites in the body.



NEUROMUSCULAR JUNCTIONS OF SKELETAL MUSCLE

The general structure of these has already been outlined on p. 554. The terminals are end branches of somatic motor fibres, each innervating from a few to many hundreds of muscle fibres, a numerical relationship determining the precision of motor control. The precise structure of a motor terminal varies with the type of muscle innervated. Two major endings are recognized: '*en plaque*' terminals typical of extrafusal muscle fibres and *plate endings* of intrafusal fibres, the latter including '*en grappe*' terminals of extraocular muscle fibres and '*trail*' endings on intrafusal fibres (Harker 1972, Barker 1974). In the first type each axonal terminal (*telodendron*) usually ends midway along a muscle fibre in a discoidal *motor end-plate* (7.40–42). In the second type, the axon has numerous subsidiary branches forming a cluster of small expansions extending along the muscle fibre (7.40). *En plaque* endings usually initiate action potentials which are rapidly conducted to all parts of muscle fibres whereas *en grappe* endings, in the absence of propagated muscle excitation, excite the fibre at several points. Both types have a specialized region, the *sole-plate*, in which a number of muscle cell nuclei are grouped within the granular sarcoplasm; ultrastructurally the sole-plate contains numerous mitochondria, endoplasmic reticulum and the folding of the sarcolemma into numerous parallel grooves (7.42). The neuronal terminal expansion is separated by about 30–50 nm from this *subneural apparatus*, the terminal containing mitochondria and many clear spherical vesicles like those in presynaptic boutons and similarly clustered against the membrane over the zone of apposition. Ensheathing the motor terminal are Schwann cells (*teloglia*), with cytoplasmic projections extending into the synaptic cleft. *En plaque* endings of 'fast' and 'slow' twitch muscle fibres differ in details, the sarcolemmal grooves being deeper and the presynaptic vesicles more numerous in the former (Padykula & Gauthier 1970). Freeze-fracture studies show numerous intramembranous particles, which represent the acetylcholine receptors, in the crests of the sarcolemmal folds nearest to presynaptic membrane (Heuser et al 1974). Opposite these the sarcolemmal membrane is slightly invaginated and vesicles cluster along borders of the groove so formed, probably the main site of their release (cf. the '*active zone*' of synapses). Microtubular arrays bearing synaptic vesicles, as in central synapses, have also been described (Gray 1978).



Physiological and pharmacological studies (Katz & Miledi 1965) show that junctions with striated muscle are *cholinergic*, the release of acetylcholine changing the ionic permeability of the muscle fibre. The earliest change occurring after neurotransmitter release is a *graded potential*; if the depolarization of the sarcolemma reaches a particular threshold, it initiates an all-or-none action potential in the sarcolemma, which is then propagated rapidly over the whole cell surface and also within its substance via the invaginations (transverse tubules) of the sarcolemma (see p. 554), causing contraction. As with synapses, the quantity of neurotransmitter released depends on the frequency of the arriving nerve impulses; since the transmitter is inactivated at a constant rate by the enzyme *acetylcholinesterase* present at the sarcolemmal surface of the sole-plate, the amount of neurotransmitter present depends on its *rate* of release, thus reflecting faithfully the *frequency* of action potentials in the nerve fibre. Thus the contraction of a muscle fibre is controlled by the firing frequency of its motor neuron. However, even in quiescent muscle fibres, sporadic depolarizations continually occur (*miniature end-plate potentials*), although too small to cause contraction. Their measured amplitudes occur at a series of preferential levels, indicating that multiples of *quanta* of transmitter are released even

in resting stages, presumably a process of slow leakage. The amount of acetylcholine necessary to cause these unitary changes is calculated to be equivalent to the volume of a single synaptic vesicle (Katz & Miledi 1965).

Acetylcholinesterase can be shown cytochemically to be present in myoneural clefts. Experiments with specialized motor endings in electric organs of the Electric Ray *Torpedo* locate the enzyme to the sarcolemma near the sites of action. The neurotransmitter can be blocked by *curare*, by a sea-snake venom α-bungarotoxin, by black widow spider venom and various other toxins, all combining irreversibly with the acetylcholine receptor molecules to paralyse the neuromuscular junctions (Miledi et al 1971). If acetylcholinesterase is inhibited, e.g. by *eserine* (*physostigmine*), transmitter action is cumulative and tetanus may ensue. Neuromuscular junctions are partially blocked by high concentrations of lactic acid, as in some types of muscle fatigue (Miledi et al 1971). For further review of structure see Duchen & Gale 1985.

AUTONOMIC MOTOR TERMINATIONS

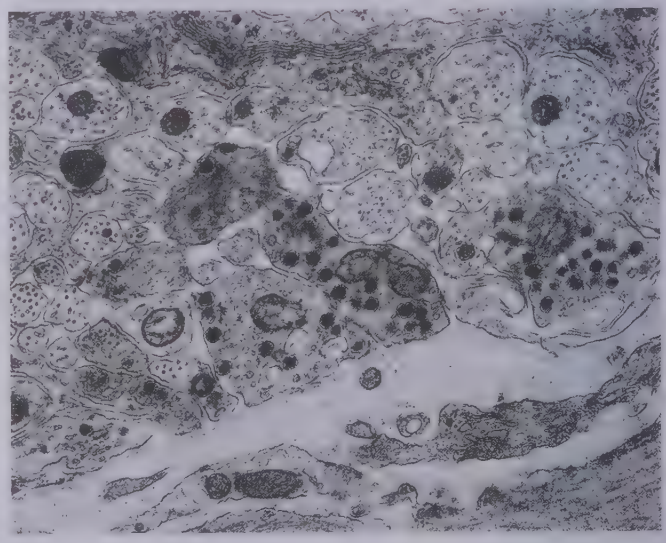
Unlike those in skeletal muscle, autonomic terminals are not usually closely applied to non-striated myocytes but end at variable distances from their surfaces (Richardson 1962). Non-myelinated autonomic axons branch into tapering, varicose collaterals (7.43). At the zone of transmission, clusters of synaptic vesicles exist in expanded regions of axoplasm and the Schwann cell is retracted to leave the axon in a shallow groove, providing a path of diffusion between axon and myocytes. In *sympathetic fibres* the vesicles are usually *dense-cored* (p. 890), and correspond in position to the characteristic fluorescence of

7.43 Diagram of an autonomic neuromuscular junction between a group of non-myelinated axons (above) and smooth muscle cells (below). The Schwann cell (blue) is reflected at intervals to expose enlargements of the axons (yellow) which contain synaptic vesicles.

catecholamines seen when preparations fixed in formalin vapour are viewed with ultraviolet light (Falck & Owman 1965), or to the positive reaction to the glyoxylic acid method. Besides noradrenalin, they contain enzymes involved in catecholamine synthesis and degradation. Other vesicles, 100 μm across, often also occur.

Noradrenalin is the usual transmitter at sympathetic postganglionic endings while *adrenalin* occurs in some of the *chromaffin cells* of the adrenal glands. Synaptic vesicles containing each catecholamine can be distinguished by electron microscopy. Catecholamines can be released experimentally by treatment with the drug, *reserpine*, which is a valuable research tool and also clinically useful. After release some of the transmitter is reabsorbed into the axon by endocytosis and may be re-used, or broken down. Sympathetic endings contain *monoamine oxidases* degrading catecholamines, the control of these enzymes being important in the clinical regulation of sympathetic function both in the peripheral and central nervous systems.

At *parasympathetic* endings are clear spherical vesicles, like those in motor end-plates of striated muscle. Much evidence indicates that they are *cholinergic*; similar terminals also occur in sympathetic endings. In addition to their action on non-nervous tissues, some cholinergic endings may perhaps cause the release of catecholamines from neighbouring sympathetic endings (Burn 1968).



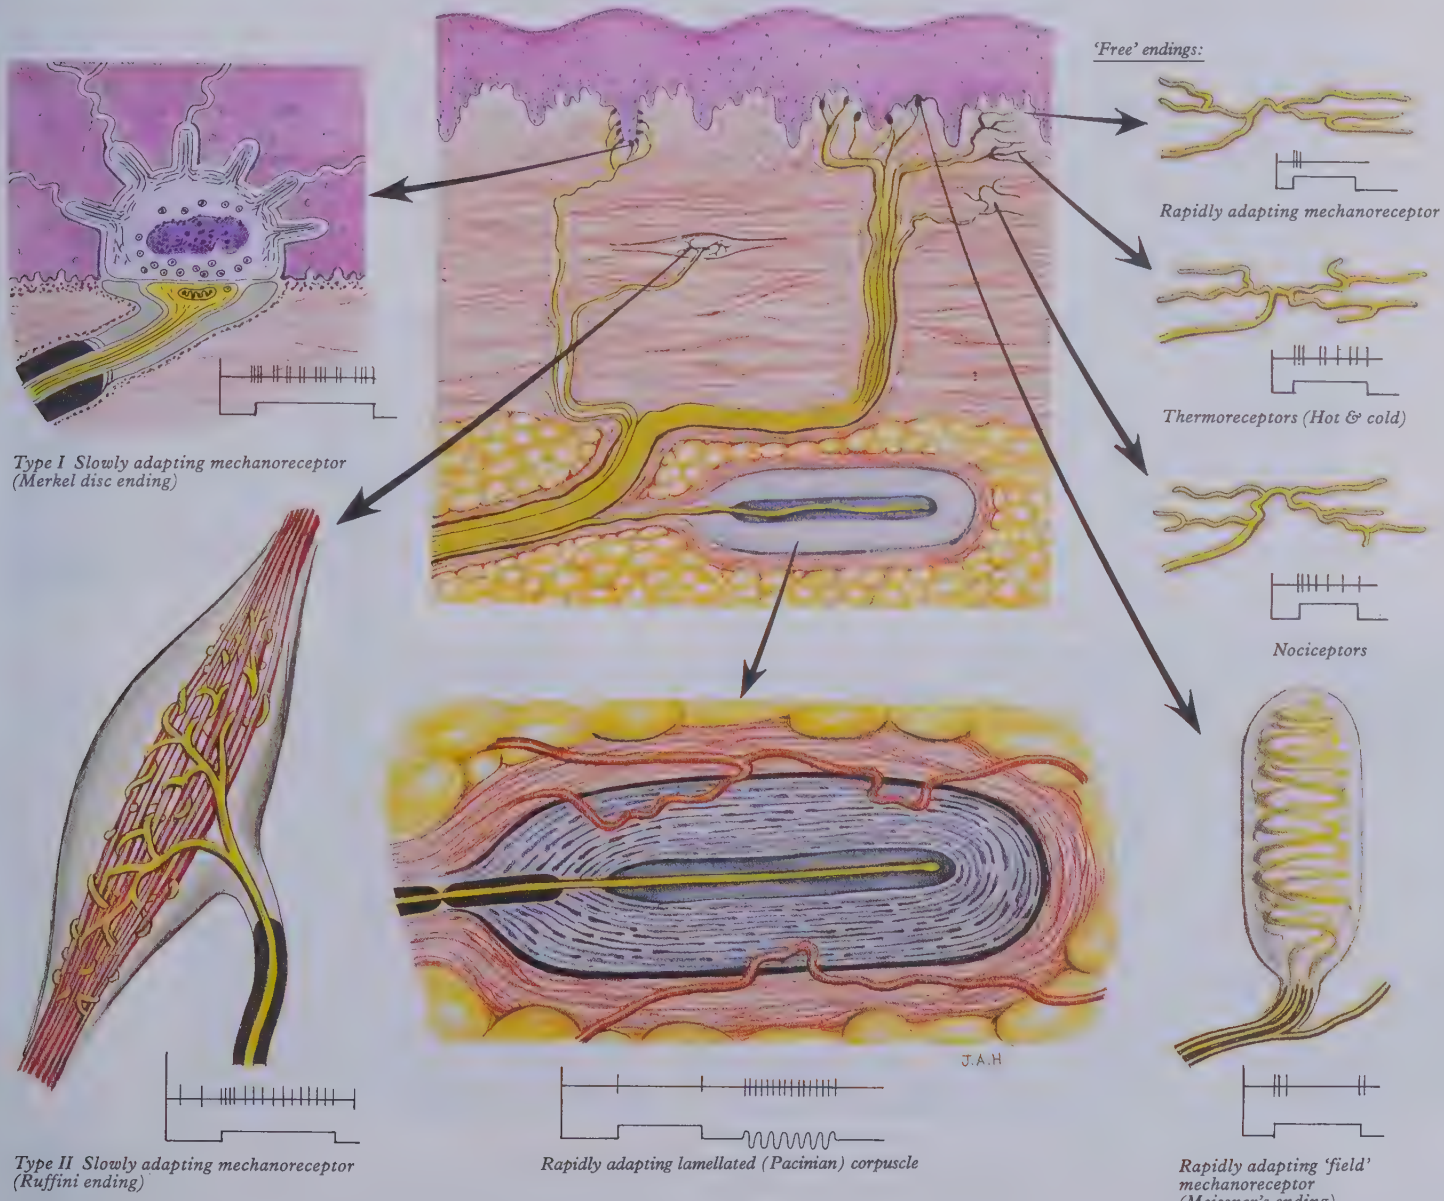
A third category of autonomic neurons differing from noradrenergic or cholinergic cells has been described by Burnstock and colleagues (Burnstock 1975). These can be described as 'non-adrenergic, non-cholinergic endings', and are now recognized to contain a wide variety of chemicals with transmitter properties (see Burnstock 1986), contained within vesicles of different forms. The conjugated purine adenosine triphosphate or ATP (a nucleoside), probably the neurotransmitter at these terminals, is classed as *purinergic*. Typically, their axons contain large, dense vesicles 80–200 nm across ('*large opaque vesicles*'), congregated in varicosities at intervals along nerve fibres. Such fibres occur in many sites in mammals, including the alimentary external muscle layers and sphincters, lungs, vascular walls, urogenital tract and central nervous system. In the intestinal wall their neuronal cell bodies lie in the myenteric plexus, their axons spreading caudally for a few millimetres, chiefly to innervate circular muscle (7.44). Purinergic neurons are under cholinergic control from preganglionic sympathetic neurons. Purinergic endings mainly hyperpolarize myocytes, causing their relaxation, e.g. preceding peristaltic waves, opening sphincters and, probably, causing reflex distension in gastric filling. The release of the transmitter resembles that in other autonomic endings, i.e. by exocytosis from axon varicosities which may be up to 100 nm away from the target cell.

The pattern of terminal branching of autonomic efferents is related to their effects (Burnstock 1970). In non-striated muscles with a slow widespread action, a single neuron may innervate a large number of myocytes, the distance between synaptic varicosities and myocytes being large (50 nm or more). In rapid non-striated muscle, with greater precision of control, e.g. the iris or ductus deferens, innervation is more localized, with less branching and close apposition to myocyte surfaces (15–20 nm), the ending sometimes being invaginated into the sarcolemma (Burnstock 1975). Other tissues innervated by autonomic efferents include glands, myoepitheliocytes, adipose and lymphoid tissue.

Sensory Receptors

As frequently stated, an organism's reaction to changes in its environment requires the presence of suitable receptors to scan the parameters important to survival. Though single-celled organisms such as protozoa have no such specialization, they can detect changes in temperature, osmotic pressure, concentrations, light and other environmental properties by means of the specialized components of their membranes. In more elaborate animals these fluctuations are recorded by cells which have differentiated to respond selectively and with great precision. Such cells are sensory receptors; they take many forms but in mammals, with minor exceptions, they have a common pattern which will be outlined below.

Sense organs have three major forms, according to the relation of the nervous system to the receptor cells. In **neuro-epithelial**



7.44 Electron micrograph of a group of autonomic axons in the myenteric plexus, showing profiles with large dense-cored vesicles typical of the putative purinergic system (see text); smaller, catecholamine-type vesicles are also visible (lower left). Magnification × 40 000.

receptors the receptors are neurons with somata situated peripherally near a sensory surface and axons extending into the central nervous system to connect with second order neurons. The only example of this type in mammals is the sensory cell of the olfactory epithelium but in many invertebrates it is the main type and can thus be regarded as phylogenetically primitive. Secondly, the sensory cell may be an **epithelial receptor**, modified from the cells of a non-nervous sensory epithelium and innervated by a primary sensory neuron, the soma of which lies near the central nervous system. Activity in this type of receptor causes the passage of excitation from the receptor by neurotransmission across a synaptic gap; examples are gustatory and auditory receptors. In gustatory receptors individual cells are constantly being renewed from the surrounding epithelium, as may also occur in other similar sensory systems (p. 1170). Visual receptors are in many ways similar in their form and relations, formed from the ventricular lining in the fetal brain, although no replacement occurs. Thirdly, a **neuronal receptor** is a primary sensory neuron, with a soma in a craniospinal ganglion and a peripheral axon whose end is the sensory terminal. All cutaneous sensors and proprioceptors are probably of this type, but the sensory terminals may be encapsulated or linked to special mesodermal or ectodermal elements forming a part of the sensory apparatus. These extra-neural cells are not necessarily excitable, but rather create the right environment for the excitation of the neuronal dendrite or modify its excitation in some way.

RECEPTOR RESPONSES

The events which occur between the incidence of a stimulus and the conduction of an electrical signal to the central nervous system have been extensively studied (e.g. Granit 1962), although much remains to be understood. It is convenient to divide these processes into a number of stages: first the preservation of an effective stimulus, then the transduction of the stimulus at the receptor surface into a graded change of electrical potential (*sensory potential*) and next the initiation of an all-or-none action potential passing to the central nervous system. All of these processes may occur in the receptor, where this is a neuron, or some

7.45 Some major types of sensory endings of general afferent fibres (omitting neuromuscular, neurotendinous and hair-related types).

may occur partly in the receptor and partly in the neuron innervating it, in the case of epithelial receptors.

Transduction varies with the modality of stimulus, but in all receptors there is a stimulus-induced change in permeability of the receptor membrane to certain ions, usually causing its depolarization (or, in the retina, hyperpolarization). How a stimulus effects this is uncertain. In mechanoreceptors it may involve the deformation of membrane structure perhaps with strain- or voltage-sensitive transducing protein molecules opening ion channels as a result; in chemoreceptors, receptor action may resemble that postulated for acetylcholine at neuromuscular junctions (p. 554), involving receptor proteins altered by binding stimulant molecules, again with the opening of ionic channels. Visual receptors appear to resemble chemoreceptors in many respects; light causes changes in receptor proteins (p. 1198) which may cause the release of *second messengers* to affect membrane permeability.

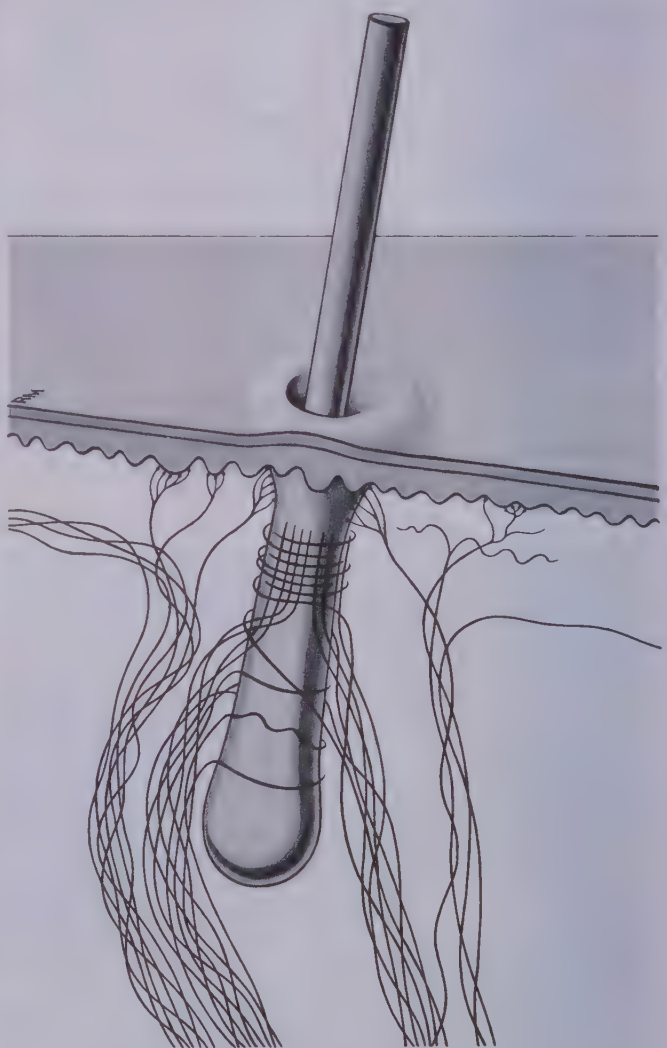
Osmoreceptors may resemble mechanoreceptors but react instead to mechanical deformation from osmotic inflow or outflow of water. In some fishes a remarkable type of transduction occurs in electroreceptors, capable of sensing changes in electric fields set up by the animal's own bioelectric processes or those of other individuals or prey (Lissmann & Machin 1958). So far, no sensory mechanism of this type has been reported in tetrapods.

The quantitative responses of sensory endings to stimuli vary greatly and give added flexibility to the functional design of sensory systems. Although increase of excitation with the increase of a stimulus level is a common pattern (*'on' response*) some receptors respond to decrease in stimulus (the *'off' response*). Even unstimulated receptors show varying spontaneous activity, against the background of which an increase or decrease in activity occurs with changing levels of stimulus. When stimulation is maintained at a steady level, there is, in all receptors studied, an initial burst (the *dynamic phase*) followed by a gradual *adaptation* to steady level (the *static phase*). Though all receptors show these two phases, one or other may predominate, giving a distinction between *rapidly-adapting* endings accurately recording the *rate* of stimulus onset and *slowly-adapting* endings which signal the constant amplitude of a stimulus, e.g. the position sense. Dynamic and static phases are reflected in the *amplitude* and *duration* of the generator or sensory potential and also in the *frequency* of action potentials in the sensory fibres. The stimulus strength necessary to elicit a response in a receptor (i.e. its *threshold level*) varies greatly between receptors, providing an extra level of information about stimulus strength.

CLASSIFICATION OF RECEPTORS

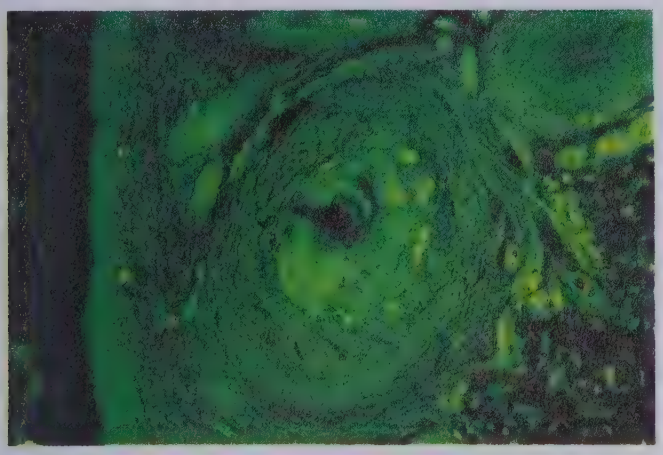
Receptors are classified in several ways; e.g. by the specific energy forms or '*modalities*' to which they are especially sensitive, such as *mechanoreceptors* responsive to deformation (touch, pressure, sound waves, etc.), *chemoreceptors*, *photoreceptors*, *thermoreceptors* and *osmoreceptors* (reacting to osmotic pressure changes). Some receptors respond selectively to more than one modality (*polymodal receptors*), usually having high thresholds and responding to damaging stimuli, associated with irritation or pain (i.e. *nociceptors*).

Another widely used, though somewhat arbitrary classification divides receptors on the basis of their distribution in the body and their role in its sensory activities into *exteroceptors*, *proprioceptors* and *interoceptors*. Exteroceptors and proprioceptors are receptors of somatic afferent components of the nervous system; interoceptors are receptors of the visceral afferent pathways.



Exteroceptors respond to external stimuli and are at or close to surfaces (Sinclair 1967). They can be subdivided into the *general* or *cutaneous sense organs* and *special sensory organs*. The general sensory receptors include the 'free' and the encapsulated terminals in skin and near hairs; special sensory organs are the olfactory, visual, acoustic and gustatory receptors.

Proprioceptors respond to stimuli *proper* to deeper tissues, especially of the locomotor system, and are concerned with detecting movement, mechanical stresses and position; they include the neurotendinous organs of Golgi, neuromuscular spindles, Pacinian corpuscles, other endings in joints and vestibular receptors. Proprioceptors are stimulated by the contraction of muscles, movements of joints and changes in the position of the body or of its parts; they are essential to the co-ordination of muscles, the grading of muscular contraction and maintenance of equilibrium.



Interoceptors include receptors in the walls of the viscera, glands and vessels, where their terminations include 'free' nerve endings, encapsulated terminals and endings associated with specialized epithelial cells. Nerve terminals occur in all the layers of visceral walls and are numerous in the adventitia of blood vessels; the functional nature of many of these endings, and indeed their detailed structure in many cases, is not well established. Encapsulated (lamellated) endings occur in the heart, adventitia, pancreas and mesenteries; 'free' terminal arborizations also occur in the endocardium, loose connective tissue, the endomysium of all muscles and connective tissue generally.

Visceral nerve terminals are not usually responsive to stimuli which act on exteroceptors and do not respond to localized mechanical and thermal stimuli. But tension produced by excessive muscular contraction often causes visceral pain, particularly in pathological states, which is frequently poorly localized and of the deep-seated variety.

Interoceptors include vascular chemoreceptors and baroceptors concerned in the regulation of blood flow and pressure and in the control of respiration.

7.46A The innervation of a large hair follicle; fine and coarse axons terminate around the intermediate and superficial regions, some branching in a circular direction and others pursuing a longitudinal course. Nerve terminals associated with Merkel's cells are also shown surrounding the neck of the follicle.

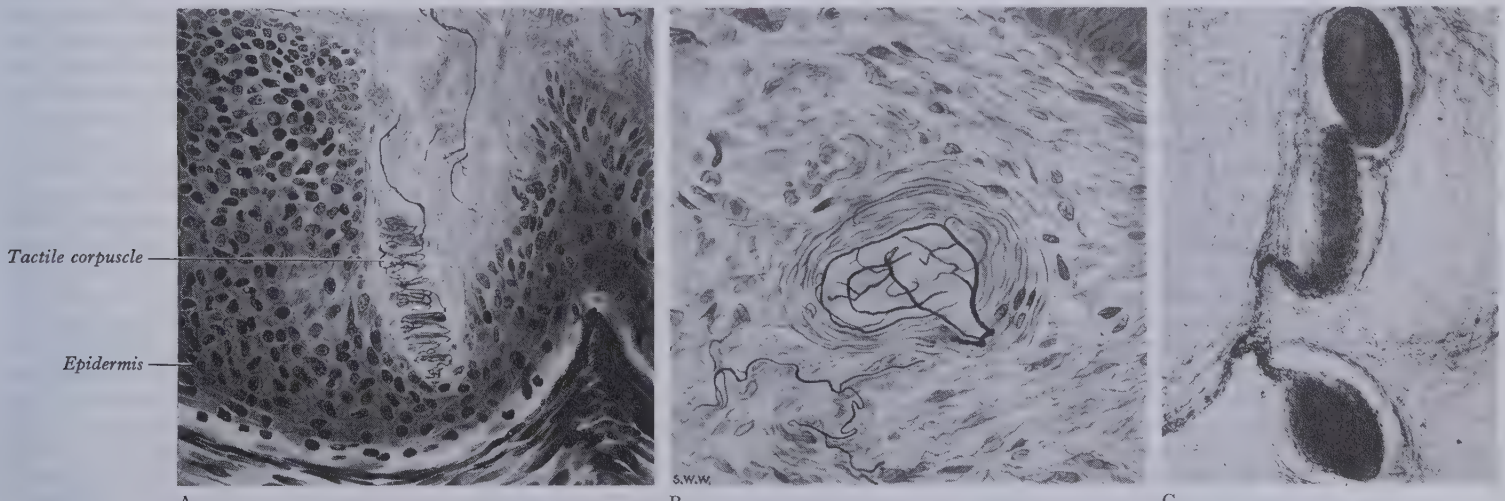
7.46B Sensory endings around a hair follicle, in transverse section. The axon terminals have been demonstrated by immunofluorescence using an antibody directed against neurofilaments. Material provided by Samantha Negus, UMDS, Guy's Campus, London. Magnification ×250.

Irritant receptors responding polymodally to noxious chemicals or damaging mechanical stimuli are widely distributed in the epithelia of the alimentary and respiratory tracts and they may initiate protective reflexes.

This scheme of classification may seem arbitrary, since many *structural* types of end-organ occur in all three classes and their activities may be closely linked in the central nervous system. For convenience, therefore, the structural classification is followed here. But this in turn is arbitrary since in some cases endings with similar structure may be physiologically distinct and a functional classification may be regarded as of deeper significance.

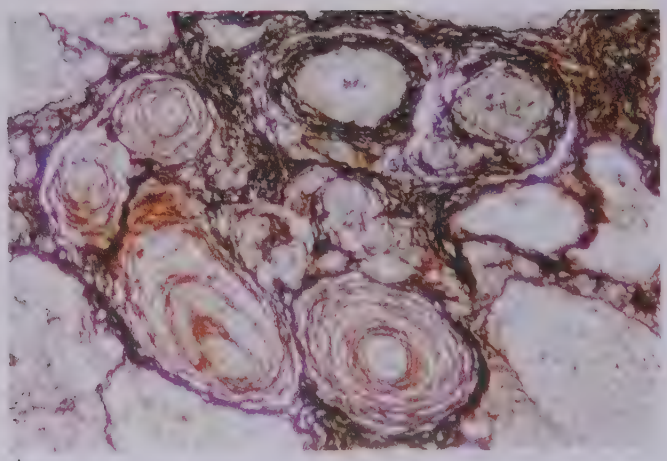
STRUCTURAL CLASSIFICATION OF GENERAL SENSORY ENDINGS

In addition to the division of receptors into functional categories, the receptors (apart from those of the special senses) can be grouped by structural features on morphological grounds (7.45–53). How much functional significance can be attached to these features is debatable. Factors which complicate this issue include variations in receptor structure linked with ageing, regeneration, local topography and with species differences. The terminology is further confused by a lack of agreement on the structural definition of many sensory endings. Some receptors are limited to one tissue or combination of tissues; others occur in many sites. Generally, one may distinguish between *free nerve endings* which form plexuses or spread without any particular association with other types of cell, *encapsulated endings* where groups of specialized non-nervous cells invest neural process, and *epidermal endings*, where sensory fibres are attached to specific non-nervous cells or tissues (Bannister 1976).



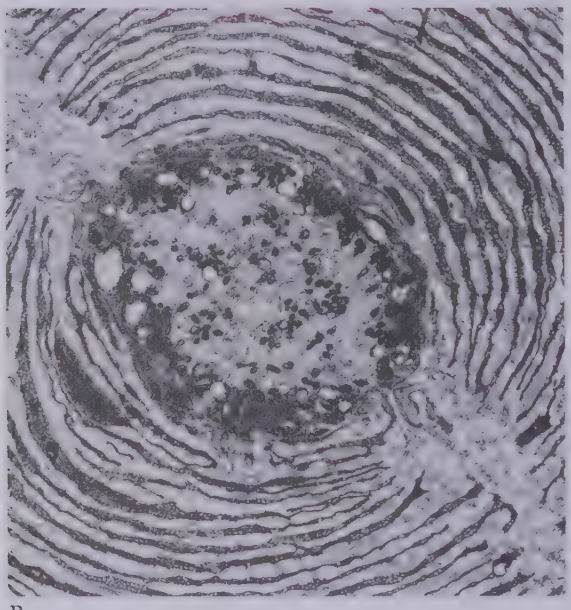
FREE NERVE ENDINGS

Sensory endings, branching to form plexuses, occur in many sites. They are found in all connective tissues including: those of the dermis, fasciae, capsules of organs, ligaments, tendons, the adventitia of blood vessels, meninges, articular capsules, periosteum, perichondrium, Haversian systems, parietal peritoneum, the visceral wall and endomysial spaces of all types of muscle. They also innervate the epithelium of the skin, cornea, buccal cavity, and alimentary and respiratory tracts and their glands, though within epithelia they are devoid of Schwann cells and are enveloped instead by epitheliocytes (and so are perhaps not 'free' endings, see Cauna 1966).



Afferent fibres from free terminals are either myelinated or non-myelinated but are always of small diameter and low conduction velocity, belonging to group III (Aδ) or IV (C) (p. 898). Where afferent axons are myelinated, their terminal arborizations are not and are probably devoid of Schwann cells at their ends. Electrophysiological recordings show that such terminals serve several sensory modalities. In the dermis, some are responsive to moderate cold or heat (*thermoreceptors*), to light mechanical touch (*mechanoreceptors*), to damaging heat, cold or deformation (*unimodal nociceptors*), or to damaging stimuli of several kinds (*polymodal nociceptors*). Similar fibres in deeper tissues may also signal extreme conditions, experienced, as with all nociceptors, as pain. Free endings in the cornea, dentine and periosteum may be exclusively nociceptor in function (see also Kruger 1987).

ENDINGS ASSOCIATED WITH EPIDERMAL STRUCTURES



Terminals associated with hair follicles are those of myelinated fibres in the deep dermal cutaneous plexus; the number, size and form of the endings are related to the size and type of hair follicle innervated (Cauna 1966). In *palisade endings* fibres approach the follicle from different directions just below the sebaceous duct, where they divide to run parallel to the hair in the outer follicular layer (7.46). Some enter it to give branches encircling the hair and terminating as free endings among collagen bundles; others

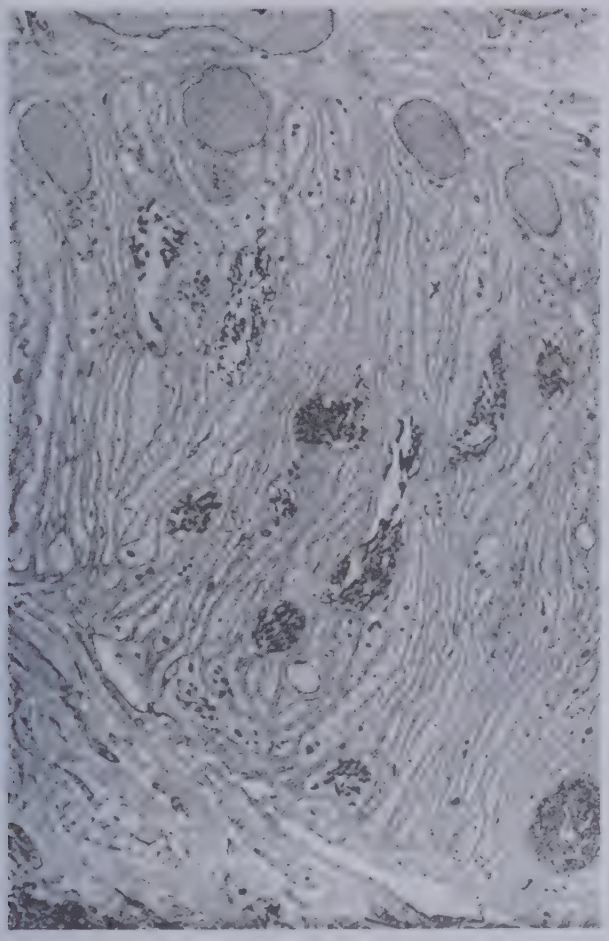
A. A cluster of Pacinian corpuscles stained with the Glees and Marsland silver technique to show the capsules and the central axons, sectioned in various planes. (Rhesus monkey finger). Provided by R Bilous, Guy's Hospital Medical School, London. Magnification × 150.

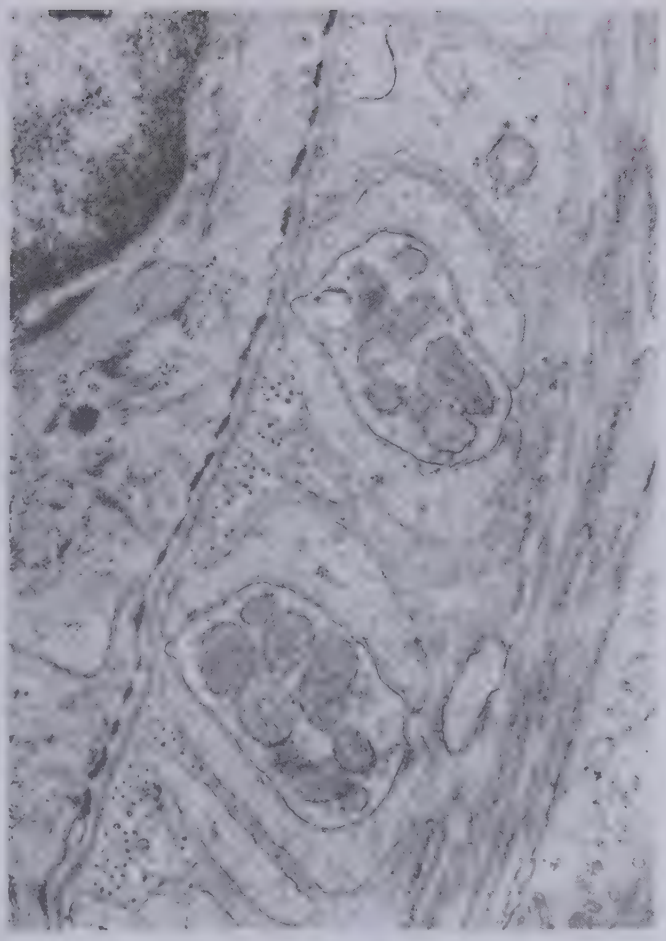
B. Electron micrograph of a Pacinian corpuscle in transverse section, showing the central core region with lamellar cells surrounding the axon. Note the presence of large intercellular spaces between the lamellar cells and the numerous mitochondria in the axon. (Rhesus monkey finger.) Magnification × 5000.

C. Electron micrograph showing a Merkel cell (M) associated with a Type I slowly-adapting cutaneous mechanoreceptor nerve terminal (N) from a rabbit touch-dome. Note the numerous dense vesicles clustered near the sensory nerve ending (arrowheads) and epidermal keratinocytes (K). Material provided by W Hamann, Dept. of Physiology, Guy's Hospital Medical School, London. Magnification × 5000.



enter the hyaline layer and, after losing their myelin sheaths, they divide into fine filaments coursing in parallel branches along the follicular axis, each ensheathed by two Schwann cells or lemmocytes. In many mammals there are fine *down hairs*, coarser *guard hairs* and *whiskers* or *vibrissae* which have erectile vascular tissue around their follicles and are the most complex, with at least three types of ending (see 7.46). Human hair is probably of the first two types. Palisade endings respond mainly to rapid movements when hair is deformed and belong to the rapidly adapting mechanoreceptor group (see also 7.50).

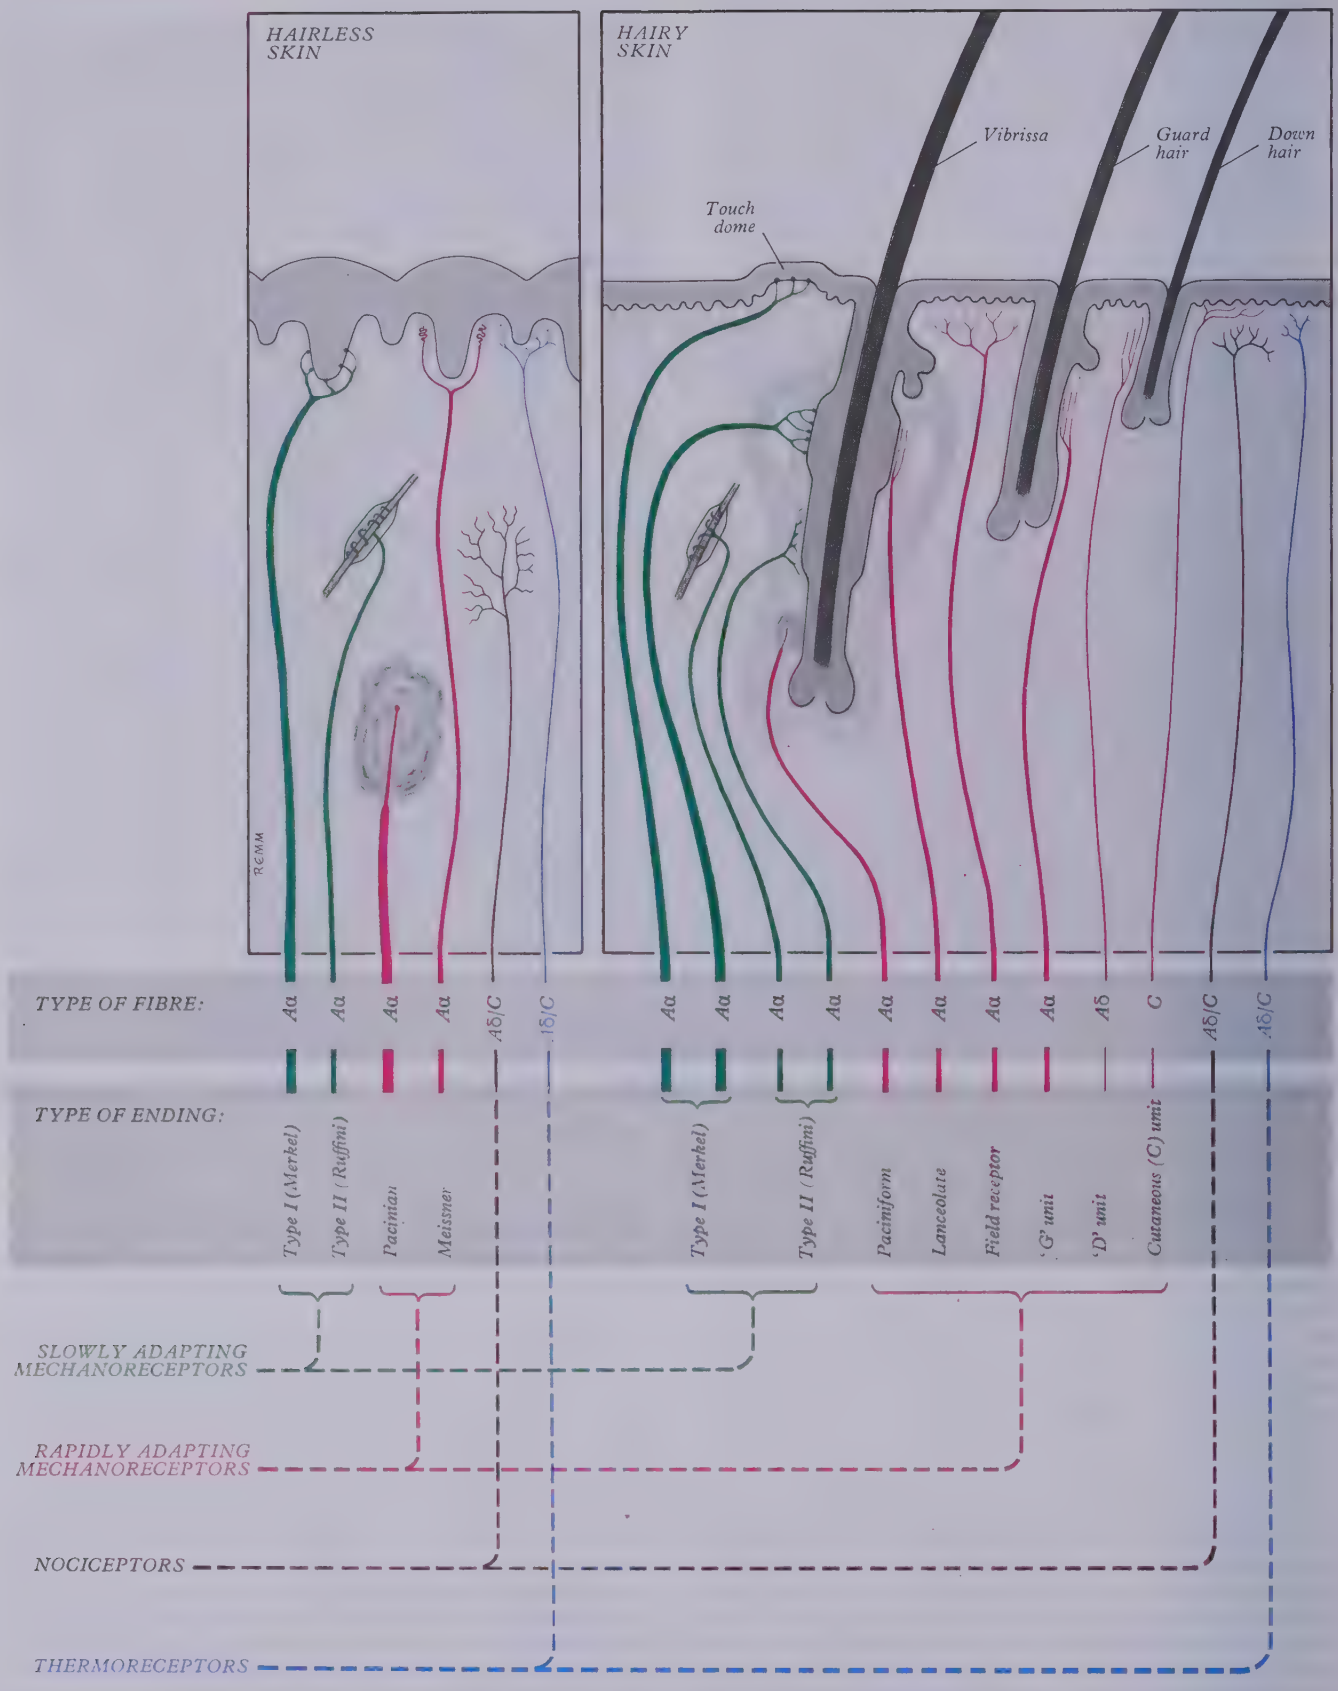
Tactile menisci (*Merkel cell* (*disc*) *endings*) lie just below the epidermis or around the apical ends of some hair follicles (7.48C). Their nerve fibre expands into a disc applied closely to the base of a specialized cell (*Merkel cell*) inserted into the base of the epidermis, bearing spike-like protrusions which interdigitate with the surrounding keratinocytes. The Merkel cells contain many large (50–100 nm) dense-cored vesicles, particularly congregated near the junction with the nerve fibre. In many mammals, groups of such units are assembled at the base of dome-like epidermal discs (*touch domes*) supplied by single, highly branched nerve fibres, also often associated with specialized hairs (*tylotrichs*). These endings are slow-adapting (Type I) mechanoreceptors responsive to vertical pressure and served by large myelinated (Aα) afferents. The ending's structure suggests some form of synaptic transmission but attempts to demonstrate this unequivocally have failed (see Iggo & Muir 1969, English 1978, Diamond et al 1988; see, however, Baumann et al 1988).



ENCAPSULATED NERVE ENDINGS

These are a major group of special end-organs exhibiting considerable variety in their size, shape and distribution but they all have a common feature: the axon terminal is encapsuled by non-excitable cells. Included in this category of ending are lamellated corpuscles of various kinds (e.g. Pacinian, vide infra), neurotendinous endings, neuromuscular spindles and Ruffini endings.

Tactile corpuscles (of Meissner) are found in the dermal papillae of all parts of the hand and foot, the front of the forearm, the lips, palpebral conjunctiva and mucous membrane of the apical part of the tongue, although they occur mainly in thick hairless skin. Mature corpuscles are cylindrical in shape, with their long axes perpendicular to the skin surface, and are about 80 μm long and 30 μm broad. The corpuscle has a connective tissue capsule and central core (7.45, 47), the capsule being only loosely attached to the core and absent at the extremities. Light microscopy indicates an external capsule of fine elastic fibres orientated mainly in the long axis of the corpuscle, interspersed with fibrocytes. The elastic fibres may anchor the corpuscle to the epidermis (Quilliam 1966). Electron microscopy shows the capsule to be continuous with the perineurium of the nerve fibres supplying the corpuscle, consisting of lamellae of greatly flattened cells and their basement membranes. Between successive lamellae there are substantial amounts of collagen, but elastic fibres are absent. Capsular extensions, often one lamella thick, may form complete or incomplete



7.49 Ultrastructure, near the apex, of a tactile corpuscle of Meissner in vertical section, showing flattened lemmal cells arranged horizontally, with their nuclei to the right of the field. The sectional profiles of the terminal nerve fibres, appearing between the lemmal cells, contain numerous dense mitochondria. From Cauna 1966 with permission. Magnification *c.* × 5000.

7.50 Ultrastructure of terminal nerve fibres in close association with a hair follicle in the auricle of a rat. Note (above) part of the nucleus and cytoplasm of a keratinocyte; the plasma membrane adjoins a well-defined basal lamina and presents a series of hemidesmosomes. The two nerve fibres contain numerous mitochondria and are enveloped by Schwann cell processes. Surrounding the latter are basal laminae, reticulin fibres (above) and collagen fibres (below). From Cauna 1969, with permission. Magnification × 35 000.

septa between lobules, particularly at the epidermal end of the capsule. The *core* consists of cells and nerve fibres. At the epidermal end, cells of the core are discoidal, transversely disposed and about 2–4 μm thick and 30–40 μm in diameter; they are claimed to be epidermal. At the other end of the core the cells are irregular with small oval or round nuclei, devoid of nucleoli, with deeply staining chromatin. They are considered to be lemmocytes. Electron microscopy also reveals occasional fibroblasts and collagen fibres, in bundles or singly, mainly parallel to the nerve fibres (7.49). Each tactile corpuscle is supplied by a few thickly myelinated nerve fibres from the deep corial plexus and possibly also by non-myelinated fibres branching from myelinated fibres in the deep plexus of the dermis. Individual sensory fibres may also branch to supply more than one corpuscle. Within the corpuscle the nerve fibres ramify profusely and decrease in size to as little as 0·1 μm in diameter; large numbers of myelinated and non-myelinated axon profiles appear in ultra-thin sections, the former being most numerous at the deep end of the corpuscle, the latter predominating at the epidermal end (7.49) and in smaller lobules. Axons and their terminal branches are all clothed with lemmocytes. Non-myelinated fibres may contain small vesicles. Tactile corpuscles develop around the time of birth, but thereafter about 80% of them eventually disappear before old age is reached; the number of nerves to each corpuscle is also reduced and, with advancing years, nerve endings are confined to the deep end of the corpuscle. Tactile corpuscles are fast-adapting mechanoreceptors of the 'field' type, providing information about rapidly fluctuating mechanical forces acting on the ventral surfaces of the fingers, toes and other areas of thick hairless skin (Valbo et al 1979).

The large lamellated corpuscles of Vater–Pacini (Pacinian corpuscles) (7.45, 47, 48) are sited subcutaneously in the ventral aspects of the hand and foot and their digits, the genital organs of both sexes, arm, neck, nipple, periostea, interosseous membranes, near the joints and in the mesentery and pancreas (cat). They are oval, spherical or irregularly coiled and are relatively huge, up to 2 mm in length and 100–500 μm or more across, the larger ones being visible to the naked eye. Each has a capsule, an intermediate growth zone and a central core containing an axon terminal. The capsule is formed by about 30 concentrically arranged lamellae of flat cells about 0·2 μm thick. Adjacent cells overlap at their edges and successive lamellae are separated by an amorphous matrix containing collagen fibres, the latter disposed circularly and closely applied to the surfaces of lamellar cells, especially their external surfaces. The amounts of collagen increase with age. The intermediate zone is cellular; occasional mitoses appear in it and the cells are incorporated into a capsule or core; the intermediate zone is not conspicuous in mature corpuscles. The core consists of about 60 bilateral, compacted lamellae, lying on both sides of the central nerve terminal and separated by two longitudinal clefts. Nucleated cell bodies exist in the outermost core, at the junction with the intermediate zone; from these arise cylindrical cytoplasmic arms passing into the clefts, where they

7.51 Schematic survey of the major types of mammalian cutaneous sensory endings and their afferent fibres. The endings are depicted symbolically according to their structural features and their mode of response to specific types of stimulus is indicated by colour coding, i.e. slowly-adapting mechanoreceptors, green; rapidly-adapting mechanoreceptors, red; nociceptors, black; thermoreceptors, blue. The class of afferent fibre is labelled according to the classification of Erlanger & Gasser referring to relative conduction velocities and fibre diameter (see text and table, p. 898). The endings typical of hairless skin are shown on the left and those of hairy skin on the right.

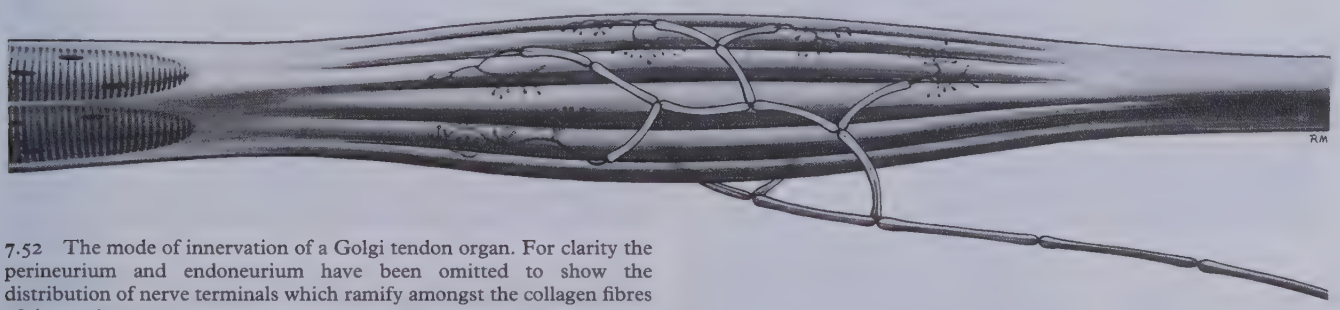
extend as flat processes passing to one or both sides to form core lamellae, interdigitating with the processes from other arms. Adjacent lamellae do not arise from the same arm.

Each corpuscle is supplied by one or, rarely, two thick myelinated fibres (Aα), the unbranched terminals of peripheral nerves. This fibre loses its myelin sheath and at the junction with the core the Schwann cell also ends. The naked axon then runs along the central axis of the core, usually without any branching to end in a slightly expanded bulb. The axon is in contact with the innermost core lamellae and is transversely oval, with the long axis in the plane of the clefts between lamellae. It contains numerous large mitochondria, of which the most superficial are usually arranged radially beneath the axolemma. Minute vesicles of about 5 nm in diameter also occur, aggregated opposite the clefts. Cells of the capsule and core lamellae are actually modified fibroblasts, as distinct from Schwann cells (Pearse & Quilliam 1957). Butyryl cholinesterase has been identified in the core. Lamellated corpuscles may lie close to glomeral arteriovenous anastomoses (p. 693) and are supplied by capillaries accompanying the nerve fibre as it enters the capsule. A condensation of richly elastic fibrous tissue forms an external capsule.

Lamellated corpuscles develop in the third fetal month; the terminal fibre is first surrounded by capsular lamellae which continue to accumulate into adult life, increasing the size of the corpuscle (Cauna & Mannan 1959). The corpuscles are said to exhibit turgidity due to fluid pressure between lamellae. Extensive studies show these endings to behave as very rapidly adapting mechanoreceptors, responding only to sudden disturbances and especially sensitive to vibration (Loewenstein 1971, Gray & Sato 1973). The rapidity may be partly due to the lamellated capsule acting like a 'high pass' frequency filter, damping slow distortions by fluid movements between lamellar cells. If the capsule is removed, the rate of adaptation, though still rapid, is considerably lessened.

Various other *lamellated endings* have been described in various species of mammal and different sites but there is little physiological evidence about their functional nature. Some, which have been described in detail, have a circumferential, concentric, lamellar pattern like the large lamellated (Pacinian) endings but are perhaps less regular and certainly smaller. Examples are found in the endings in the connective tissue sheaths of the vibrissae in cats and in other mammals (Gottschaldt et al 1973) in joint capsules and other such sites (see Polacek & Halata 1970), where they have often been called *paciniform endings*. Endings with similar organization are the *end bulbs of Krause*, *bulbous corpuscles*, *genital corpuscles* and probably the '*innominate corpuscles*' and *Golgi–Mazzoni endings* (see Bannister 1976).

Type II slowly-adapting cutaneous mechanoreceptors (Ruffini endings) occur in the dermis of hairy skin, consisting of highly branched, non-myelinated endings of Aα (or II) myelinated afferents, which invade and ramify among bundles of collagen fibres within a spindle-shaped structure enclosed partly by a fibrocellular sheath derived from the perineurium of the nerve (Chambers et al 1972). Though less organized, these structures resemble the neurotendinous ending of Golgi (vide infra) and appear electrophysiologically similar, being responsive to maintained stresses in dermal collagen. Similar structures appear in joint capsules.



Neurotendinous endings (Golgi tendon organs) are found chiefly near musculotendinous junctions (7.52). More than 50 may occur at any one such site. Each terminal is related closely to a group of muscle fibres (up to 20) which insert into the tendon fasciculus enclosing the ending. Neurotendinous endings are about 500 μm long and 100 μm in diameter, consisting of small bundles of tendon fibres enclosed in a delicate capsule. The collagen bundles (*intrafusal fasciculi*) are less compact than elsewhere in the tendon, the collagen fibres being smaller and the fibroblast larger and more numerous. The capsule consists of concentric cytoplasmic sheets, about 100–300 nm thick, belonging to capsular cells which are closely opposed, the successive layers being separated by intervals of variable width containing basal laminae. Numerous endocytic vesicles occur, suggesting that capsular cells may assist in maintaining the ending's internal environment. Outside is a thin layer of collagen fibres. One or more thickly myelinated group 1β nerve fibres pierce the capsule and divide. Their ramifications, which may lose their Schwann cell sheaths, terminate in clasp- or leaf-like enlargements, rich in vesicles and mitochondria and wrapped round the tendon fasciculi with a basal lamina or Schwann cell cytoplasm intervening (Schoultze & Swett 1972, 1974). The endings are activated by passive stretch of the tendon but are much more sensitive to active contraction of the muscle. Classically, they were considered to initiate myotactic reflexes inhibiting the development of excessive tension during muscle contraction, but it has now been shown that they are important in providing proprioceptive information complementing that from neuromuscular endings (p. 915), in all conditions of muscle activity (see e.g. Prochazka & Wand 1980). Their responses are slowly adapting, signalling maintained tension well (see Matthews 1973). The structural and physiological evidence indicates that the endings may be deformed by surrounding collagen fibres as they straighten under tension.

Special Arrays of Sensory Endings

Now that varieties of individual sensory endings have been considered separately, *arrays* of several types of ending, being functionally significant, must be briefly described. Although our knowledge of such multiple patterns is as yet only partial, there are at least three well studied receptive arrays providing sensory data on the forces acting on a particular locality and analysed, finally, together in the central nervous system. These are the receptors of skin, joints and muscles.

CUTANEOUS ARRAYS

Skin, a major sensory organ, contains the receptors of multitudes of sensory nerve fibres reporting on the mechanical and thermal state of the body surface, including the presence of noxious or damaging stimuli. How this array discriminates between different types of stimulus is much debated. For over a century it has been widely supposed that histologically different types of end-organ had specific modalities, e.g. touch, pressure and cold, though conclusive evidence was lacking. In the 1950s various areas of the body sensitive to different stimuli were seen to lack complex end-organs (e.g. Weddell et al 1955). Each sensory ending was then

7.52 The mode of innervation of a Golgi tendon organ. For clarity the perineurium and endoneurium have been omitted to show the distribution of nerve terminals which ramify amongst the collagen fibres of the tendon.

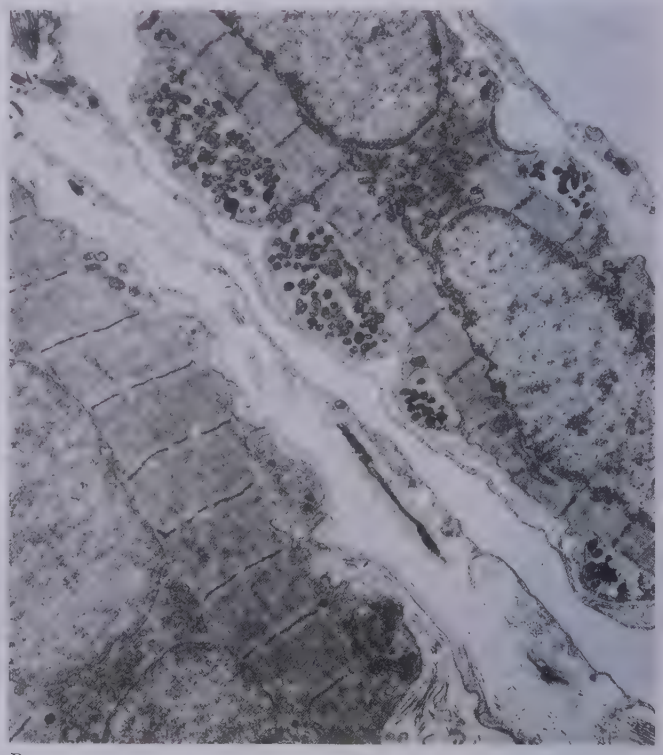
considered responsive to a range of stimuli, small differences in optimum sensitivities of a large number of sensory impulses forming a pattern of activity detectable in the central nervous system and each pattern typifying a particular category of stimulus (see Sinclair 1967). Although this idea was attractive, improved electrophysiological and electron microscopic techniques have reinstated the wide range of specific nerve endings, each highly sensitive to a particular stimulus type (Brown 1973, Burgess & Perl 1973, Iggo 1978), although not always structurally distinct. Although all endings fall into three major categories, mechanoreceptors, thermoreceptors and nociceptors, several subdivisions of each of these have been discovered (see 7.51). Mechanoreceptors may be *rapidly adapting endings*, responding only or chiefly to deformational *changes* in mechanical stimulation, or *slowly adapting endings* reacting to steady deformations. Examples of the former are the palisade endings near hair follicles, subcutaneous large lamellated (Pacinian) endings and the tactile (Meissner's) corpuscles adjacent to the epidermis; the second class includes Type I slowly adapting cutaneous mechanoreceptors (Merkel endings), generally associated with a thickened epidermis (e.g. 'touch domes') responding to steady pressures perpendicular to the surface, and Type II slowly adapting cutaneous mechanoreceptors (Ruffini endings) sensitive to steady dermal stresses. Another, distinctly different type has a low threshold but requires prolonged stimulation to be excited; these are 'free' ending class C fibres (7.51).

Thermoreceptors with branched neural endings include those increasing their firing frequency when warmed and those more active when cooled, supplying small restricted areas of skin corresponding to 'warm' and 'cold' spots, first described by Blix in 1882.

Nociceptor fibres have similar free endings, responding to various damaging stimuli, signalled centrally as pain, discomfort or irritation of the skin. Some only respond to extreme cold, others to extreme heat or severe mechanical insult; others can be stimulated by more than one type of noxious stimulus (*polymodal nociceptors*). Nociceptor endings may often be activated by the release of inflammatory products in the surrounding tissues, producing prolonged pain or itching (Iggo 1974).

The precise forms of sensory endings varies with their location and with species. In primates the skin of hairless areas on the palms and soles has its own pattern of endings. The density of endings and therefore the fineness of discrimination vary. But broadly similar arrays of sensory ending occur in each area of skin, ranging from the complex encapsulated or tissue-associated endings of large myelinated nerve fibres, to 'free' endings of fine myelinated or non-myelinated fibres. The entire complex must provide abundant data regarding the state of the body's surfaces, to be further analysed in the central nervous system.

JOINT RECEPTORS



The arrays of receptors placed in and near articular capsules provide information on the position, movements and stresses acting in their vicinity (Wyke 1967). Structural and functional studies have demonstrated at least four types of such receptors, their proportions and distribution varying with site. Three are encapsulated endings, the fourth a free terminal arborization.

Type I endings are encapsulated corpuscles of the type II slowly adapting mechanoreceptor (Ruffini) type (see p. 913), situated in the superficial layers of fibrous capsules in small clusters and supplied by myelinated afferent fibres of the group II class. Being slowly adapting, they provide awareness of joint position and movement, responding, it is thought, to patterns of stress in articular capsules (Skoglund 1973) and particularly common in articulations where static positional sense is necessary for the control of posture (e.g. hip, knee, etc.).

Type II endings are lamellated (Paciniform) receptors, like but smaller than the large (Pacinian) terminals elsewhere in connective tissue (p. 911). They occur in small groups throughout the joint capsules, particularly in the deeper layers and other articular structures (e.g. the fat pad of the temporomandibular joint). They are rapidly adapting, low-threshold mechanoreceptors, sensitive to movement and pressure changes and responding to joint

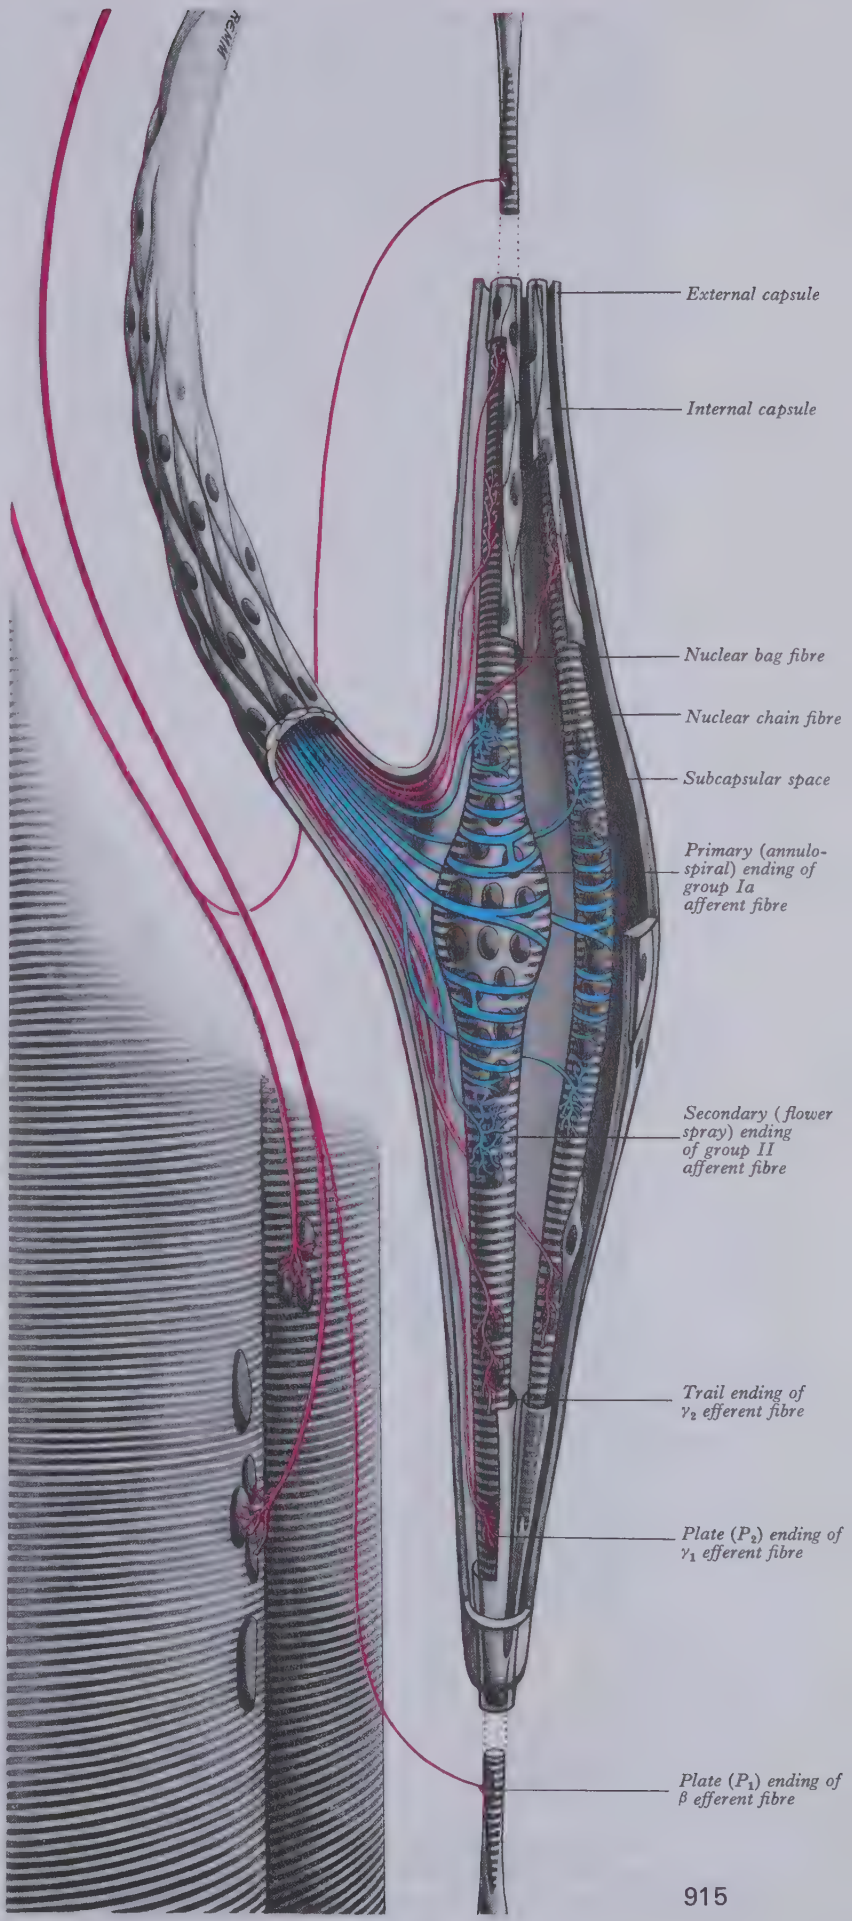
7.53 A. An electron micrograph of a neuromuscular spindle of a rat, in transverse section, showing the capsule, capsular space and four intrafusal muscle fibres, one with a centrally positioned nucleus. B. An electron micrograph of a longitudinal section through two intrafusal muscle fibres from a neuromuscular spindle of a rat. Note the primary (annulospiral) afferent nerve fibre endings cut in cross-section as they spiral around the equatorial region of a nuclear chain fibre (top right) and of a nuclear bag fibre (lower left). Note also the large numbers of mitochondria present in the sensory fibres. See text for further description. Provided by D N Landon, National Hospital for Nervous Diseases, London.

movement and transient stresses in the joint capsule. They are supplied by group II or III myelinated afferent fibres, but are probably not concerned in the conscious awareness of joint sensation.

Type III endings are identical with neurotendinous organs (Golgi) in structure and function (p. 913); they occur in articular ligaments, but not their capsules. They are high-threshold, slowly adapting receptors and apparently serve, at least in part, to prevent excessive stresses at joints by reflex inhibition of the adjacent muscles. They receive large myelinated group Ib afferent nerve fibres.

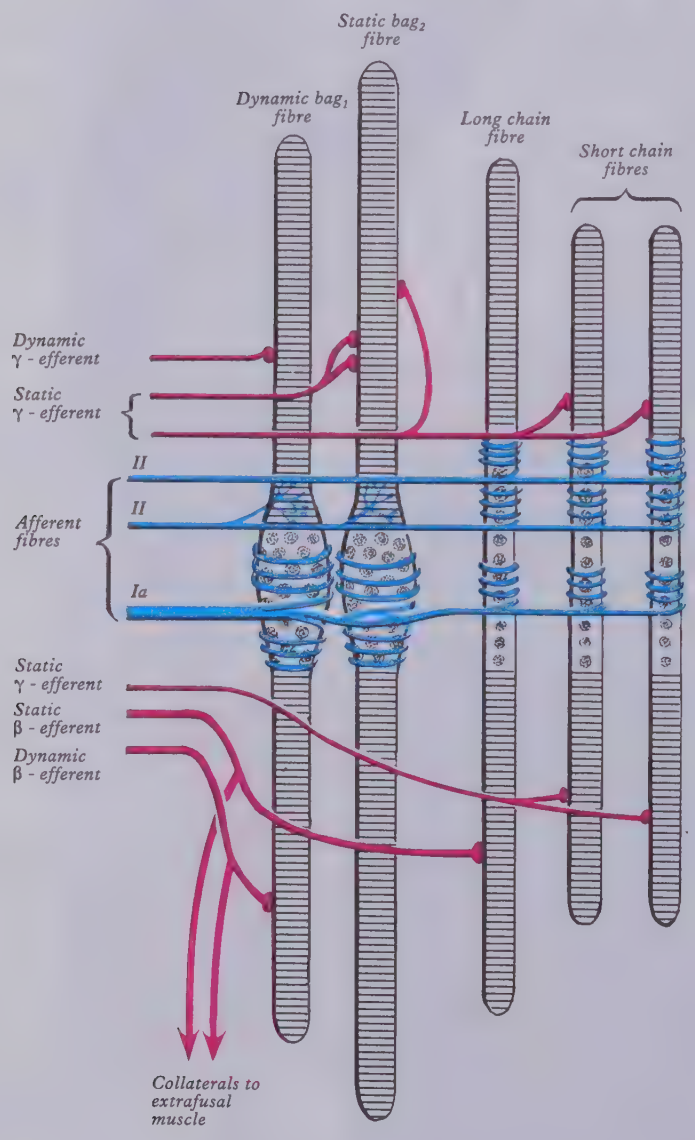
Type IV endings are free terminals of group III myelinated fibres and type IV non-myelinated fibres, ramifying in articular capsules, the adjacent fat pads and around the blood vessels of the synovial layer. These are high-threshold, slowly adapting receptors and are considered to respond to excessive movements, providing a basis for articular pain.



NEUROMUSCULAR SPINDLES

Neuromuscular spindles are essential to the control of muscle contraction, a complex activity reflected in the complicated structure and function of the spindle, which are not entirely understood. Their structure varies much in submammalian species and this account applies only to mammals (Bowden 1966, Landon 1966, Matthews 1971, Barker 1974, Banks et al 1975, Boyd 1985).

Each spindle contains a few, small, specialized *intrafusal muscle fibres*, innervated by both sensory and motor nerve fibres (7.53A,B, 54). This complex is surrounded equatorially by a fusiform *spindle capsule* of connective tissue, arranged as an *external capsule* of flat fibroblasts and collagen, as in the perineurium (p. 897), and an *internal capsule* (axial sheath of Sherrington) forming delicate tubes around individual intrafusal fibres. Between the two sheaths is a fluid rich in glycosaminoglycans of gelatinous consistency.



There are usually 6–14 intrafusal fibres, varying in muscles and species, and two major types of muscle fibre, *nuclear bag* and *nuclear chain fibres*, distinguished by the arrangement of nuclei in their equatorial sarcoplasm. In the former the equatorial cluster of nuclei makes the fibres bulge slightly, whereas in the latter the nuclei form a single axial row. Nuclear bag fibres are greater in diameter than chain fibres and extend beyond the surrounding capsule to the endomysium of nearby extrafusal muscle fibres; nuclear chain fibres are attached at their poles to the capsule or to the sheaths of nuclear bag fibres. Two subtypes of nuclear bag fibres have more recently been demonstrated, the bag_1 (or *dynamic* bag_1 fibres) and bag_2 (static bag_2 fibres), distinguishable by their ultrastructure, histochemistry and physiological properties. Human spindles may contain three or four bag_1 and bag_2 fibres and as many as 10 chain fibres.

In their contractile apparatus the intrafusal fibres resemble the extrafusal, except that the zone of myofibrils is thin where they surround the nuclei. Ultrastructurally, intrafusal dynamic nuclear bag_1 fibres generally lack M lines, possessing little sarcoplasmic reticulum but having an abundance of mitochondria and oxidative enzymes; they have a low alkaline ATP-ase activity and little glycogen. 'Static' bag_2 fibres have distinct M lines and a moderate to high level of alkaline ATP-ase and glycogen. Nuclear chain fibres have marked M lines, sarcoplasmic reticulum and T-tube elements, more glycogen and higher alkaline ATP-ase activity; they also have fewer mitochondria and lower oxidative enzyme levels. There are also differences in the extracellular environments of the fibre types, static bag_2 fibres being surrounded in their polar regions by prominent elastic fibres, whereas dynamic bag_2 fibres are not. These variations in the structural and other properties of intrafusal fibres are reflected in their contractile properties (vide infra).

7.54A Schematic three-dimensional reconstruction of a mammalian neuromuscular spindle, showing nuclear bag and nuclear chain fibres; these are innervated by the sensory annulospiral and 'flower-spray' terminals (blue) and by the γ and β fusimotor terminals (red). For further details consult text and 7.54B.

The sensory innervation of muscle spindles is of two types, both of which are the non-myelinated terminations of large myelinated axons. *Primary annulospiral* endings are equatorially placed and form spirals around the nucleated parts of intrafusal fibres; they are the endings of large sensory fibres (group Ia), each of which gives branches to a number of intrafusal muscle fibres. Each terminal lies in a deep sarcolemmal groove beneath the basal lamina and contains mitochondria, vesicles, neurofilaments, microtubules and a pervading flocculent material. *Secondary* (*flower spray* and annulo-spiral) endings, largely confined to nuclear chain fibres, are the branched terminals of somewhat thinner myelinated (group II) afferents; they are beaded and spread in a narrow band on both sides of the primary endings. Ultrastructurally, the varicosities are like the primary endings and lie close to the sarcolemma, though not in grooves. Primary endings are rapidly adapting, while secondary endings have a regular, slowly adapting response to static stretch (Matthews 1972, Hunt 1974, Boyd 1984). However, this statement is an oversimplification of the complex properties of the primary and secondary endings of different types of intrafusal fibres, since these depend on: (1) the mechanical properties of different regions of the bag_1, bag_2 and chain fibres on which they end; (2) the contractile characteristics of these muscle fibres when stimulated by their efferent terminals; and (3) variations in the numbers and patterns of afferent primary and secondary endings and of the efferent terminals. To give an example of this complexity, the primary spiral endings of the dynamic bag_1 fibres are highly sensitive to small stretches but rapidly adapt, probably because of mechanical 'creep' in the bag fibre on either side of it which decreases the tension of the central part of the fibre. In static bag_2 fibres, this tendency is much less marked, presumably due to the presence of elastic fibres surrounding the bag fibre and also because of differences in bag fibre cytology.

7.54B Schematic diagram of the organization of intrafusal fibres and their innervation within a neuromuscular spindle.

Motor endings in muscle spindles include three types, two from fine, but myelinated, fusimotor (γ-) efferents and one from β-efferent (also myelinated) collaterals of extrafusal slow twitch muscle. The first two are situated nearest to the equatorial region, ramifying to form cholinergic motor terminals with no obvious end-plate or sole; the P_2 *endings* placed further away from the equator, have a typical 'en plaque' end-plate and sole. At the extreme ends of nuclear bag fibres are P_1 endings of the β-efferents, forming 'en grappe' end-plates (p. 904). Stimulation of efferent endings causes the contraction of intrafusal fibres, with the activation of their sensory endings. Bag_1, bag_2 and chain fibres contract differently and their motor endings reflect this. The terminals of γ-efferents on dynamic bag_1 and static bag_2 fibres differ in their detailed structure, the bag_1 fibres receiving distinct synaptic end-plates (P_2, or m_b terminals) and bag_2 fibres (usually) long 'trail' (m_a) endings; chaim fibres have a third (m_c) type of more complex form or in many cases share branches of m_a terminals. For further details of structure and ultrastructure, see Arbuthnott et al (1982), Boyd (1984).

Muscle spindles signal the length of extrafusal muscle both at rest and throughout activity and relaxation, the velocity of their contraction and changes in velocity. These modalities may be related to the different behaviours of the three major types of intrafusal fibres and their sensory terminals. Dynamic nuclear bag_1 fibres are particularly concerned with signalling rapid changes in length occurring during movement; static bag_2 fibres, in contrast, are less responsive to movement; chain fibres have relatively slowly adapting responses at all times. These elements therefore can detect complex changes in the state of the extrafusal muscle surrounding spindles and can signal fluctuations in length, tension, velocity of length change and acceleration. Moreover, they are under complex central control; recently, sympathetic endings have been described in muscle spindles, adding further possibilities of changes in sensitivity mediated by the central nervous system. *Nuclear bag fibres* are probably concerned with *position*, *velocity* and *acceleration*, giving responses of a rapidly adapting, *dynamic* type, while *nuclear* efferent nerve fibres can adjust the length of the intrafusal fibres and therefore the activity of sensory fibres by causing contraction of the polar regions, thus compensating for the shortening caused by the contraction of extrafusal fibres during normal muscle activity. Such changes in tension can also magnify or reduce the responses of the afferent endings (see Boyd 1984). In summary the organization of spindles is such that they are capable of *actively* monitoring muscle conditions to allow *comparisons* between intended and actual movements and to provide a detailed input to the spinal, cerebellar, extrapyramidal and cortical centres of the nervous system concerning the state of the locomotor apparatus.

The development of neuromuscular spindles has been studied in detail by various investigators (Zelená 1957, Landon 1972, Milburn 1973). Initially, intrafusal fibres form by the fusion of myoblasts, as in extrafusal muscle; the primary sensory endings are established (in rodents) before birth, followed by motor terminals, secondary sensory endings and the opening of the capsular space. Early development is absolutely dependent on the formation of primary sensory endings (Zelená 1957) but later spindles may survive denervation, although they may undergo marked changes even if regenerating crushed nerves reinnervate them (Schiaffino & Pierobon Bormioli 1976).

The Life History of Neurons

The structure of mature neurons, as considered so far, applies only to limited aspects of their life and activities. Their mature

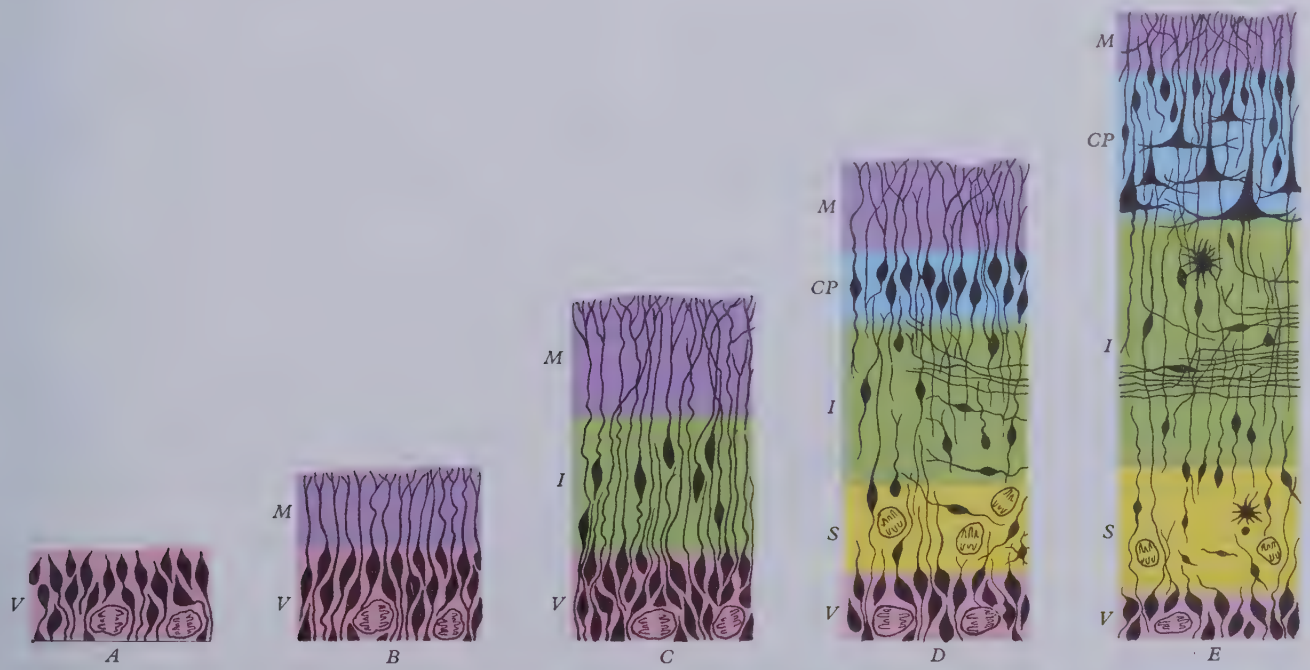
structure must be considered in the context of their development, maturation, reactions to morphogenetic and pathological factors, senescence and death.

ORIGIN AND DEVELOPMENT OF NEURONS

Neurons come from two major embryonic sources: central neurons from the neural plate and tube and ganglionic neurons from the neural crest (p. 178). The neural plate also provides ependymal and macroglial cells, while from the neural crest arise peripheral Schwann cells and chromaffin cells. Olfactory (sensory) neurons and ganglionic neurons of the vestibulocochlear nerve are *placodal* in origin (see p. 138).

The development of cells in the central nervous system has received much attention since the descriptions by His (p. 178). Recently many difficulties in determining the sequence and timing of events in nervous development have been resolved by the use of autoradiography, microinjection cell culture and related techniques for showing the origins and lineages of cell types in the developing nervous system.

The earliest observers described the wall of the neural tube as divided into ependymal, mantle and marginal zones (p. 178), later modified to include a layer of matrix cells (p. 179); more recently (Sidman 1970) the wall of the neural tube has been subdivided into four major strata: the *ventricular*, *subventricular*, *intermediate* and *marginal zones* (7.55).



The neural plate (p. 132 et seq.) and early neural tube have a single layer of pluripotent epithelial stem cells which give rise to all cell types in the central nervous system except the microglia. The nuclei of these stem cells lie close to the ventricular surface in the *ventricular zone*, with a nucleus-free cytoplasmic *marginal zone* of the laterally extending 'tails' of the stem cells. As these begin to divide mitotically they change shape, their form becoming rounded as the nucleus moves towards the ventricular surface, then, after division, elongating as the nucleus moves away from the ventricular surface, within the ventricular zone. Since mitoses are not synchronized, nuclei appear at varying levels in this zone. Later, the progeny of some of these divisions abandon mitosis and move away from the ventricle to form an *intermediate* (mantle) *zone* where they differentiate into neuroblasts; others form a *subventricular zone* between the ventricular and intermediate layers, there continuing to multiply to provide further generations of neuroblasts and later glioblasts. Both of these cell types subsequently migrate into the intermediate and marginal zones but in some regions of the nervous system (e.g. the cerebellar cortex, p. 188) some mitotic subventricular stem cells migrate across the entire neural wall to form a subpial population, thus establishing a new zone of cell division and differentiation. Many cells formed in this site remain subpial in position but others migrate back towards the ventricle through the developing nervous tissue, finishing their migrations in various definitive sites where they finally differentiate into neurons and macroglial cells.

During the genesis of these various cell types, neuroblasts are the first to be formed, followed by glioblasts. The timing of events differs in various parts of the central nervous regions and between species. Most neuroblasts are formed prenatally in mammals but some postnatal neurogenesis does occur, e.g. of the small granular cells of the cerebellum, olfactory bulb and hippocampus. Gliogenesis continues after birth in periventricular and other sites in the nervous system.

Autoradiographic studies show that different classes of neurons develop at specific times. Large neurons tend to differentiate before small ones; but their subsequent migration appears independent of the times of their initial formation. Neurons can migrate extensively through populations of maturing, relatively static cells, to reach their destination e.g. cerebellar granule cells pass through a layer of Purkinje cells en route from the external pial layer to their final, central position. Later, the final form of their neurites, cell volume and indeed their continuing survival depend on the establishment of patterns of functional connection (pp. 860–867).

STRUCTURE OF DEVELOPING NEURONS

Initially neuroblasts are rotund or fusiform, their cytoplasm containing a prominent Golgi apparatus, many lysosomes, glycogen and numerous unattached ribosomes (Tennyson 1969). As maturation proceeds cells send out fine cytoplasmic processes (neurites); these contain neurofilaments, microtubules and other structures, often including centrioles at their bases where microtubules form (p. 29). Internally, endoplasmic reticulum cisternae appear and attached ribosomes and mitochondria proliferate but the glycogen content progressively diminishes.

7.55 Schema of five sequential stages (*A* to *E*) in the development of part of the neural tube's wall, in section, to form the cerebral cortex. Modified from Boulder Committee recommendations 1970. Abbreviations: *V* = ventricular zone; *M* = marginal zone; *I* = intermediate zone; *S* = subventricular zone; *CP* = cortical plate. See accompanying text and also p. 179 et seq for details.

One neurite becomes the axon and other processes establish a dendritic tree. Axonal growth, studied in tissue culture, may be as much as 1 mm in a day. At the tips of growing axons and dendrites are bulbous *growth cones*, containing actin microfilaments (p. 184) and numerous membranous vesicles, with small surface filopodia ('microspikes') constantly 'exploring' the surrounding intercellular space (Tennyson 1970, Bunge 1976, Pfenninger & Rees 1976). Like other developments, axonal growth appears dependent on the elaboration of a cytoskeleton.

The direction of axonal growth is the subject of much current research. It appears to be partly governed by extracellular factors such as the architecture and composition of the intercellular matrix, the presence of other axons and Schwann cells along which generations of axons grow to form bundles and hence peripheral nerves (see p. 184). Within the central nervous system there is evidence that axonal growth is at least partly determined by the appearance of various *adhesion molecules* at the surfaces of ependymal astrocytes, there being complementary adhesive receptor molecules on the axonal surfaces. Adhesion molecules may vary in chemical nature in different parts of the nervous system; the nerve cell adhesion molecule (N-CAM) has been characterized in some areas (Edelman 1985). Others include the proteins *contactin* and, peripherally, laminin (see p. 67). The final direction and termination of axons appear to be related to an overall genetically determined plan. Much evidence indicates that growth patterns are determined by embryonic chemical concentration gradients, 'field effects' and chemical recognition of other cells (vide infra). Experiments on various vertebrates, in which grafting or displacement of parts is possible to achieve in the embryonic nervous system, indicates that axons can precisely contact target regions in spite of mechanical interference, as though guided by surrounding structures and stopped by chemical recognition of their target cells. Similar considerations apply to motor innervation. The mechanisms of specific connections are unknown in detail but may involve sensing of metabolites, such as 'nerve growth factor' (NGF) produced by target tissues, and recognition of particular cells by their surfaces (Sidman 1974, Moscona 1976) or impulse firing characteristics. There is much evidence (Hughes 1968) that if an axon fails to make the correct contacts, its parent soma atrophies and dies, probably as a result of toxic materials liberated within it at a programmed time of development. Such mechanisms may explain the numerical correspondence between neurons in a motor pool and the muscle fibres innervated (Tennyson 1969).

The final growth of dendritic trees is also influenced by patterns of afferent connections and their activity; if deprived of afferents experimentally, dendrites fail to develop fully and, after a critical period, may become permanently affected even if functional inputs are restored, e.g. in the visual systems of young animals visually deprived (Blakemore 1974). Metabolic factors also affect the final branching patterns of dendrites; e.g. thyroid deficiency in perinatal rats results in a small size and restricted branching of cortical neurons. This may be analogous to the mental retardation of cretinism (Eayrs 1955).

Once established, dendritic trees appear remarkably stable and partial deafferentation affects only dendritic spines or similar small details. If cells lose all afferent connections or are totally deprived of sensory input (see Guillery 1974), atrophy of much of the dendritic tree and even the whole neuron ensues, though different regions of the nervous system vary quantitatively in their response into such *anterograde transneuronal degeneration* (p. 871). Similar effects occur in retrograde transneuronal degeneration. As development proceeds plasticity is lost and soon after birth a neuron is a stable structure with a reduced rate of growth. Two main alterations may ensue; the first follows trauma to any part of the neuron, the second involves hypothetical permanent memory traces.

Reaction to trauma has been studied most extensively in motor neurons with conveniently accessible peripheral axons, but also centrally where axons form well-defined tracts (p. 872). When an axon is crushed or severed, changes occur proximally and distally to the site of injury (see also p. 901) (Nauta & Ebesson 1970). Distally, axons swell and break up into membrane-bound spheres, this change progressing distally. These *anterograde* changes, involving also the axon terminals (*terminal degeneration*), continue until the total removal of debris has occurred (p. 876). Proximally, similar changes may occur near the point of injury, followed by sequential (*retrograde*) changes in the soma (Cragg 1970) and firstly causing the removal of much original protein-synthesizing apparatus by autophagic lysosomal action. Cytoplasmic RNA first rises, which is followed by the dispersion of Nissl granules and consequent loss of staining in cytoplasm (*chromatolysis*) due to a reduced amount of RNA (Lieberman 1974). New protein-synthesizing organelles are then formed to produce proteins destined partly for the regrowth of the axon. Nucleoli become peripheral in position and ribosome clusters in the cytoplasm are restored, with the return of staining affinity in the cytoplasm. Meanwhile synapses on the soma may be retracted from the surface membrane and glial processes invade the gap (Matthews & Nelson 1975).

Where axonal regrowth is possible, as in peripheral nerves, an intact endoneurial sheath is essential to the satisfactory regrowth and contact with its end-organ. Degeneration of the myelin sheath distal to the injury has been mentioned (p. 901); this is accompanied by a mitotic proliferation of Schwann cells filling the old endoneurial tube (Webster 1964). Where a gap exists between the severed ends, proliferating Schwann cells emerge from the stumps (mainly distal) to form cords (*bands of Bungner*) across the gap, which may persist for a long time even in the absence of neural regeneration. The proximal axon then swells and many small axonal sprouts grow out from it, the majority ultimately abortive but a successful one entering the endoneurial tube's proximal end to grow down it in contact with its contained Schwann cells. *Contact guidance* (p. 115) involves the growing axonal tip of the axon and Schwann cell surfaces in the tube and Bungner's bands. When a tip reaches and successfully reinnervates an end-organ, the surrounding Schwann cells synthesize new myelin sheaths. If regeneration occurs in mature animals, no increase in the lengths of the internodal segments of myelin occurs; these remain uniformly short (often about 200 μm). Before full *functional regeneration* can occur, a considerable period of growth of both axonal diameter and myelin sheath thickness is necessary. When a high proportion of effective connections has been re-established, the nerve fibre population eventually recovers a normal diameter spectrum but this does not occur without the formation of appropriate peripheral connections, or if regeneration is long delayed.

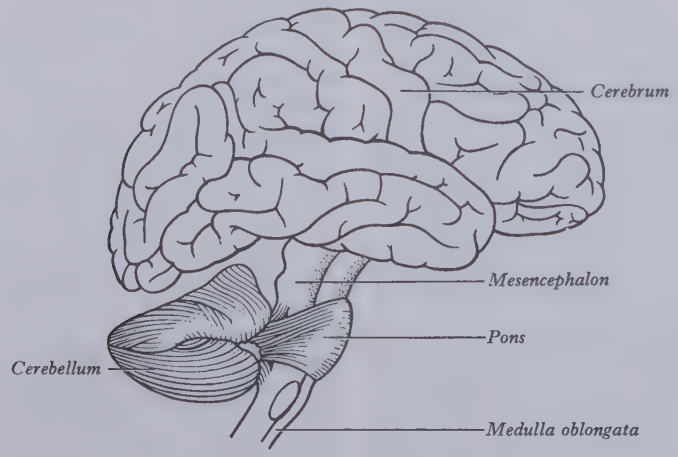
The regeneration of central axons in mammals does not normally occur. The reasons for this failure are the subject of extensive investigations at present.

A second series of changes occurs throughout the life of the individual. In addition to the continuous turnover of the cytoplasm and surfaces of neurons, constantly changing patterns of afferent nerve fibre activity, circulating hormone levels and numerous other factors affect neuronal behaviour. In every individual, cyclic or intermittent processes, such as memory, feeding, reproduction, aggression and so on, are obviously connected with such varying activity. Possibly changes in the chemical microenvironment can alter a cell's electrical firing pattern probabilistically, changing the responses of whole cell populations. More subtle alterations may occur at the biochemical level to modulate responses (and structure) of neurons with reference to previous events, a probable basis of some acts of memorization, much studied of late. Changes in RNA content and composition are said to accompany learning of conditional responses and experimental inhibition of protein synthesis is also claimed to inhibit certain types of memory (Barondes 1969). But it is uncertain what relevance these data have to the learning processes in intact nervous systems.

During fetal development many neurons degenerate and die, a process which continues postnatally until in senescence it has been estimated that 20% of neurons or more may be lost. In embryos the loss of neurons is a process of 'thinning out' those failing in functional connections (Prestige 1970) or losing in competition with other neurons to innervate structures (Hamburger 1975). Postnatal neuronal loss is less easily understood; it may be a similar process, perhaps related to the stabilization of early behaviour patterns. Certainly, with increasing age, logical

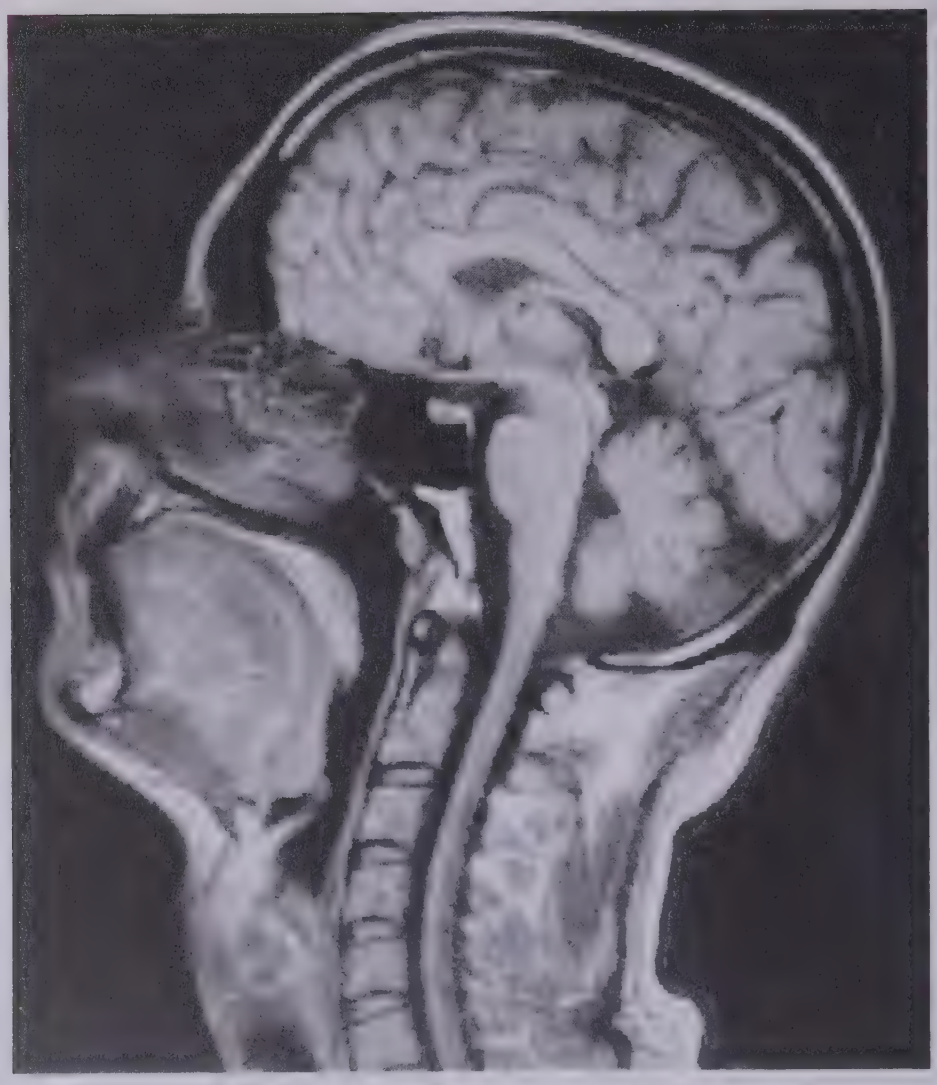
efficiency and reaction speeds in general deteriorate, changes perhaps related to this loss of neurons, although whether as a direct result is unknown, and in any case great individual variation exists.

TROPHIC INFLUENCE OF NEURONS



In addition to conduction, neurons have other functions during development and postnatal life in the maintenance or metabolic regulation of some tissues. Nervous tissue is not unique in this respect, since most tissues influence the metabolism of other cells in some way. Neuronal effects are, however, perhaps more marked and far reaching. The most obvious example is the mutual dependence of motor neurons and muscles. If, during development, a nerve fails to connect with its muscle, both degenerate. But if the innervation of slow (red) or fast (white) skeletal muscles, each with peculiar functional properties, is exchanged, the muscles change structure and properties in accordance with innervation, indicating that nerve determines muscle type and not vice versa (Buller 1970, and see p. 553). However, in this case the type of muscle is apparently determined chiefly by the firing pattern of the efferent nerve fibre, rather than by any release of trophic chemical (Lomo & Westgaard 1974). Trophic influences are clearest in lower vertebrates, however, where a whole limb amputated may be regenerated, but only if its nerves are not destroyed (Hamburger 1968). In higher vertebrates the trophic influences of axonal growth on the dendritic trees they innervate are well known (p. 918); the developmental differentiation of sensory cells, such as seen in the specificity of lingual gustatory sensory cells (p. 1170), appears to be under direct trophic afferent influence (Rosenthal 1977). Conversely, if auditory sensory cells are eliminated, the auditory neurons begin to degenerate and many eventually die, suggesting that in this case the trophic influence is the reverse of the usual situation. In many invertebrates, also, the regeneration of metameric segments is under neurosecretory influence, suggesting that the nervous system may have originated in ancestral metazoans as a system co-ordinating regeneration and development. In this light, the neurosecretory activity of hypothalamohypophyseal neurons may be a primitive survival, other neurons being subsequent specialization for rapid communication.

Role of growth factors. The presence of specific neurotrophic factors in the nervous system has been known for a long period, the best characterized of these being the polypeptide, *Nerve growth factor* (*NGF*). This substance is synthesized by various peripheral target organs of the nervous system (e.g. the salivary glands, Levi Montalcini & Angeletti 1968) from which it is taken into the nerve endings and transported back to the neuronal somata. It is necessary for the survival of many types of neurons during early development and for the maintenance of neurotransmitter synthesis during subsequent life. It is becoming increasingly clear that such factors are of great importance for the maintenance of many pathways within the nervous system and their loss may be a precipitating factor in various nervous disorders (see also the review by Korschung 1986).



MAJOR DIVISIONS OF THE NERVOUS SYSTEM

Although essentially continuous, the nervous system is conveniently divided into parts, regions and systems. The *encephalon* or brain (7.56, 57, 58) and *medulla spinalis* or spinal cord form a *central nervous system*. Extending from this in pairs are: 12 cranial and 31 spinal nerves, a *peripheral nervous system*, which includes not only all their ramifications, mediating *somatic sensory* and *motor* functions but also *visceral* or *splanchnic* nerves connected to the central nervous system (which they reach running with the somatic channels) but forming a *peripheral autonomic nervous system*. Division into central and peripheral parts is basically functional; the latter consists of relatively simple conductors connecting peripheral receptor and effector organs to each other through the intermediation of the brain and spinal cord. Though the latter contain proximal extensions of afferent and efferent pathways deployed through the peripheral nerves, the special properties of the central nervous system reside in complex interconnections of neurons, in which arise the appropriate patterns of response to stimuli from external and internal environments. This same intricate intermediation, between incoming patterns of information and emerging arrays of 'commands' to effectors, is also the domain in which learning, memory and consciousness are intrinsic, each dependent upon the level of development of the central apparatus. Elaboration of these activities, in general increasing along the lines of evolution, especially that leading to the human animal, is clearly related to the increasing populations of central interneurons, rather than to changes in the peripheral afferent and efferent conductors. Nevertheless, the essential continuity and interdependence of all parts of the nervous system is never to be overlooked.

Elements of the nervous system have already been described (p. 875). Whereas peripheral nerves largely contain, except in somatic and autonomic ganglia, roughly parallel, unconnected fibres, central nervous systems contain not only terminations or ('peripheral') neuronal somata of these peripheral axons but also large numbers of complete ('central') neurons, including their dendrites, the ramifications and synapses of which make up most

7.56 Semi-diagrammatic scheme of the main divisions of the brain.

of the volume of the brain and spinal cord. Both these parts also contain amounts of connective tissue, neuroglia and numerous blood vessels. Central nerve fibres and somata are so organized that one or the other predominates in particular regions. Somata of neurons are usually (but not always) gathered into masses, termed *nuclei* or *ganglia*; being devoid of myelin they appear darker to the eye than collections of nerve fibres, unless these are non-myelinated. This difference, accentuated by fixation with alcohol, which renders aggregations of nerve cells somewhat grey and myelinated nerve fibres almost white, is the origin of the crude but useful terms 'grey' and 'white matter' (substance), though their colours are buff and cream with the more commonplace formalin fixation. It is not to be supposed, however, that 'grey matter' contains *no* fibres; most central axons are myelinated and every group of nerve cells must contain at least the proximal parts of their own fibres; hence the grey or buff hue is due to a *relatively* low proportion of myelin. Similarly, tracts of myelinated nerve fibres, identified as 'white matter', often contain small numbers of nerve cells; where fibres are largely non-myelinated the colour will be 'grey'. With these provisos the terms are useful in grosser descriptive topography.

The spinal cord occupies about the cranial two-thirds of the vertebral canal and is arbitrarily continuous with the medulla oblongata just below the foramen magnum, the first pair of spinal nerves emerging from the cord immediately caudal to this. Its walls are thick, the central nervous cavity being here an almost microscopic *central canal*, extending nearly throughout the cord.

The encephalon or brain (7.56, 57, 58) wholly within the cranium is divisible, for convenience, into regions on the bases of morphology and function. Ascending from the spinal cord these are: the rhombencephalon or *hindbrain*, **mesencephalon** or *midbrain* and **prosencephalon** or *forebrain*. The rhombencephalon includes the **myelencephalon** or *medulla oblongata*, **metencephalon** or *pons* and the **cerebellum**. The prosencephalon is subdivided into the **diencephalon** ('between brain'), its central connecting part corresponding approximately to the dorsal thalamus and hypothalamus (but also the epithalamus and subthalamus) and the **telencephalon**, mainly comprising the two so-called cerebral 'hemispheres' or *cerebrum* (but with a small transmedian *telencephalon impar*). Midbrain, pons and medulla oblongata form the *brain stem*, connecting the forebrain and spinal cord. The relation of these divisions to each other is appreciated more clearly from their development (p. 184). The pattern of fore-, mid- and hindbrain is not only an expression of ontogenetic growth in individuals; it is also phylogenetic, representing the basic central nervous hierarchy in vertebrates. These levels are sometimes termed 'segments' of the brain; the telencephalon, particularly its cortex and connections, is often described as 'suprasegmental', a term also applied to the cerebellum. Both are phylogenetically later outgrowths of the basically elongated primitive vertebrate brain. (Other authorities use the term suprasegmental in a different sense, i.e. for structures not involved in varieties of segmentation, e.g. metameric, branchiomeric and neuromeric, referred to elsewhere in this volume.)

7.58 Diagram of 7.57. Illustration by V Martin.

The *medulla oblongata* is the most caudal (inferior) part of the brain stem, immediately above the basilar occipital bone and continuous with the pons above and spinal cord below. The *pons* is also related to the basi-occiput, extending to the sphenoidal dorsum sellae; it is greater in transverse and anteroposterior dimensions than the medulla and easily distinguished by the mass of transverse nerve fibres on its ventral aspect. The *cerebellum*, consisting of paired *hemispheres* and united by a median *vermis*, is dorsal to the pons, medulla and caudal midbrain, occupying the posterior cranial fossa; ventrally it is continuous with all three: midbrain, pons and medulla. The cavity of the rhombencephalon is the expanded *fourth ventricle*, which lies dorsal to the pons and upper half of the medulla, and continuous with a canal in the caudal medulla and, through this, with the spinal central canal. The fourth ventricle contracts above to the narrow, mesencephalic and inappropriately termed *cerebral aqueduct*. The *midbrain* is a short segment of brain stem, narrower than the pons but expanding above. The *diencephalon*, almost completely embedded in the cerebrum and largely hidden, contains a median *third ventricle*, communicating caudally with the aqueduct.

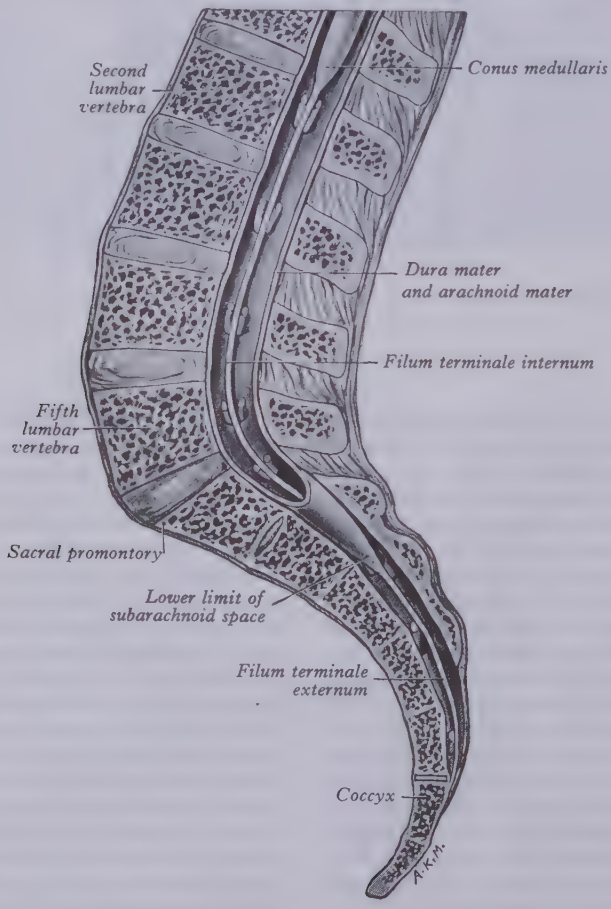
The *cerebrum*, the most rostral part, is in mankind a major fraction of the brain's volume, occupying the anterior and middle cranial fossae and directly related to the cranial vault. It consists of two large convoluted *cerebral hemispheres*. (Strictly its halves are *not* hemispherical but together form approximately *one* hemisphere; perhaps the term was originally used in the singular, but the plural however unsuitable is customary.) Each half is equal to about a quarter of a sphere, containing a crescentic *lateral ventricle*, continuous medially with the third ventricle in the diencephalon. Each has an external grey layer, the *cerebral cortex*, and a central white core of *medullary substance*, in which are several large *basal nuclei* of grey matter (earlier, incorrectly, called 'ganglia').

As noted, the *peripheral nervous system* contains a somatic *cerebrospinal* and a visceral *autonomic system*. In the former, efferent nerve fibres pass from central neurons to effector organs, mostly muscles. Efferent autonomic fibres terminate in the peripheral ganglia, forming synapses with neurons whose axons innervate non-striated muscle and glandular tissue. Autonomic efferent pathways thus have *pre-* and *postganglionic* neurons, though autonomic ganglia also sometimes include a variety of interneurons (p. 865). The arrangement of afferent fibres is similar in cerebrospinal and autonomic systems.

The autonomic nervous system has *sympathetic* and *parasympathetic* divisions, often functionally opposed. Preganglionic sympathetic efferent fibres issue from a spinal region extending from the first thoracic to the second or sometimes third lumbar segments. Preganglionic parasympathetic efferent fibres emerge only in certain cranial nerves (oculomotor, facial, glossopharyngeal, vagus with accessory) and the second to fourth sacral spinal nerves. These groups of autonomic efferents are usually designated *thoracolumbar* (sympathetic) and *craniosacral* (parasympathetic) *outflows*. A detailed description of the autonomic system appears on p. 1121 et seq.

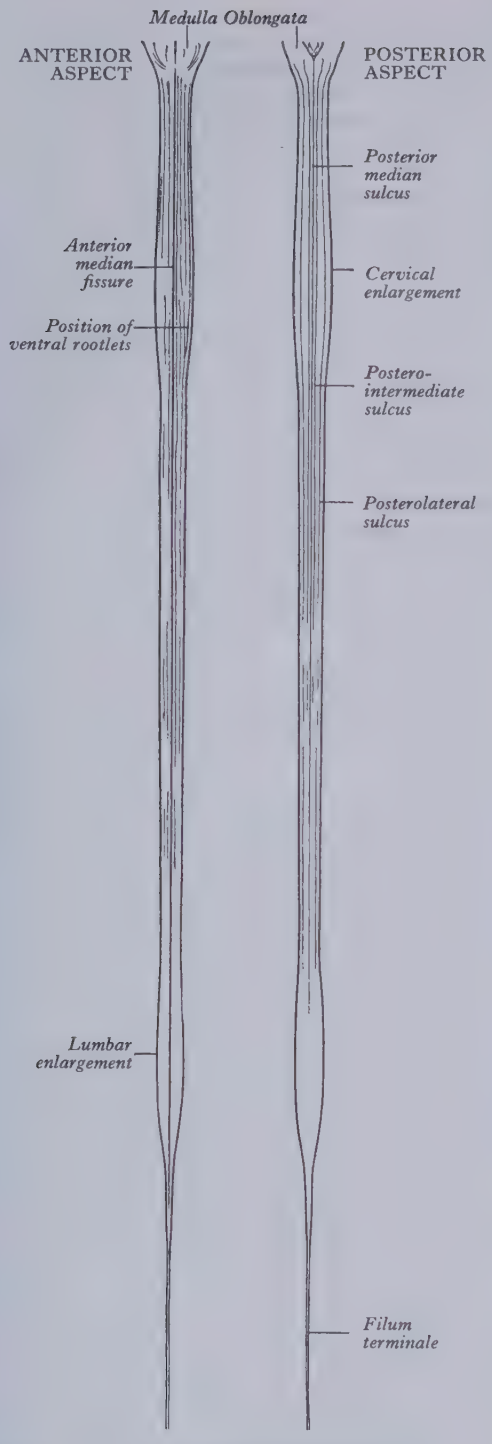
SPINAL MEDULLA OR CORD

The spinal cord (medulla spinalis) is an elongated, approximately cylindrical part of the central nervous system, occupying the superior two-thirds of the vertebral canal (7.60A,B, 61, 62, 63). Its average length in European males is 45 cm, its weight about 30 g. (For dimensional data consult Barson & Sands 1977.) It extends between the levels of the atlantal upper border and the junction between the first and second lumbar vertebrae, the latter level varying, with some correlation with length of trunk, especially in females (Jit & Charnalia 1959). The termination may be as high as the twelfth thoracic vertebra's caudal third or as low as the disc between the second and third lumbar; its position rises slightly in vertebral flexion. The spinal cord is enclosed in the *dura*, *arachnoid* and *pia maters* and separated by the *subdural* and *subarachnoid spaces*, the former being merely potential, the latter containing cerebrospinal fluid (p. 1050). Continuous cranially with the medulla oblongata, the cord narrows caudally to the *conus medullaris*, from whose apex descends the *filum terminale*, a connective tissue filament, to the dorsum of the first coccygeal segment (7.59). In *transverse width* the spinal cord varies, with a general tapering towards its caudal end, partly obscured by cervical and lumbar enlargements. It is not cylindrical, being greater transversely at all levels and especially in the cervical segments.



The *cervical enlargement* is more pronounced, being the source of large spinal nerves supplying the upper limbs and extending from the third cervical to the second thoracic segments, its maximum circumference (about 38 mm) being in the sixth cervical. (A spinal cord segment provides the attachment of the rootlets of a pair of spinal nerves.)

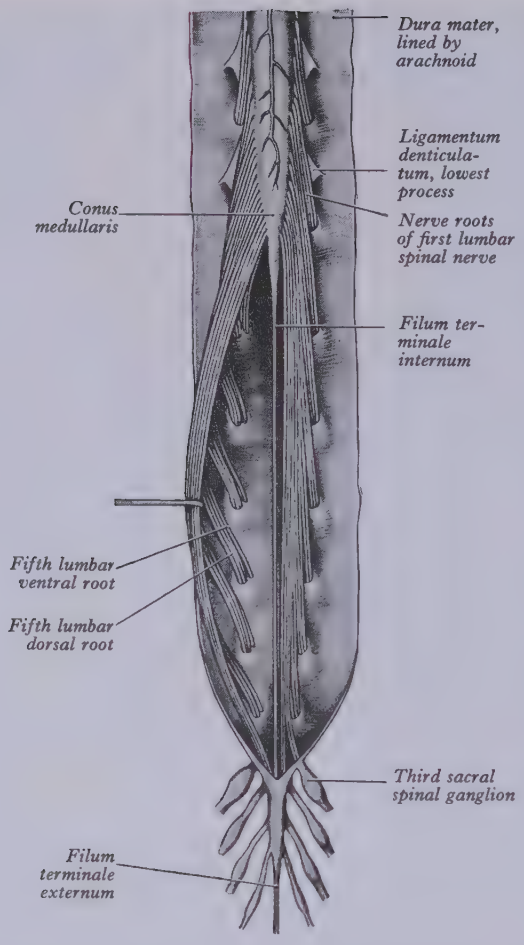
The *lumbar enlargement* similarly corresponds to the innervation of the lower limbs, extending from the first lumbar to the third sacral segments, the equivalent *vertebral* levels being the ninth to twelfth thoracic. The greatest circumference (about 35 mm) is near the twelfth thoracic vertebral body's lower part, below which it rapidly dwindles into the conus medullaris.



Fissures and *sulci* extend along most of the external surface; an anterior median fissure and a posterior median sulcus and septum almost completely separate the symmetrical right and left halves but these are joined by a *commissural band* of nervous tissue containing a *central canal* (7.62, 63).

The *anterior median fissure* along the whole ventral surface has an average depth of 3 mm, deeper than this at caudal levels. It contains a reticulum of pia mater. Dorsal to it is the *anterior white commissure*. Perforating branches of the spinal vessels pass from fissure to commissure to supply the central spinal region. The *posterior median sulcus* is shallower; from it a *posterior median septum* of neuroglia penetrates more than halfway into the cord, almost to the central canal, varying in anteroposterior extent from 4–6 mm and diminishing caudally as the canal becomes more dorsal and the cord contracts.

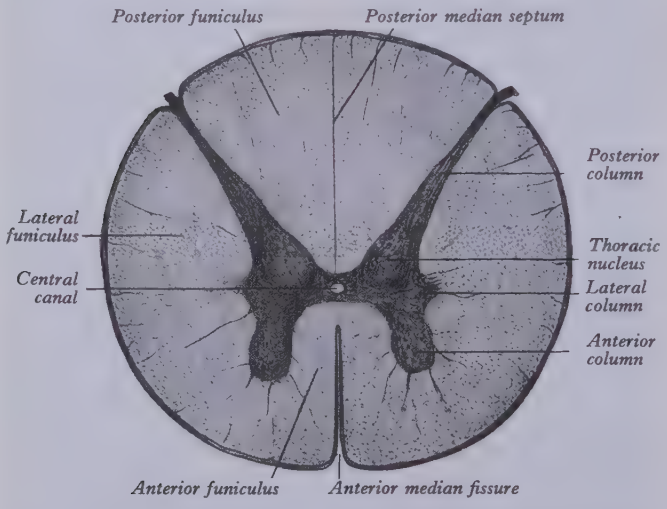
A *posterolateral sulcus* exists from 1·5–2·5 mm lateral to each side of the posterior median sulcus; along it dorsal roots (strictly rootlets) of spinal nerves enter the cord. The white substance between the posterior median and each posterolateral sulcus is the paired *posterior funiculus*; in cervical and upper thoracic segments a longitudinal *postero-intermediate sulcus* marks a septum dividing each posterior funiculus into two large tracts: the *fasciculus*



7.59 Median sagittal section of the lumbosacral part of the vertebral column to show the conus medullaris and filum terminale. The section has opened up the subarachnoid space as far as the first sacral vertebra. Note the difference in levels between the inferior limits of the spinal cord and its meninges. This illustration retained from an earlier edition has two major inaccuracies. The periosteum lines the vertebral canal and is separated from the dura by internal vertebral venous plexuses etc: at lumbar levels the fibres of interspinous ligaments slope dorsocranially (p. 491).

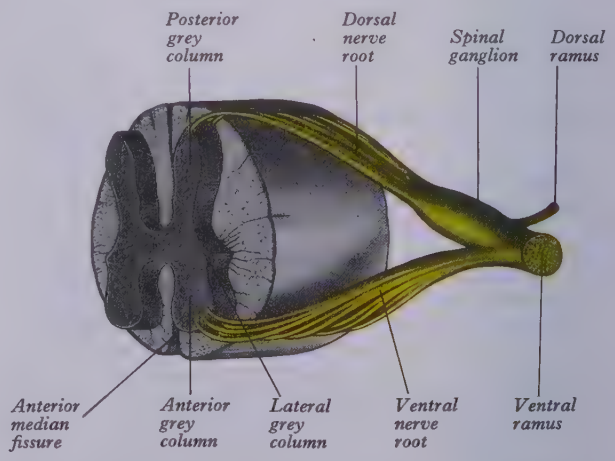
7.60A (*above*) The main features of the spinal cord.

7.60B (*right*) The brain and spinal cord with attached spinal nerve roots and dorsal root ganglia, photographed from the dorsal aspect. Note the relative sizes of the cerebral and cerebellar hemispheres and the fusiform cervical and lumbar enlargements of the spinal cord. The median longitudinal fissure between the hemispheres which receives the falx cerebri and falx cerebelli is visible, together with the horizontal cleft between cerebrum and cerebellum which receives the tentorium cerebelli. Contrast the irregular pattern and dimensions of the cerebral gyri and sulci with the more regular, largely transverse pattern of the smaller cerebellar folia and their intervening fissures. Note also the changing obliquity of the spinal nerve roots in their rostrocaudal progression, the stouter roots attached to the limb enlargements and the formation of the cauda equina and filum terminale. The cauda is undisturbed on the right and has been fanned out on the left to facilitate identification of its individual components. Dissection by M C E Hutchinson, photograph by Kevin Fitzpatrick, both of Dept. of Anatomy, Guy's Hospital Medical School, London.



7.61 The lower end of the spinal cord, the filum terminale and the cauda equina exposed from behind. The dura mater and the arachnoid have been opened and spread out.

gracilis (medial) and *fasciculus cuneatus* (lateral). Between the posterolateral sulcus and anterior median fissure is the *anterolateral funiculus*, subdivided into *anterior* and *lateral funiculi* by issuing ventral spinal roots. The anterior funiculus is medial to (and includes) the emerging ventral roots, the lateral funiculus being between the latter and the posterolateral sulcus (7.62, 63). In upper cervical segments nerve radicles emerge *through* each lateral funiculus to form the spinal accessory nerve, ascending in the vertebral canal lateral to the spinal cord to enter the posterior cranial fossa via the foramen magnum (7.85).



The *filium terminale* (7.59, 61), a filament of connective tissue about 20 cm long, descends from the apex of the conus medullaris. Its upper 15 cm, *filum terminale internum*, is surrounded by extensions of the dural and archnoid meninges and reaches the second sacral vertebra's caudal border. Its final 5 cm, *filum terminale externum*, fuses with the investing dura mater, descending thence to the dorsum of the first coccygeal vertebral segment. The filum is continuous above with the spinal pia mater; adherent to its upper part are a few strands of nerve fibres probably representing roots of rudimentary second and third coccygeal spinal nerves. The central canal is continued into the filum for 5–6 mm. A roomy part of the subarachnoid space surrounds the filum's internal part; it is the site of election for spinal (lumbar) puncture.

Continuous with the cord is a series of paired dorsal and ventral *roots* of spinal nerves (7.63). These cross the subarachnoid space and traverse the dura mater separately, uniting in or close to their intervertebral foramina to form the (mixed) spinal nerves. Since the spinal cord is shorter than the vertebral column, more caudal spinal roots descend for varying distances around and even beyond the cord to reach their corresponding foramina, thus forming, largely distal to the cord, a divergent sheaf of spinal nerve *roots*, the *cauda equina*, which is gathered round the filum terminale in the *spinal theca*. (For developmental changes consult p. 180 and Pearson & Sauter 1971.)

Ventral spinal roots contain efferent somatic and, at some levels, efferent sympathetic nerve fibres emerging from their spinal sources. Each ventral root emerges as a variable number of rootlets which appear over an elongated *vertical elliptical area*. *Dorsal spinal roots* have ovoid swellings, *spinal ganglia*, one on each root proximal to its junction with a ventral root in an intervertebral foramen; each fans out into six to eight rootlets entering the cord in a *vertical row* in the posterolateral sulcus. Dorsal roots are usually said to contain only afferent axons (both somatic and visceral) from unipolar neurons in spinal root ganglia; but a small number (3%) may be efferent (Young & Zuckermann 1936) and autonomic vasodilator fibres may issue in them: views which have received little support. Each ganglionic neuron has a single short 'stem' axon which at once divides into a medial branch entering the spinal cord via a dorsal root and a lateral one passing peripherally to a sensory end-organ. The central branch is an axon, the peripheral is derived from a dendrite (but when traversing a peripheral nerve is, in general structural terms, indistinguishable from an axon). The region of spinal cord associated with the emergence of a pair of nerves is a *spinal segment*, but there is no actual surface indication of segmentation. (Further, the deep neural sources or destinations of radicular fibres may lie far

7.62 Typical transverse section of the spinal cord at a mid-thoracic level. Magnification × 8.

7.63 Diagram of a spinal cord segment showing mode of formation of a typical spinal nerve and the gross relationships of the grey and white matter. Note dorsal nerve rootlets in a single linear row; ventral rootlets in three or more rows.

beyond the confines of the 'segment' so defined.) Recent researches show that ventral spinal nerve roots contain only one neuromediator (acetylcholine), whereas dorsal roots contain at least seven (glutamate/aspartate, substance P, VIP, CCK, somatostatin, dynorphin and angiotensin II; see p. 891).

Internal Structure of the Spinal Cord

Internally the spinal cord may be considered from several complementary points of view. Ignoring supply and support tissues, blood vessels and neuroglia, the arrangement of neurons and their processes can be studied by dissection and macroscopic inspection of sections, by light and electron microscopy, neurohistochemical approaches of great variety, by experimental techniques and combinations of these. Dissection reveals little more than the general layout of fibres and cells; microscopy details cellular types, fibre calibres and their intimate disposition. While light and electron microscopy have greatly clarified connections between neurons, their potential can only be fully exploited with experimental manoeuvres, such as degeneration, microelectrode and chemical tracing methods. Spinal organization is hence considered in steps: (1) the general arrangement of grey and white matter, (2) the distribution of neurons in grey matter, (3) the deployment of tracts of fibres in white matter, and (4) the detailed organization of the spinal neurons.

GENERAL ARRANGEMENT OF GREY AND WHITE MATTER

Spinal grey matter is central (i.e. deep to the white matter) and shaped like a fluted column, except where modified at its continuation into the medulla oblongata and conus medullaris. In transverse sections (7.64) this column has symmetrical right and left comma-shaped masses connected by a narrow transverse *grey commissure*, the whole resembling a letter H. The commissure is traversed by the central canal, which may be just visible to the unaided eye. Each lateral crescentic mass has a lateral concavity and *anterior* and *posterior columns*. At some levels a small, intermediate *lateral column* projects from the concavity. In transverse sections columns appear as projections and are often called 'horns' (*cornua*), a picturesque nomenclature misleading and unnecessary; being elongated longitudinally they are better referred to as *columns*. Central grey matter is surrounded by white matter, the latter consisting largely of nerve fibres, many (but by no means all) being longitudinal and grouped into *funiculi* or *white columns*. The general arrangement of these as dorsal, lateral and ventral funiculi has been noted and further details appear later (p. 930 et seq.).

The anterior or ventral grey column projects ventrolaterally from the grey commissure. It is short, broad and separated from the surface by part of the anterior funiculus (7.64). Its anterior and posterior regions are sometimes named its head and base.

The posterior or dorsal grey column projects dorsolaterally, is transversely narrow and extends almost to the surface near the posterolateral sulcus, separated from it by a thin *dorsolateral tract* (p. 936). It also is considered to have a *base*, continuous with the *intermediate* grey region, a constricted neck expanding into an oval or fusiform *head* and an apex, capped by a crescent of semitranslucent nervous tissue, the *substantia gelatinosa* (*Rolandi*), intimately connected with the afferent nerve fibres (p. 941).

The lateral grey column is a small, angular projection between the second thoracic and first lumbar *spinal cord segments*. (These must be carefully distinguished from vertebral levels.)

The boundary between white and grey matter is usually clear; but at cervical levels strands of grey matter invade the lateral funiculus from the base of the dorsal grey column, separated by interlacing nerve fibres like a net, whence its name, the *reticular formation*. Similar regions appear at lower spinal levels; brainstem reticular formations also exist, where physiological investigations have led to a concept of an extensive *reticular 'system'* widely deployed throughout the neuraxis (pp. 988–996).

This main pattern of white and grey matter is what might be expected in simple terms of peripherally placed conductors, i.e.

7.64 Transverse sections through the spinal cord at representative levels. Note changes in overall profile and the relative changes in grey and white regions, their shape, size and proportions. Magnification × 5.

longitudinally arranged spinal tracts of fibres, but with their sources and interconnections centrally placed; however, it is also an expression of spinal development (p. 178). Dimensions and relative volumes of peripheral (white) fibres and centrally aggregated (grey) neurons at different levels (7.64) can be explained partly by the amounts of muscle, skin and other tissues innervated by different segments and by the sequential expansion of longitudinal tracts (both ascending and descending) as progression is made in a cranial direction. At thoracic levels the grey matter is absolutely and relatively small in volume, while the white substance shows an ascending increase. In the cervical and lumbar enlargements grey matter, especially of the ventral columns, is augmented by large accumulations of neurons innervating limbs; but while white matter at cervical levels is also pronounced, in the lumbar enlargement and particularly the conus medullaris, white funiculi contain many less fibres passing through; 7.64 shows the details in representative segments; it is obvious that various levels can easily be distinguished. It is, however, more useful to recognize the explanation of these differences.

The central canal traverses the whole spinal cord and caudal half of the medulla oblongata, opening above into the fourth ventricle (p. 979). In the conus medullaris it expands as a fusiform *terminal ventricle*, triangular in section with a ventral base, 8–10 mm in length, obliterating at about 40 years. At cervical and thoracic levels the canal is slightly ventral, central in the lumbar enlargement but more dorsal in the conus medullaris; it extends for 5–6 mm into the filum terminale. It contains cerebrospinal fluid, is lined by columnar, ciliated *ependyma* and encircled by a zone of neuroglia containing a few neurons and a network of fine nerve fibres, the *substantia gelatinosa centralis*, which is traversed by processes spreading from the basal aspects of ependymal cells. Grey matter around it, external to the *substantia*, is the *grey commissure*. Ventrally the commissure is thin. Anterior to it is a thin *ventral white commissure* (p. 875). The grey commissure is traversed by two longitudinal veins (p. 948) and, dorsal to the canal, is continuous with the posterior median septum; it is thinnest at the thoracic level, thickest in the conus medullaris; it is permeated by transverse myelinated nerve fibres, sometimes termed the *dorsal white commissure*.

Internal Structure of the Grey Matter

Spinal grey matter (7.65A,B) is a complex mixture of neurons and neurites, neuroglia and blood vessels. The predominance of neuronal somata is responsible for the so-called *grey* appearance. Neuroglia (p. 892) forms an intricate lattice among the somata and neurites, particularly condensed as gelatinous substance round the central canal. Neurites will be described later, with formation of tracts (p. 891) and the organization of interneurons (p. 938); they also include initial or terminal parts of efferent and afferent peripheral fibres, with collaterals from all these sources, resulting in a complex neuropil of innumerable neurites confined to the grey matter or at least to the spinal cord. Many neurites cross in the commissures; the right and left halves of the cord, including

its grey matter, are, therefore, a functional continuum. Neurons in the grey substance are multipolar, varying in size and other features, particularly in length and the arrangement of axons and dendrites. Many are Golgi types I and II neurons (p. 876), axons of the former passing out of the grey matter into ventral spinal roots or spinal tracts. Axons and dendrites of Golgi type II neurons are largely confined to the nearby grey matter. Some neurons are *intrasegmental*, deployed within a single segment; others spread through several, thus being *intersegmental* in distribution (p. 946).

In much of the central nervous system nerve cell somata are grouped, often in large numbers, usually indicating common function. A large group may be divided with a constancy justifying specific names. Such constant patterns of distribution inevitably suggest functional implications, though the influence of developmental processes may sometimes be of greater significance. Neurons of the spinal grey matter are not distributed uniformly, occurring in major and minor aggregations, some with obvious functional significance, which in others is subject to controversy. The following cytoarchitecture of the spinal grey substance is first described in purely topographical terms and, for convenience, separately in ventral, dorsal and lateral grey columns. Functional interpretations of some groups in them will be considered later.

NEURONAL GROUPS OF THE ANTERIOR GREY COLUMNS

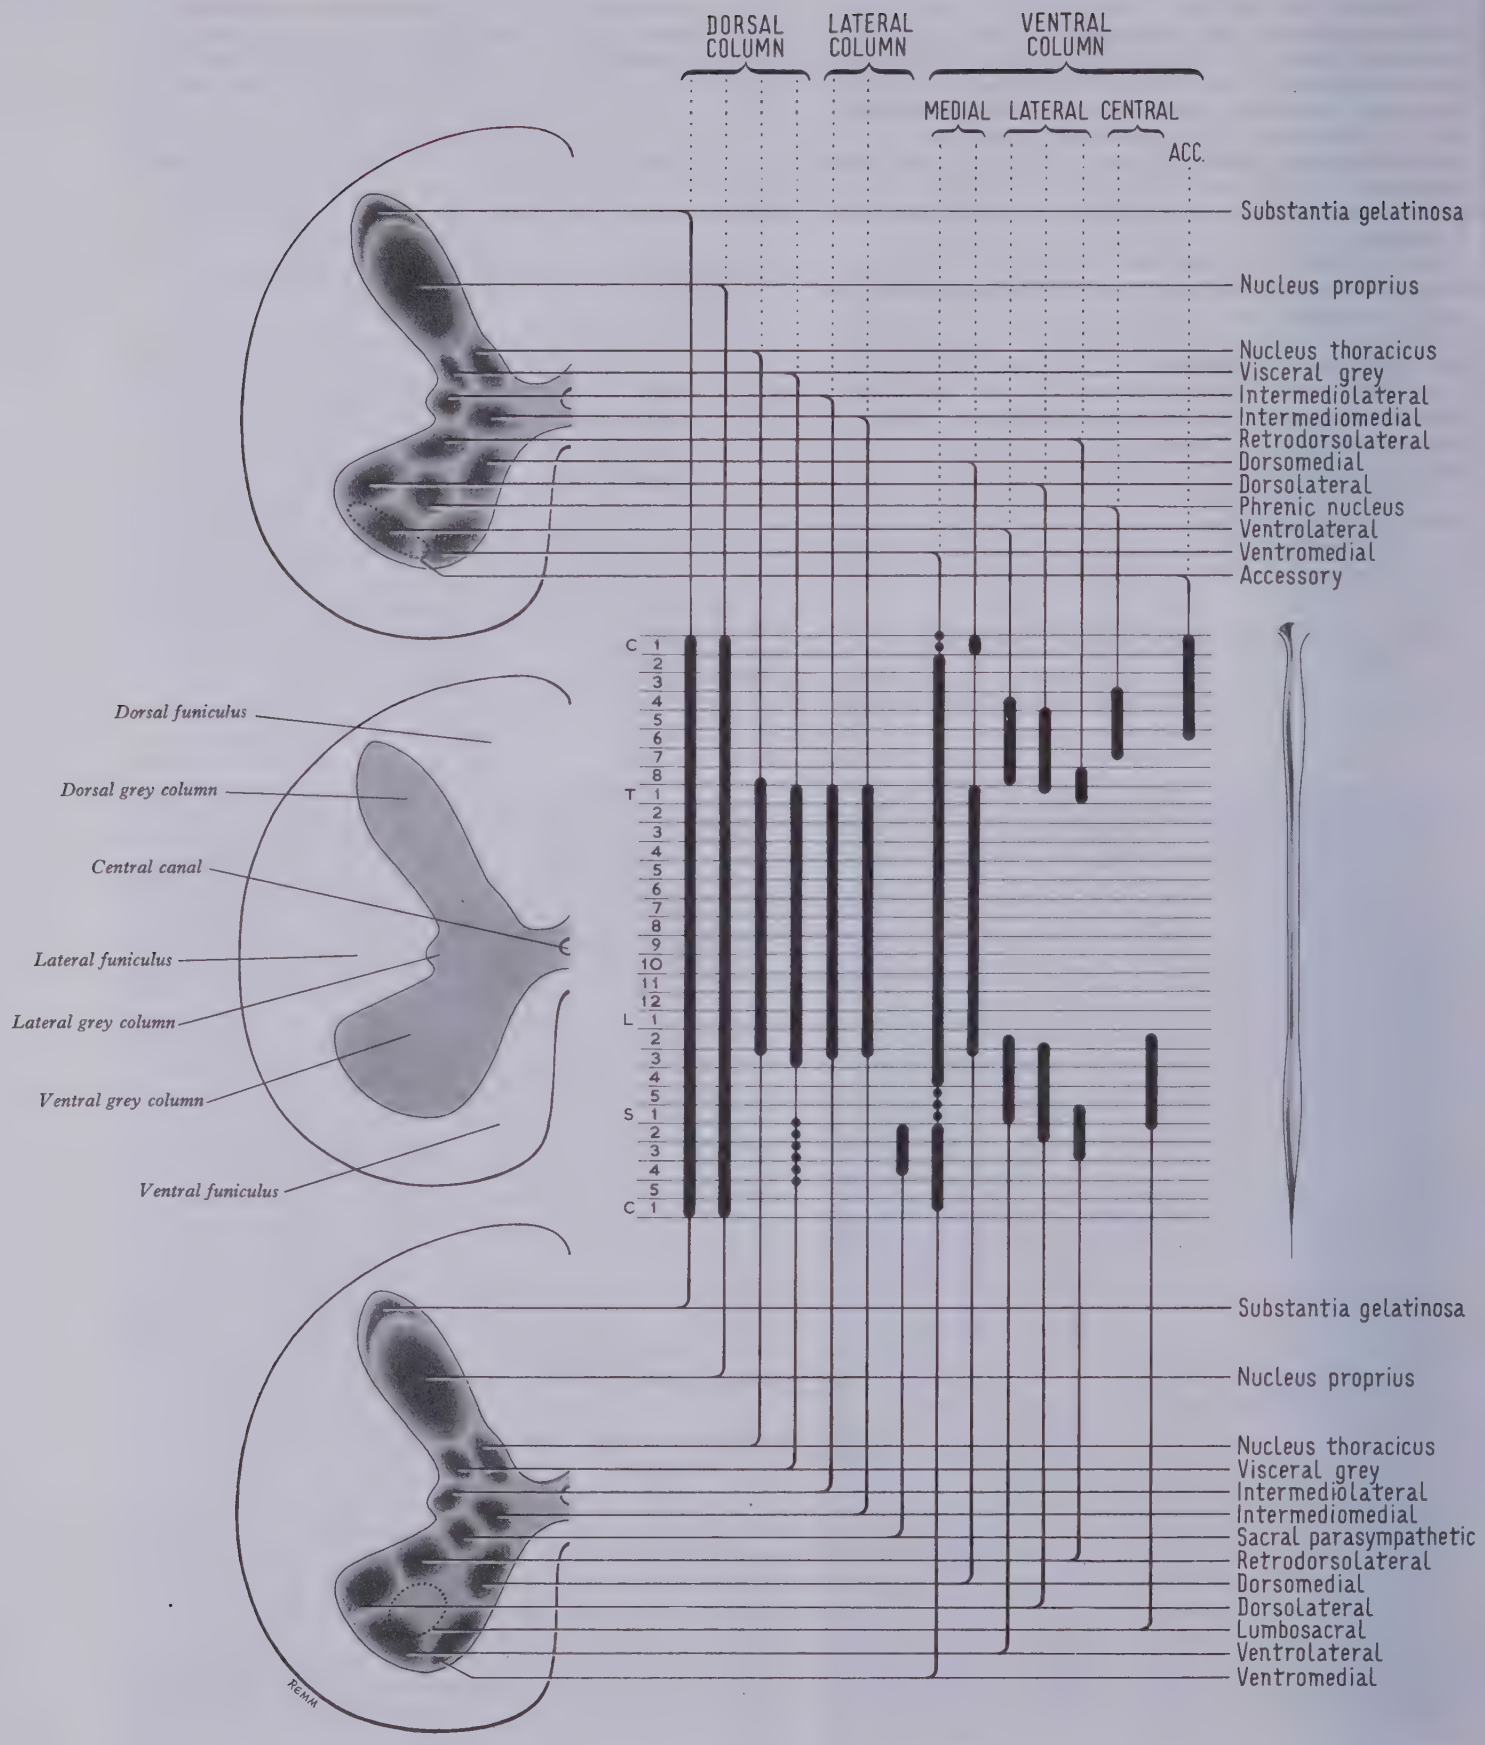
Neurons in the ventral columns vary in size; largest are the multipolar cells exceeding 25 μm in average dimensions of soma, with axons emerging in ventral roots to innervate the striated skeletal muscles as α-efferents. Large numbers of smaller neurons of 15–25 μm also occur and some of their axons are γ-efferents innervating the intrafusal fibres of neuromuscular spindles. By the evidence of retrograde degeneration, many smaller neurons in this column do not have such efferents and *most* are interneurons (p. 939).

As in other spinal regions, the ventral column neurons are in elongate groups, a number of separate longitudinal columns extending through several segments, seen most easily in transverse sections (7.65A); longitudinal sections are rarely depicted but these clearly show that the neuronal columns are not uniformly continuous (7.65B), each being a series of small aggregations, too diminutive for segmental significance (Laruelle & Reumont 1933). Basic division of the ventral grey region is into *medial*, *central* and *lateral* columns and all exhibit subdivision at certain levels, usually into dorsal and ventral parts. This promotes a nomenclature; but while agreement on the organization is satisfactory, confusion persists in terminology. The terms employed here are derived from an authority widely consulted (Crosby et al 1962); only recently (1977) have these terms been accepted into *Nomina Anatomica*. As can be seen in Figure 7.66, a **medial group** extends through most segments, perhaps absent from the fifth lumbar and first sacral; in thoracic and the upper three or four lumbar segments it is subdivided into **ventromedial** and **dorsomedial groups**; in segments cranial and caudal to this, the medial group has only a ventromedial moiety, except in the first cervical where only the dorsomedial group exists. The **central group**, the least extensive, is identifiable only in some cervical and lumbosacral segments. In the cervical cord, through the third to seventh segments, is a central columnar **phrenic nucleus**; abundant experimental and clinical evidence shows that its neurons innervate the diaphragm, being probably the least controversial motor pool in the entire cord. For experimental data in some mammals, including primates, see Kohnstamm (1898), Sharrard (1955), Keswani & Hollinshead (1956), Warwick & Mitchell (1956), Ullah (1978), Kuypers 1985. The **lumbosacral nucleus**, in the second lumbar to first sacral segments, is also central; the distribution of its axons is unknown. Neurons whose axons are said to enter the spinal accessory nerve form an irregular **accessory group**, in the upper five or six cervical segments, at the ventral border of the anterior grey column and intermediate in position but lateral to the dorsomedial group in the first cervical segment; the ventral siting of this nucleus may be due to the absence of lateral groups from the first three cervical segments (7.66).

The **lateral group** in the ventral column is subdivided into **ventral, dorsal** and **retrodorsal groups**, all largely confined to the spinal segments innervating the limbs. Their extents are indicated in Figure 7.66 and their significance will be discussed later (p. 829). Onufrowicz (1899) described a ventrolateral group in the first and second sacral segments, considered to innervate the perineal striated muscles. This '*nucleus of Onufrowicz*' has been confirmed in mankind by Mannen et al (1977) and by Konishi et al (1978) in cats.

NEURONAL GROUPS OF THE POSTERIOR GREY COLUMNS

Groups in the dorsal regions of spinal grey matter comprise two extending the cord's whole length and two limited to the thoracic and upper lumbar segments. No less than 15 neuromediators have been identified in the spinal dorsal grey column.



Substantia gelatinosa (of Rolando), present at all levels, consists of small Golgi type II neurons with some larger ones. Connections with afferents of the dorsal roots and the spinothalamic tract complex have long been accepted, but a revision of the details has followed experimental work (pp. 941, 942). A second long group of large neurons, ventral to the *substantia*, is the **dorsal funicular group** or *nucleus proprius*. As in the ventral column, a thin lamina of neurons, distinguishable from those of the substantia by their larger size, is the *marginal zone* of some observers, dorsal to the substantia (7.65A, 66).

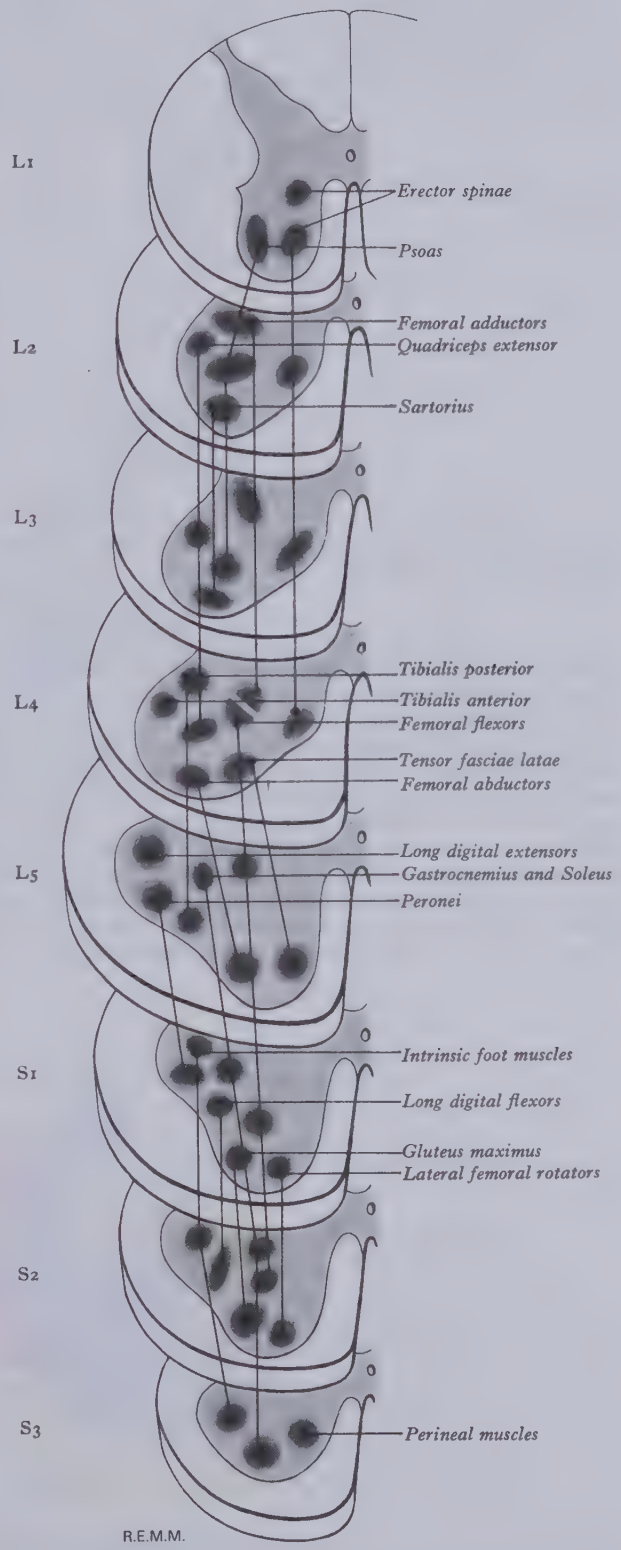
Nucleus dorsalis or *thoracicus* ('Clarke's column') is basal in the posterior grey column, immediately dorsal to the intermediate zone in laminae VI–VII (p. 944). At most levels it is near the dorsal white funiculus and may project into it. In the human spinal cord it can usually be identified from the eighth cervical to the third or fourth lumbar segments. Similar groups have been described at cervical levels superior to the nucleus dorsalis; also prolongations at caudal levels appear to exist in some long-tailed monkeys (Chang 1951). But these 'cervical' and 'sacral' nuclei consist of different neurons and have been described only in some mammals; hence it is premature to extrapolate such groups to the human spinal cord (p. 944). Neurons of the dorsal nucleus itself vary, most being large, especially in the lower thoracic and lumbar segments; some send axons into the dorsal spinocerebellar tracts (p. 935) while some are interneurons. Petras & Cummings (1977) have described the neurons and connections of this nucleus in neonatal dogs, confirming a role as a 'relay' in the dorsal spinocerebellar paths; they ascribed a similar role to the **nucleus centrobasalis**, which is in the dorsal grey column, like the nucleus thoracicus, but situated in the lower cervical and lumbosacral segments. These groups have not been established in human spinal cord.

Lateral to the nucleus dorsalis and dorsal to the intermediolateral column (7.66), a small region of neurons of medium size extends through the same segments (first thoracic to third lumbar) as the intermediate columns (Takahashi 1913); this group is identifiable in the human cord, but functionally obscure.

NEURONAL GROUPS OF THE INTERMEDIATE GREY MATTER

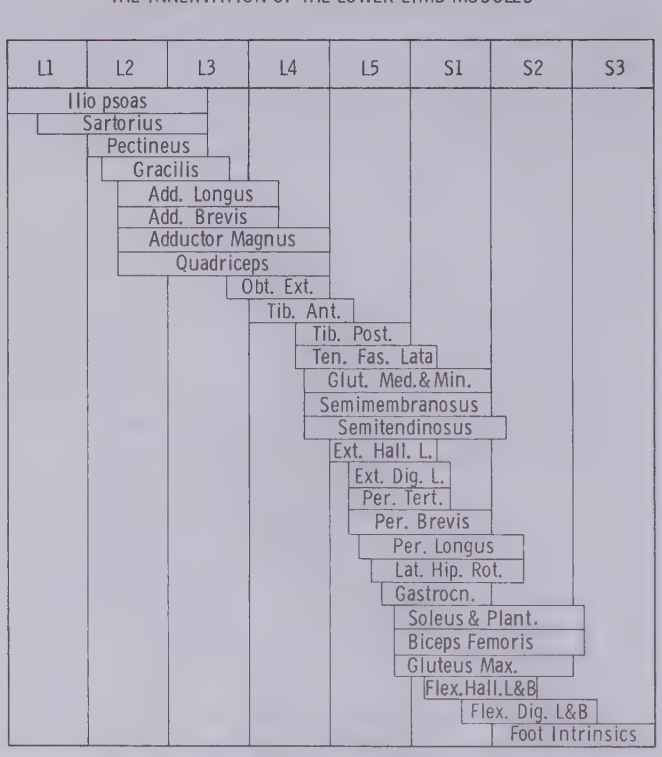
The intermediate region of spinal grey matter (7.65A, 66), including the lateral grey columns, contains small neurons, many like autonomic preganglionic cells, developing in the embryonic cord at first dorsolateral to the central canal. Many migrate lateral to it, forming an **intermediolateral column**. An **intermediomedial column** is formed from neurons nearer the central canal. The intermediolateral is the projecting lateral grey column proper; many of its neurons send axons into ventral spinal roots and via white rami communicantes to the sympathetic trunk (p. 1156). Preganglionic fibres are similarly derived from some cells of the intermediomedial column (the remainder being interneurons). Both groups extend from the eighth cervical or first thoracic segment to the second or third lumbar, corresponding approximately to the thoracolumbar outflow. In the second to fourth sacral segments a similar group, intermediate in position, is the source of the sacral outflow of

7.66 The groups or nuclei of nerve cells in the grey columns of the human spinal cord as generally accepted. Relative positions of these columnar groups, as well as their extension through varying series of spinal segments, are as indicated. Adapted from data in Crosby et al 1962, with permission of the authors and publishers.



parasympathetic preganglionic nerve fibres (p. 1155). This **sacral parasympathetic grey column** also lies lateral to the central canal and substantia gelatinosa centralis in the zone between the bases of the anterior and posterior grey columns and shows no mediolateral division, nor does it project like the thoracolumbar lateral grey column. The emergence of parasympathetic preganglionic nerve fibres from other segments has been described by Kure et al (1930) and Sheehan (1933), their origins being ascribed to the basal region of the dorsal grey column and perhaps the intermediate grey zone; the fibres were stated to issue in the *dorsal* roots, to be vasodilator and to synapse in the corresponding dorsal spinal root ganglia (Kiss 1932, Kure et al 1934). These interesting views have received neither general acceptance nor confirmation.

This description of spinal cytoarchitecture largely depends on material stained to show the *somata* of neurons rather than their processes; it has been amplified by a *laminar concept* of spinal organization (p. 938). More widely based on interconnections, its structural data are correlated with the results of degeneration experiments and microelectrode studies. The laminar pattern yields a more precise definition of spinal cord activities; but the two modes of description are not exclusive, the older scheme of columnar groups being in most features adaptable into the newer description. The main modifications concern the structural relations between the dorsal grey column neurons and the fibres of dorsal roots and spinal tracts.

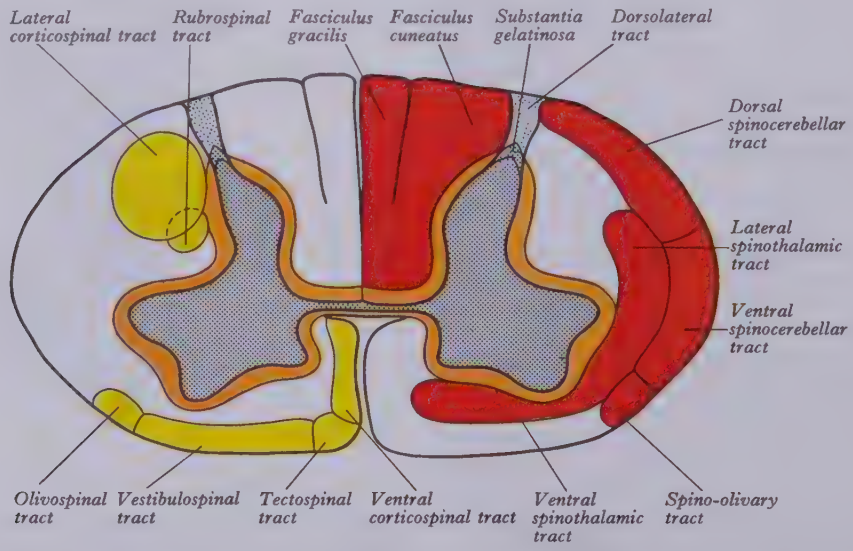


FUNCTIONAL IMPLICATIONS OF ANTERIOR GREY COLUMN CELL GROUPS

Even in the earliest accounts of spinal columnar arrays of neurons, mostly based on Nissl-stained transverse sections (from a miscellany of animals, including tadpoles, an ostrich, a gorilla and even man!), a somatotopic interpretation was advanced with confidence (Elliot 1942). Thus, an early tenet was that medial groups innervate the axial musculature (by posterior primary rami), the limbs being innervated from lateral groups. This attractive speculation, based initially on structural data, has been confirmed to some degree by subsequent experiment, as will appear. Few investigators have inspected the grouping of ventral grey column cells in longitudinal sections and errors arising in tracing elongated aggregations through transverse sections may account for some disagreements between earlier topographical results. Obviously an agreed pattern of groups is a necessary prelude to attempts to assess whether a group represents, e.g. innervation of an individual muscle. Considerable agreement is apparent in more recent work, particularly among observers examining the distribution of groups in fetal material, where they are more discrete and identifiable (Romanes 1941, Elliot 1943). Such results proved markedly similar in feline and human material, though only one human fetus was examined. In contrast motor cell grouping in ventral columns is much *less* developed in amphibians and reptiles or even mammals such as bats and moles, all possessing complex forelimb musculature, than in whales, in which the same muscles are much simplified (Romanes 1953). Comparative observations are of limited value, being mostly on a heterogeneous collection of vertebrates, in extremely small series, with little reference to taxonomy. Moreover, little such information has been added in recent decades and certainly no major series.

These difficulties must be mentioned to introduce some caution into the functional interpretations of neuronal groups, not to deny their existence. Pattern is always significant and a topographical pattern certainly exists in the ventral column. The question is: What is its physiological meaning? That it concerns the innervation of muscles seems inescapable. It would appear simple, if tedious, to cut the nerves supplying individual muscles and observe the distribution of the resultant retrograde degeneration. Few such experiments have been carried out on an extensive scale. Since they have involved different species and different spinal levels, they provide only limited checks. In an investigation of lumbosacral cord in cats, various nerves being divided in the hind limb (Romanes 1951), affected groups were all lateral in the anterior columns and cells innervating more distal muscles were dorsal to the 'motor columns' for proximal muscles. These findings generally corroborated earlier speculations. Limited experimental confirmation, also in cats, has been recorded for anterolateral leg muscles (Balthasar 1952). Romanes concluded that topographical cell groups were not usually *motor pools*, but more often represented groups innervating muscles involved in some *common effect on a joint*.

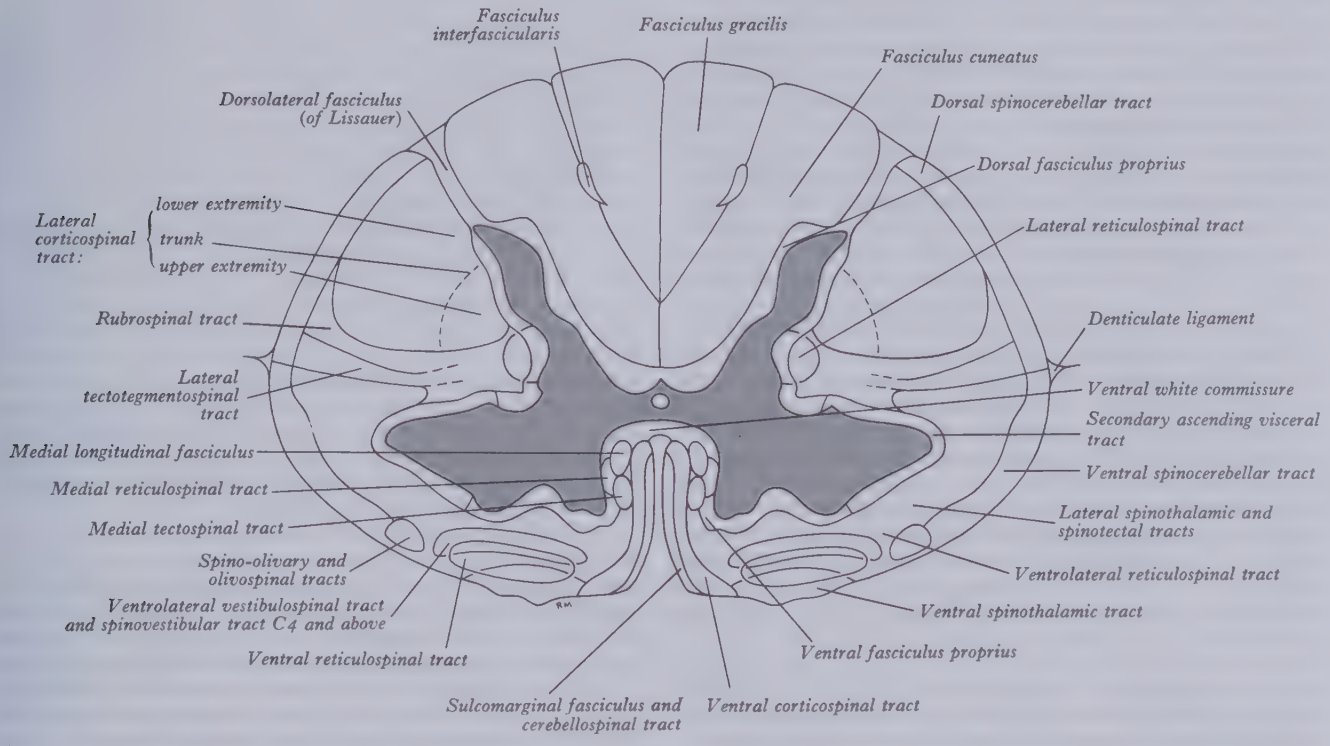
7.67A The approximate location in the transverse plane, and in longitudinal extent, of the nerve cell groups innervating muscles, chiefly in the leg, in the lumbosacral segments of the human spinal cord. Based on clinicopathological studies of poliomyelitis; see Sharrard 1955.



7.67B The segmental arrangement of the innervation of the lower limb muscles (see Sharrard 1964).

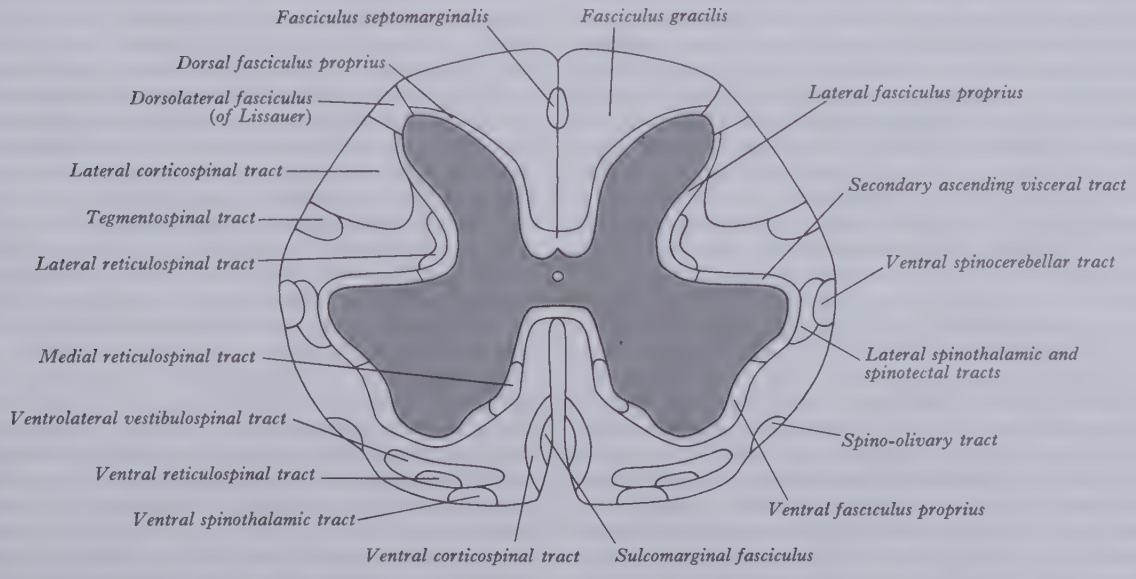
Another investigator claimed that experiments in monkeys indicated that ventral column groups can be explained not only as above, but equally well in terms of peripheral nerves, limb segments and muscles grouped on a developmental basis (Sprague 1948). The effects of the division of dorsal and ventral primary rami were studied in segments innervating limbs and at thoracic levels, leading to a denial of differentiation into medial and lateral groups in thoracic segments. Even in spinal limb enlargements, where both groups existed, both appeared sources of fibres entering dorsal and ventral rami, refuting the classic assignment of axial and limb musculature to the medial and lateral groups (Kaiser 1891). Sprague later re-emphasized that concepts of columnar organization had become so ingrained as to obfuscate interpretation. While perhaps an extreme view, this does underline the unsatisfactory state of knowledge and need of a wider re-investigation in primate animals, a formidable undertaking. More precise information might prove of limited interest but would clearly be of some value. The effects of poliomyelitis on the neurons in ventral columns have been correlated with the resultant paralysis by several clinical observers. The most detailed report (Sharrard 1955, 1956) is of special interest, firstly in concerning human conditions and secondly in its partial confirmation of the experimental findings in cats (7.67A,B). Further data of this kind are much needed.

To summarize: despite a copious literature, a plethora of topographical speculations and a much smaller corpus of experimental data, large uncertainties remain. That the topographical arrangement of ventral grey column neurons is columnar is well established, but perhaps columnar organization (to some extent inevitable in an elongated spinal cord) has been overemphasized. Somatotopic organization related to muscles, individually or in functional groups, appears generally confirmed; but evidence does not favour discrete motor pools for individual muscles, few being satisfactorily identified. Overlapping 'pools' for associated muscles seems a more common pattern of organization. Most workers have apparently concentrated on the *somata* of neurons, ignoring the *dendritic regions* between them, which occupy a much greater volume of spinal grey matter. To this aspect of organization we shall return after consideration of spinal 'white matter'.



Nerve Fibre Tracts of the Spinal Cord

The spinal 'white matter' contains nerve fibres, neuroglia and blood vessels, surrounds the fluted column of grey matter and owes its hue to large numbers of myelinated nerve fibres. Its arrangement into anterior, lateral and posterior funiculi has been noted (7.62). Fibres vary in calibre, many being small and lightly- or non-myelinated. Some tracts are typically of small fibres, e.g. the dorsolateral tract, fasciculus gracilis and central part of the lateral funiculus. Nerve fibres in the fasciculus cuneatus, anterior funiculus and peripheral zone of the lateral funiculus all contain many large fibres. Most 'white' regions show a wide *spectrum of fibre diameters*, from 1 μm or less to about 10 μm. Fibres of 3 μm or less predominate; the larger (few exceeding 10 μm) form a small fraction. Detailed studies of the distribution of fibre diameters in human spinal cord have been few (Haggqvist 1936, Giok 1956) but many tracts are claimed to be identifiable on this basis. The proportions of fibres of particular diameters have been



7.68 Simplified diagram of the main tracts of the spinal cord. The ascending tracts are shown in red on the right side of the figure; the descending tracts are shown in yellow on the left side; the 'intersegmental' tracts are in orange on both sides. Many tracts are omitted (see 7.69A,B).

occasionally estimated (Szentágothai-Schimert 1941) but precise data of this kind are few. Delineation of tracts by such inspection in transverse sections of normal material must be confirmed by experimentation. Most information regarding spinal tracts is derived from selective spinal damage in experimental animals; but the effects of damage to dorsal nerve roots and lesions in the brain stem, cerebellum and cerebrum have also provided information. In such experiments retrograde degeneration indicates the neurons from which particular axons proceed, anterograde terminal degeneration indicating the sites of termination. Suitable staining to reveal Wallerian degeneration at intermediate levels can demonstrate the position of a tract and the degree of compaction, dispersal or overlap of its fibres. While certain tracts are largely discrete and their central regions regularly located in funiculi, reciprocal overlap at their fringes (often much more) is usual (vide infra). This partly accounts for variation in extent in diagrams of transverse spinal sections according to different authorities; in all such diagrams arbitrary boundaries delineate the *supposed* limits of tracts, especially in the human cord, where deliberate experimentation is impossible; the data available result only from disease and injury, neither producing clear-cut lesions. Such investigations, particularly experiments (see p. 870) on other primates, are likely to provide results similar to human arrangements; but it is unwise to assume that they are identical. Evidence from the examination of human spinal cords affected by disease or injury does support the presumption that the general layout of tracts in the human primate is much the same as in others. Information from this source is surprisingly abundant,

A

B

7.69 The approximate relative positions of nerve fibre tracts of the human spinal cord at mid-cervical (A) and lumbar (B) levels. Adapted from Crosby et al 1962.

though usually less precise; it was the principal source of early data and a large number of reports is scattered through neurological literature (Nathan & Smith 1955, 1959). The predominance of clinical data has produced a curious vicious circle in associating the observed *syndromes* of sensory and motor disturbance with injury or disease in particular spinal regions but the exact extent of the trauma is often imprecisely assessed. Because some tracts are undeniably concentrated in certain parts of the white funiculi, delineation has become artificially crystallized. The fringe overlap mentioned above may be extensive; some tracts are almost completely mingled, others are a concept rather than a circumscribed reality, their fibres scattered far and wide. Experimental observation, in parallel with clinical deduction, has now outstripped the latter in the recognition of intermingling of tracts, whose supposed separateness is still accepted in much clinical practice: an impediment rather than an aid to accurate diagnosis.

The following account of spinal tracts is concerned with human arrangements; but reference to findings in animal experimentation must often be made where adequate clinicopathological data are unavailable. In a later section (p. 938), dealing with the finer details of neuronal organization in the spinal cord, evidence from animals other than man must predominate, but it is probable that deductions from this source are in many instances applicable to the human spinal cord (but with some notable exceptions).

As a convenient simplification, nerve fibres in spinal white matter are assigned to five groups: (1) afferent fibres from neurons in dorsal root ganglia entering by dorsal roots and extending variable spinal distances; (2) long ascending fibres, derived from spinal neurons conducting afferent impulses to supraspinal levels; (3) long fibres descending from supraspinal sources to synapse with spinal neurons; (4) fibres effecting intrasegmental and intersegmental connections; (5) fibres from motor neurons in ventral and lateral grey columns issuing in ventral nerve roots. Fibres in all except the last category form *longitudinal tracts*. Arrangements are not, however, so simple. Examination in different planes reveals that many fibres proceed in oblique and even horizontal directions, particularly across the midline in grey and white commissures, many being *decussating* fibres. Many others are *commissural* intrasegmental connections linking the neurons in grey columns to contralateral neurons. Some longitudinal tracts are polysynaptic, i.e. composed of trains of neurons. Most, if not all, fibres entering by the dorsal root divide into horizontal ascending and descending rami, all with collateral branches extending into the grey matter, in which the number of neurons sending axons into ventral nerve roots or long projection tracts is a mere fraction of the total, most being local interneurons (p. 939).

In the following account an arbitrary order has been adopted: tracts in the anterior, lateral and posterior funiculi are described in that order, in each of which descending, ascending and intersegmental tracts are successively described. This is primarily to present a topographical picture useful in the context of medical diagnosis, experiment and phylogenetic studies. However, tracts vary in relative positions at different spinal levels (and in different species). For a detailed analysis of tracts in the cat and monkey, see Verhaart (1953, 1954), van Beusekom (1955), Verhaart & van Beusekom (1958). The general positioning of major tracts is illustrated in 7.68 and in greater detail at two levels in 7.69A,B. Some features are further summarized in 7.72A,B, 73.

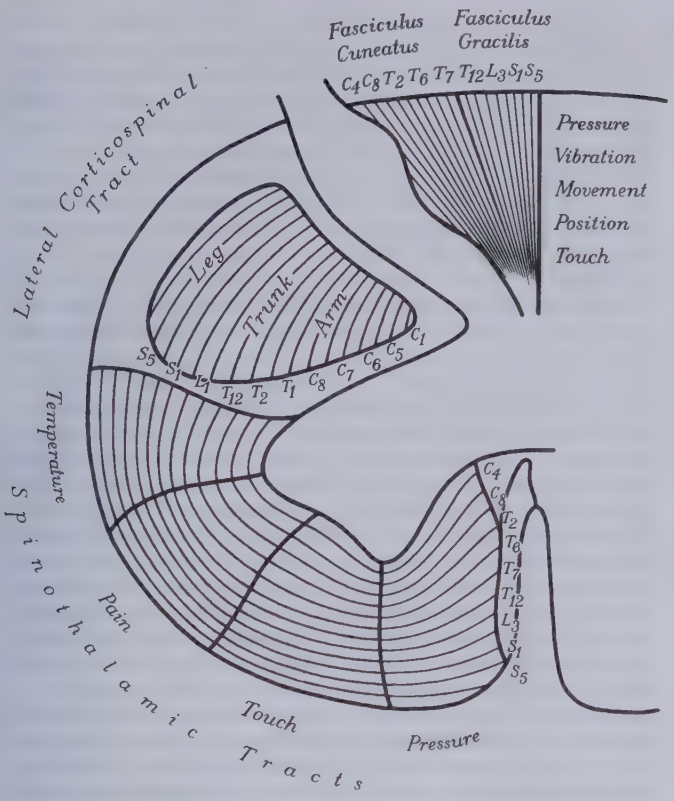
TRACTS IN THE ANTERIOR FUNICULUS

1. Descending Spinal Tracts

(*a*) **The anterior corticospinal tract,** usually small and inverse in size to the *lateral* corticospinal tract, adjoins the anterior median fissure but is separated from it by the sulcomarginal fasciculus (vide infra). Present in the upper spinal cord, it diminishes as it descends and cannot be traced below middle thoracic levels. Its fibres are considered with those of the lateral corticospinal tract (p. 933). It occurs only in primates, is of uncertain function and very variable (Nyberg-Hansen & Rinvik 1963); it may be absent or, very rarely, contains almost all corticospinal fibres, but usually about 10–30% of them. Its variability may be linked with its late phylogenetic and ontogenetic development (Humphrey 1960).

(*b*) **The vestibulospinal tract,** principally derived from large and small neurons in the lateral vestibular nucleus (p. 958), descends superficially in the periphery of the anterior funiculus to end around the neurons in the anterior grey column. Being uncrossed, it brings ipsilateral anterior column neurons under control of the vestibular nuclei, as an efferent path for equilibration. The most medial fibres have, however, been ascribed to medial and perhaps lateral and inferior vestibular nuclei (Rasmussen 1932) but only the medial nucleus is confirmed (Pompeiano & Brodal 1957). These medial fibres, descending by a different course in the medial longitudinal fasciculus (p. 985), constitute the *medial vestibulospinal tract*, partly crossed and probably ceasing above the lumbar cord, perhaps concerned only with the upper extremity and neck. In the anterior funiculus it is dorsal to the tectospinal tract and next to the anterior median fissure, sited as a so-called *sulcomarginal fasciculus* (7.69A,B). Most vestibulospinal fibres are uncrossed and descend from the lateral nucleus as a *lateral vestibulospinal tract*, which extends to all levels. Fibres of both tracts end medially in the anterior grey column (laminae VII and VIII, p. 939), influencing α and γ motor neurons through the interneurons (Gernandt 1959); some may end monosynaptically on motor neurons. There is some degree of somatotopic representation in the lateral vestibular nucleus.

(*c*) **The tectospinal tract,** variably sited lateral to the anterior median fissure, arises in the contralateral superior colliculus, ending in synapses with the interneurons (Szentágothai 1948) in cervical segments of the anterior column, with terminations probably in laminae VI–VIII (p. 939). A suggested bilateral origin from superior colliculi may be due to confusion with a *lateral tectotegmentospinal tract* of some authors; when this is described, tectospinal fibres in the anterior funiculus become a *medial tectospinal tract*. Autoradiographic fibre-tracing in primates (Frankfurter et al 1976) suggests that only a minority of tectal fibres reach the spinal cord, most ending in various brain-stem nuclei. For further discussion see pp. 946, 985.



(*d*) **Reticulospinal fibres** scattered in the anterior funiculus, largely in its medial part, arise from ipsilateral pontine reticular nuclei (p. 991), some perhaps decussating shortly before their spinal termination (Torvik & Brodal 1957). Descending the whole cord in the anterior funiculus, they probably synapse with interneurons medially in the ventral grey column (laminae VII and VIII, Nyberg-Hansen 1965, p. 946), perhaps facilitating the motor neurons. Commonly known as the *medial* (pontine) *reticulospinal tract*, its pontine origin corresponds to the 'facilitatory area'. (Contrast the lateral reticulospinal tract, p. 934.) These details are unconfirmed in mankind (Nathan & Smith 1955, Brodal 1957, Webster 1978, and p. 991).

(*e*) **The interstitiospinal tract**, uncrossed, descends from the interstitial nucleus (p. 985) in the medial longitudinal fasciculus and its spinal continuation, the ipsilateral fasciculus proprius (anterior intersegmental tract). In cats the tract is considered traceable to sacral levels (Nyberg-Hansen 1966) but no details are available for the human spinal cord, where nevertheless it has long been recognized (Muskens 1914).

(*f*) **The solitariospinal tract** (Cajal 1909) is a small group of fibres descending in part from the caudal part of the solitary nucleus (p. 954); it is clear in cats (Torvik 1957) but has also been equated with part of the medial reticulospinal tract (Crosby et al 1962). It may be involved in visceral reflexes involving the oesophagus and stomach.

2. Ascending Spinal Tracts

The anterior spinothalamic tract is continuous with the lateral (p. 935) but may be considered the anterior funicular part of the spinothalamic complex, lying medial to fibres of the ventral spinal roots and dorsal to the vestibulospinal tract (7.68), which it overlaps with all its other neighbours. Largely on clinical evidence, it is said to be concerned with crude tactile and pressure sensibility but this is not confirmed by physiological investigations (p. 944). According to Applebaum et al (1975) segregation by modality in the anterior/lateral spinothalamic complex does not accord with experimental data and they are to be considered

7.70 The general plan of segmental organization of the fibres in the posterior funiculus, the lateral corticospinal tract and the lateral and anterior spinothalamic tracts. The probable cross-sectional areas of these tracts are enlarged to provide adequate space. This general plan applies to *all* segmentally organized tracts whether ascending, descending, ipsilateral or contralateral. After Foerster 1936, with permission.

as a continuum structurally (as stated) and functionally. However, neurons of spinothalamic axons are diverse in distribution and modalities and simple segregations of sensory mediation in the spinothalamic system (or other ascending tracts) are not likely. But, functionally, neurons in the spinal laminae of spinothalamic origin provide some data; thus neurons in laminae I and V respond to cutaneous 'noxious' mechanical and thermal stimuli and some lamina V neurons to other cutaneous stimuli. Laminae VII and VIII are linked with muscular and articular receptors and some with cutaneous stimulation. The precise neuronal locations of origin of this tract are uncertain, though usually described as 'secondary neurons' in the dorsal grey column, receiving direct synapses from axons entering dorsal roots from primary sensory neurons in dorsal root ganglia. Cajal (1909) showed that axons of neurons in all grey columns (dorsal ventral and intermediate) *decussate* before ascending in the anterolateral funiculus. Investigators using Golgi techniques have claimed that they are concentrated in laminae IV–VII, especially lamina V, with contributions from pericornual neurons, superficial to the substantia gelatinosa (lamina I) and lamina VIII (Webster 1977). some details have been physiologically confirmed in cats and rats (Dilley et al 1968); electrical stimulation near the entry of the medial lemniscus and spinothalamic tracts into the thalamus, combined with intracellular recording of antidromic responses from spinal laminae, showed responding somata in laminae V and VI, providing some confirmation of spinothalamic origins. But the limited sampling inherent in the technique may have missed neurons in other laminae. Further, all spinothalamic fibres are not necessarily axons of 'secondary neurons'; one or more interneurons may be interposed between primary dorsal root afferents and spinothalamic neurons.

Evidence from human cordotomies suggests that most spinothalamic fibres decussate in the anterior white commissure, probably within or near their segment of origin. Though physiological studies (p. 944) suggest some separation of spinothalamic neurons by sensory *modalities* in the dorsal grey column, the arrangement of ascending fibres in these tracts has long been considered *somatotopic* (Nathan 1963, Morin et al 1951). Fibres crossing at any level join the medial aspect of those already crossed and both tracts are hence segmentally laminated (7.70), fibres from the lower segments, of greater total length, being most superficial. A slight spiral twist is also described, the superficial fibres becoming progressively more dorsal as they ascend. This continues through the medulla and pons to the thalamic nucleus ventralis posterior lateralis (p. 1002). However, their precise arrangement, whether somatotopic, dermatomic or otherwise, is uncertain. Mingled with the anterior spinothalamic are descending *reticulospinal fibres* (already noted) and ascending *spinoreticular fibres*. Spinothalamic fibres may send collaterals to brain-stem reticular nuclei but most of their afferents are now said to form separate spinoreticular paths, some probably polysynaptic. As in other ascending tracts, the spinal origins of spinothalamic tracts, or the associated interneurons, may be selectively inhibited by fibres from neurons in sensory and motor parts of the cerebral cortex and others in the anterior cerebellar lobe and brain-stem reticular formation; but spinal distribution and the termination of inhibitory fibres are uncertain (Carpenter et al 1963, Webster 1977). A small *spinovestibular tract*, mingled with vestibulospinal tracts, conveys exteroceptive and cutaneous information to vestibular nuclei. It may be confined to cervical levels; its degree of decussation is unknown but it may end in the lateral and descending vestibular nuclei. Its origins probably correspond to those of the spinocerebellar tracts.

3. Intersegmental Tracts

The remaining anterior funicular axons form an **anterior intersegmental tract**, partly decussated and probably with intermingled reticulospinal and descending autonomic fibres. The tract is continuous with the medial longitudinal fasciculus. Though all intersegmental or propriospinal fibres in the anterior funiculus are usually thus combined under one term, separate entities elsewhere in the cord have been described by classic neuroanatomists (Nathan & Smith 1959). Details of such fibres are considered with the dorsolateral tract (p. 936).

TRACTS IN THE LATERAL FUNICULUS

1. Descending tracts

(*a*) **The lateral corticospinal tract** descends through almost the whole spinal cord, progressively diminishing to end about the third or fourth sacral spinal segment. It occupies an oval area anterolateral to the posterior grey column and medial to the posterior spinocerebellar tract (7.69A,B); in lumbar and sacral regions, where the latter is absent, the lateral corticospinal reaches the surface. Both corticospinal tracts are motor but physiological evidence suggests other functions (pp. 944, 945). They together contain, on each side, about a million fibres of varying diameter, 70% myelinated; about 90% have a diameter of 1–4 μm, about 9% 5–10 μm, and less than 2% 11–22 μm. However, these figures, particularly those for small fibres, may need substantial revision with systematic quantitative electron microscopy. Many fibres are from neurons in frontal cortical area 4; fibres of 11–22 μm are believed, from cell and fibre counts, to be axons of giant pyramidal neurons of Betz (p. 1044). Some issue from other layers in area 4 but at least two-thirds of corticospinal fibres do not, some being from other frontal and parietal areas, especially 3, 1, 2 and 6. However, the origins of about 50% only can be thus explained (Lassek 1954). All fibres descend via the internal capsule, traverse the cerebral peduncle and pons to enter the medullary pyramid, in the caudal part of which a variable number (usually about two-thirds) decussate and turn caudally in the lateral funiculus as the *crossed lateral corticospinal tract*, the remainder continuing ipsilaterally as the *anterior corticospinal tract*. The lateral tract contains also some ipsilateral *uncrossed lateral corticospinal fibres* (Fulton & Sheenan 1935).

Corticospinal tracts, thus defined, are commonly dubbed the *pyramidal pathway*, a usage likely to persist. They certainly traverse the medullary pyramids (p. 951) but the expression

usually includes *corticobulbar* fibres diverging above this level to end in the motor nuclei of cranial nerves (p. 1049). But the chief objection to 'pyramidal' lies elsewhere: corticospinal tracts have a single distinction; they descend without interruption from the cerebral cortex to the spinal grey matter in which they contrast with the rubrospinal, vestibulospinal and other descending tracts, which have intermediate subcortical synapses in the deep cerebrum and brain stem and are collectively often labelled 'extrapyramidal'. The functional distinction between these so-called 'systems' is diminishing; clinical concepts misplaced upon them are dissolving. The subsequent revelation of a so-called reticular system (p. 988) has added to this confusion, since structurally and functionally it overlaps the 'extrapyramidal system', a concept probably obsolescent. Hence the term 'pyramidal' is better avoided.

Throughout the cerebrum and brain stem, except perhaps in the pons, somatotopy in these tracts is established, chiefly by clinical observations (7.70). Details are to be found in the appropriate sections. Whether the arrangement is identical in medullary pyramids and the spinal cord is uncertain (Foerster 1936, Barnard & Woolsey 1956). In the cord longer fibres are said to be the most superficial, the shorter ones internal. Most corticospinal fibres, in both anterior and lateral tracts, probably synapse with *interneurons* in the *dorsal* grey column's base, which spread ventrally through the intermediate zone to the ventral grey column, laminae IV–VII (Hoff & Hoff 1934, Chambers & Liu 1957, Nyberg-Hansen 1969 and p. 939). In experiments, mostly in cats, no corticospinal fibres reach the spinal motor neurons directly; but some monosynaptic connections occur in monkeys (Liu & Chambers 1964), suggesting similar human arrangements, perhaps in greater numbers. But it seems certain that most corticospinal fibres, exciting neurons which innervate skeletal muscle, do so through chains of interneurons. Physiologically this influence is facilitatory for flexors and inhibitory for extensors, the reverse of the effects of the lateral vestibulospinal tracts (p. 932). (It is imperative to note that here, and elsewhere, such functional allusions assume, without being stated, that the influences flow from an *increased* flux of potentials in fibres of the tract. With a net reduction, of course, the reverse obtains.) The α and γ motor neurons share these corticospinal influences; fibres from the precentral motor cortex may end ventral to those from the postcentral sensory cortex (Scheibel & Scheibel 1966) and many (perhaps a quarter) terminate ipsilaterally. The effects of corticospinal activity on sensory transmission are discussed elsewhere (pp. 944, 945). Modifications of sensory inputs were discussed in extenso by Schmidt (1973), Gordon (1973), Tone (1973) and McCoskey & Torda (1975). Phillips & Porter (1977) have surveyed the evolutionary status, neuroanatomy, electrophysiology and functional roles of corticospinal neurons.

Ascending spinopontine and *spinocortical fibres* have been described in both anterior and lateral corticospinal tracts in cats (Walberg & Brodal 1953) and in man (Nathan & Smith 1955), derived from all spinal levels but especially the cervical and perhaps concerned in the transmission of cutaneous information (Brodal & Walberg 1952). (These further confuse the traditional concepts of 'pyramidal' and 'extrapyramidal' systems.)

(*b*) **The rubrospinal tract** contains fibres of variable diameter descending from large and small neurons in the red nucleus; caudal to this they decussate and form in the lateral funiculus a compact band ventral to the lateral corticospinal tract (7.68, 69A,B). Fibres may also arise from other tegmental neurons, caudal to the nucleus, forming a *tegmentospinal tract* near the ventral border of the rubrospinal (Woodburne et al 1946). First established in cats, in which it has been chiefly studied, a rubrospinal tract also appears in macaque monkeys, in both species descending to lumbosacral levels. Axons of smaller neurons reach the most caudal segments: this is important to note, since an erroneous view, once current, considered the largest neurons (p. 984) to be the sources of the longest fibres; since large neurons are few in human red nuclei, a persuasion developed that the human tract is negligible, an opinion aided by a dearth of clinical information (Nathan & Smith 1955). Since it is well attested in monkeys and the chimpanzee, it is likely to exist in mankind. The details stated here apply to other mammals; the human condition must await clarification.

At their origin in the red nucleus, rubrospinal fibres show, in cats (Pompeiano & Brodal 1957), a dorsoventral, somatotopic lamination, the shortest fibres descending from the most dorsal cells to cervical levels to influence, presumably, the muscles of the neck and upper limbs, probably through interneurons. Axons of most ventral rubral neurons are considered to be concerned with the lower limbs. Some leave the tract to reach the motor neurons of cranial nerves, probably through interneurons; some such *rubrobulbar* axons may end in the ipsilateral inferior olivary nucleus (Walberg et al 1958).

Distribution of the rubrospinal terminals resembles those of the corticospinal tracts, being largely to laminae V–VII but they do not extend so far ventrally, none reaching the motor neurons directly. This terminal overlap of two tracts suggests close interaction on the motor neurons through a common interneuronal pool. Note that afferents to the red nucleus come not only from the cerebellum but also the cerebral cortex, including area 4 and other corticospinal origins (p. 984) (also many other subcortical regions, p. 984). The corticorubral projection is somatotopic in cats (Mabuchi & Kusama 1966) and primates (Kupyers & Lawrence 1967), like the corticospinal arrangements. Both tracts appear to exercise similar effects on the spinal motor neurons, such as facilitation of those for the flexor musculature; thus it is all the more undesirable to contrast them, physiologically or clinically, as 'pyramidal' or 'extrapyramidal'. However, a revised outlook upon their functions *in man* would be premature, despite suggestive data from other primates.

Neurons of the *tegmentospinal fibres*, noted above, probably synapse with the terminals of *tectotegmental fibres* from both superior colliculi; some direct tectospinal fibres from both may accompany the tegmentospinal fibres. This descending complex (near the rubrospinal tracts) is accordingly termed the *lateral tectotegmentospinal tract*.

(*c*) **The lateral reticulospinal tract**, usually described as medial to both rubro- and corticospinal fibres, is in fact dispersed among the adjacent tracts; in some mammals the reticulospinal fibres descend *lateral* to the rubro- and corticospinal fibres (7.73) and such paths are likely to exist in the human spinal cord, but evidence of this is sparse. The lateral tract differs, anatomically and physiologically, from the medial (p. 932); its axons are largely from large neurons in the medullary reticular formation (*nucleus reticularis gigantocellularis*), some from smaller neurons, explaining the varying diameters of its fibres. Unlike the pontine reticulospinal fibres in the anterior funiculus, the lateral tract is largely crossed but partly ipsilateral. *Each half* of the medullary reticular formation hence exerts bilateral spinal effects. Like the medial tract the lateral's terminals synapse with interneurons in the intermediate and medial zones of the anterior grey columns but are more dorsal (chiefly lamina VII), though some may reach the motor neurons (lamina IX). These details apply to cats (Nyberg-Hansen 1965); reticulospinal fibres were also found to reach all levels, contrary to earlier views (Torvik & Brodal 1957). The medullary origin of the lateral tract approximates to the brain-stem 'inhibitory area', contrasting with the facilitatory effects of the medial tract. In addition to the motor effects of both on α and γ neurons, reticulospinal axons may also modify afferent transmission (7.23 and pp. 988–996).

(*d*) **Descending autonomic fibres**, for ipsi- and contralateral connections between brain-stem visceral nuclei and spinal preganglionic neurons, are amply attested by physiological evidence; but their positions and terminations are uncertain. That they are largely in the lateral funiculus is agreed; but some may descend in the anterior funiculus. Failure to define any spinal grouping of degenerating fibres, as a result of hypothalamic or brain-stem lesions, implies that the descending autonomic connections are diffusely dispersed. Various experimenters have ascribed them to the lateral corticospinal, reticulospinal and intersegmental tracts, some to a superficial position in the lateral funiculus (Enoch & Kerr 1967). They are considered to be mostly fibres of small diameter, probably in polysynaptic chains. Since attempts to interrupt the reticulospinal paths have disturbed visceral functions, such as vasomotor and sudomotor control (Johnson et al 1952), some fibres may be autonomic. Vasomotor effects follow stimulation of the precentral cortex; hence some

corticospinal fibres may be autonomic. The evidence, much of it negative, suggests that descending autonomic fibres *are* dispersed in the anterolateral spinal region, in which lesions may disturb visceral control.

(*e*) **The olivospinal tract** is uniformly described as a small triangular area in transverse sections, external to the most lateral fibres of ventral spinal nerve roots, and said to be confined to the upper cervical segments and to contain fibres ending in the ventral grey column, some ascending as a *spino-olivary tract* (Jansen & Brodal 1954, p. 936). The tract was first identified in the human spinal cord, but no experimental evidence connects it with the inferior olivary nucleus (Brodal 1969), suggesting the term *bulbospinal* which merely displaces the uncertainty elsewhere.

2. Ascending Tracts

(*a*) **The posterior spinocerebellar tract**, a flat, posterior band lying peripherally in the lateral funiculus, adjoins medially the lateral corticospinal tract and dorsally the dorsolateral tract. It begins about level with the attachments of the second or third lumbar spinal nerves, enlarges as it ascends and enters the inferior cerebellar peduncle. Its fibres are from the ipsilateral thoracic nucleus, which receives *afferent* impulses from: (i) many long ascending fibres in the posterior funiculus with collaterals synapsing with neurons in this nucleus; and (ii) terminals of intermediate ascending fibres of the posterior column, especially in thoracic segments. Which source preponderates is uncertain.

(*b*) **The anterior spinocerebellar tract,** in transverse section, is a crescentic area peripherally placed in the lateral funiculus, anterior to the posterior tract. Its precise origin is uncertain but it is usually said to be large neurons in the posterior grey column, which are thus secondary in the spinocerebellar path. The primary neurons are probably like those of the posterior tract (vide supra) but ascending axons of these secondary neurons mostly decussate, few remaining ipsilateral (Jansen & Brodal 1954). Experiment indicates that such 'secondary neurons' are dorsolateral in the *ventral* grey column (Ha & Liu 1968). The tract starts in the upper lumbar region and reaches a high pontine level, whence it descends dorsally into the superior cerebellar peduncle.

The spinocerebellar tracts are laminated; fibres carrying impulses from the lower limbs are the most superficial (Yoss 1952/3, Smith 1957). They convey exteroceptive and proprioceptive impulses from dermal and locomotor receptors, essential for synergic control during voluntary movements. The thoracic nucleus diminishes upwards (p. 927) and does not extend above the first thoracic or last cervical segments, suggesting that the posterior spinocerebellar tracts are concerned chiefly with the trunk and lower limbs. Evidence shows that proprioceptive impulses from the upper limbs travel by the posterior external arcuate fibres, originating in the accessory cuneate nucleus in the medulla oblongata (p. 953) as a *cuneocerebellar tract*. In addition to these classic spinocerebellar routes, at least two indirect paths, interrupted in the inferior olivary and lateral medullary reticular nuclei, may project to the cerebellum and receive afferents respectively from the dorsal funiculi and spinothalamic tracts (Brodal 1969).

Spinocerebellar are long established proprioceptive tracts. Physiological evidence shows that the posterior also conveys impulses from touch and pressure endings. Both tracts display a marked somatotopic cerebellar termination in experimental animals, including monkeys, and in man (p. 975). The posterior ends in the cerebellar cortex concerned with the hind limb, its associated cuneocerebellar tract reaching a fore-limb area. Anterior spinocerebellar fibres end only in the hind-limb cortex; but physiological evidence (Oscarsson & Uddenberg 1964, Oscarsson 1965) shows that fibres in the *anterior* tract may serve tendon receptors in *fore-limb* muscles; these form a *rostral spinocerebellar tract*. A spinocerebellar projection for proprioceptors in the neck muscles has been ascribed to the *nucleus cervicalis*; chiefly identified in young mammals, but not in the human spinal cord, it exists at high cervical levels. According to Cummings & Petras (1977) cerebellar ablations in newborn dogs produce a retrograde response in this nucleus, especially the *nucleus cervicalis centralis*, but not in the *nucleus cervicalis lateralis*, as claimed by Rexed & Brodal (1951). Petras investigated the spinal origins of spinocerebellar tracts in monkeys by retrograde degeneration and retrograde transport of horseradish peroxidase, with similar results.

Some neurons contributing to spinocerebellar tracts have been subjected to intracellular recording. Some receive only one type of exteroceptive or proprioceptive afferent, other neurons show the convergence and interaction of different afferents. Parameters of transmission are modifed by activity in the descending brainstem tracts.

(*c*) **The lateral spinothalamic tract**, medial to the anterior spinocerebellar in the lateral funiculus, is continuous with the anterior tract (p. 932). As in the latter (in the anterior white column, 7.69), the simple zonal, 'modality-specific' pattern still widely ascribed to both tracts contrasts with the variation in physiological responses of cells investigated in laminae IV–III, some probably contributing spinothalamic fibres. Variations include marked differences (pp. 944-945) in the receptive fields of different neurons and in the degree of convergence of different primary afferent fibres on one interneuron. At least some spinothalamic fibres may transmit complex patterns; that they are all modality-specific is a simplification. Nevertheless, somatotopic lamination in the anterior is also evident in the lateral tract (an arrangement of surgical importance) and maintained throughout the medulla oblongata and pons. In the midbrain, fibres from the lower limbs spread dorsally and here it is claimed possible to divide pain and temperature fibres from the upper limb and trunk without injury to those from the lower (Earl Walker 1942).

Though the lateral spinothalamic tract is accepted as a major path serving somatic pain and thermal sensibilities, an alternative route is suggested in a series of intersegmental fibres from neurons in the spinal grey matter (p. 936). The spinotectal tract has also been regarded (Earl Walker 1943) as an alternative for pain and thermal sensibility.

Brief reference must be made to the *spinocervical tract* and an associated *spinocervico-thalamic 'system'* of connections. The *lateral cervical nucleus*, small in man, is in the lateral funiculus lateral to the dorsal grey column in the first two cervical segments (Truex et al 1970). The tract is derived from neurons in the column, particularly laminae IV–VI, among those of the spinocerebellar tracts. It ascends from lumbosacral levels. Its projection from the lateral cervical nucleus was first said to be cerebellar but more recent anatomical and physiological data indicate that its axons ascend with the medial lemniscus to the nucleus ventralis posterior lateralis of the contralateral thalamus, mediating light tactile and pressure sensation (perhaps also joint sensibility); hence they are to be associated with the spinothalamic tracts (Morin & Catalano 1955, Ha & Liu 1966). Some of its neurons also respond to noxious stimuli (Brown & Gordon 1977). Gwyn & Waldron (1968) have described a column of similar neurons in rats throughout the spinal cord.

Little is known of routes of impulses arising in painful pathological conditions of viscera. Primary axons travel in splanchnic nerves and almost certainly enter the spinal cord via *white rami communicantes* and *dorsal spinal roots*. Whatever their subsequent path, all are interrupted by the bilateral division of the lateral funiculi in the first thoracic segment (Hyndman & Wolkin 1943), suggesting that they are in the lateral spinothalamic tract.

Since fibres of the lateral spinothalamic tract cross at once, lesions affecting the commissural regions, e.g. *syringomyelia*, produce bilateral loss of pain and thermal sensibilities in areas represented in the diseased segments.

Note that the spinal lemniscus, usually defined as the superior continuation of both spinothalamic tracts, is now more accurately described as continuous only with the lateral tract.

(*d*) **The spinotectal tract** is medial to the anterior spinocerebellar and anterior to the lateral spinothalamic, the three remaining intimately related throughout their ascent in the cord and brain stem. Its fibres start deep in the contralateral grey matter and soon cross to the opposite lateral funiculus. Most easily identified at cervical levels, its fibres ascend to the midbrain to end in the superior colliculus, providing routes for spinovisual reflexes, the superior colliculi being the reflex stations in the visual path but not concerned with transmission to the cerebral cortex. Spinotectal impulses evoke movement of the head and

eyes towards the source of stimulation. Some spinotectal fibres reach the ventral thalamus and may mediate cutaneous pain and perhaps other modalities.

(*e*) **The dorsolateral tract** is a small strand of fine myelinated and non-myelinated fibres between the apex of the posterior grey column and the surface of the spinal cord, close to the dorsal roots; it is formed in part by axons from the lateral bundles of dorsal roots, which bifurcate into ascending and descending branches. The former ascend one or two segments in the tract, giving collaterals to and terminating around neurons in the posterior grey column (pp. 941, 944). Though the tract exists at all levels, no fibres travel more than a few segments; it is hence a *fasciculus*, a term all the more desirable in view of experimental confirmation (Poirier & Bertrand 1955, Earle 1952, Szentágothai 1964) of an old suggestion (Flechsig 1876) that it contains many propriospinal fibres, the contribution from dorsal root fibres being no more than 25% at any level (Earle 1952). (Flechsig's suggestion considerably predated Lissauer's description in 1886.) Many of its fibres are from small neurons of the substantia gelatinosa (laminae II and III, p. 939).

(*f*) **Spinoreticular fibres**, described in the feline lateral funiculus (Brodal 1949), intermingle with spinothalamic fibres. Few of these ascending fibres cross in the cord but appear to project bilaterally to brain-stem reticular nuclei at all levels, particularly in the pons and medulla. The existence of such connections is claimed in the human brain stem (Mehler 1962).

(*g*) **The spino-olivary tract**, described as arising from neurons in the deeper laminae of spinal grey matter, decussates, then ascends superficially at the junction of the anterior and lateral funiculi and ends in the 'spinal' regions of dorsal and medial accessory olivary nuclei (Mizuno 1966). The tract probably mediates cutaneous and proprioceptive receptors and those in the muscle and tendon (Grant & Oscarsson 1966). A functionally similar route, *the dorsal spino-olivary*, has been deduced from physiological data as ascending with the dorsal white funiculi, relaying in dorsal column nuclei and projecting to accessory olivary nuclei (Oscarsson 1967). Interest in such paths has been augmented by increasing indications of olivocerebellar climbing fibres with specific localized excitatory effects on the Purkinje cells (pp. 965, 968).

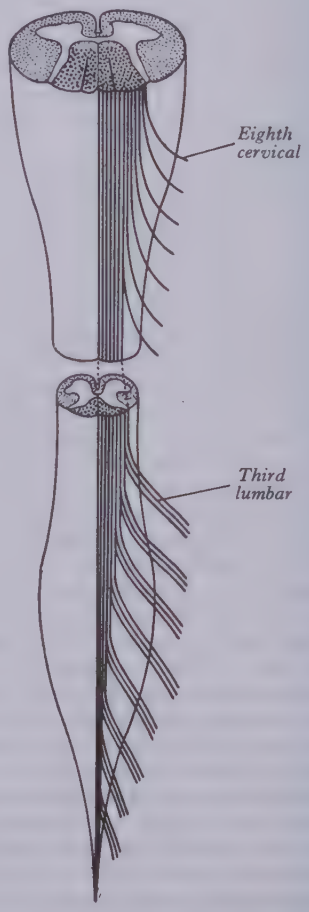
3. Intersegmental Tracts

The lateral intersegmental tract fills the rest of the lateral funiculus, separated ventrally from the *anterior* intersegmental by emerging fibres of ventral spinal nerve roots. It contains intersegmental fibres, some crossed, and possibly reticulospinal and descending autonomic fibres.

TRACTS IN THE POSTERIOR FUNICULUS

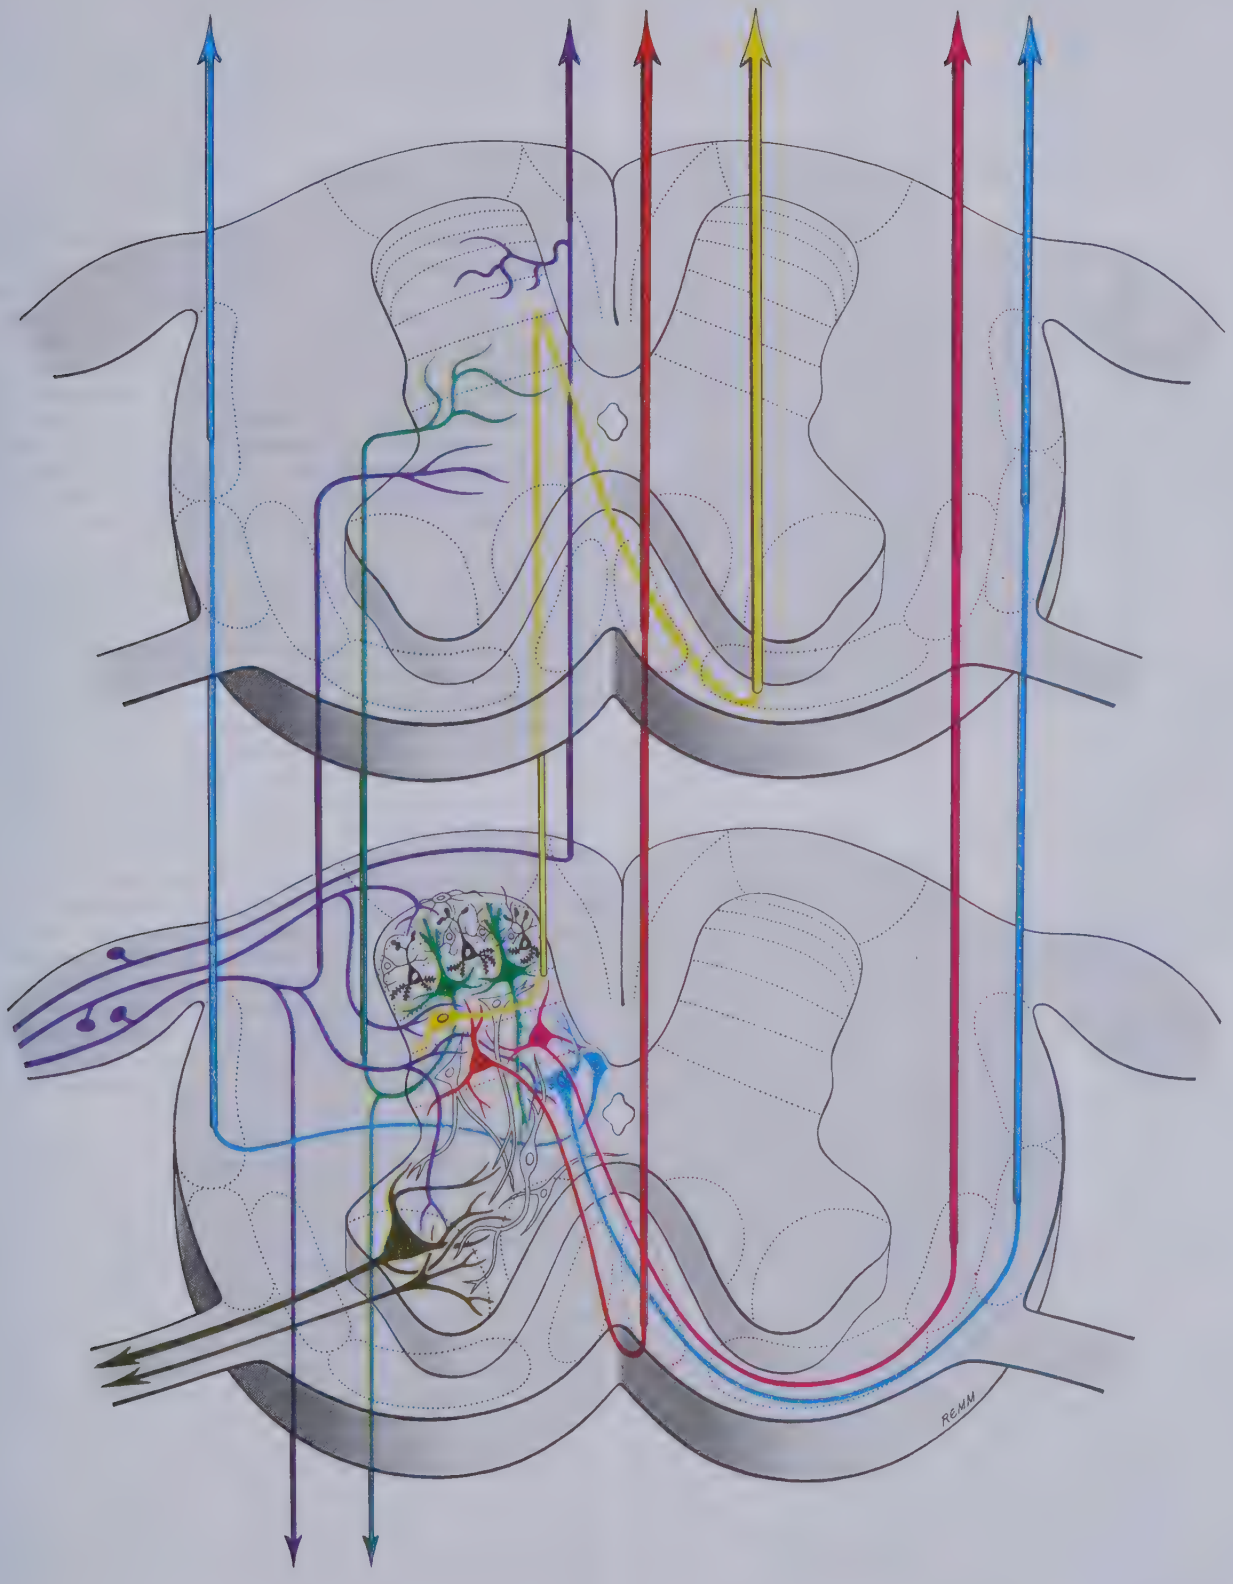
1. Ascending Tracts

This funiculus contains the large fasciculi gracilis and cuneatus, separated by the postero-intermediate septum. The two dorsal funiculi connect dorsal root ganglia *and* posterior grey columns to the gracile and cuneate nuclei; but many fibres do not reach the nuclei and many are *propriospinal*. Some axons come by other routes.



The fasciculus gracilis, commencing at the caudal end of the spinal cord, contains mainly long ascending branches of axons of medially placed bundles of fibres of dorsal spinal roots; but a considerable fraction (15% according to Rustioni & Dekker 1974) are axons of *secondary* neurons in the ipsilateral dorsal grey column (Laminae III and IV). All ascend the posterior funiculus, augmented by each dorsal root. Fibres entering in coccygeal and lower sacral regions are pushed medially by successive additions. The fasciculus gracilis, derived from the lower thoracic, lumbar, sacral and coccygeal segments, is medial to the fasciculus cuneatus, in the posterior funiculus of the upper spinal cord (7.70, 71).

The fasciculus cuneatus, commencing at mid-thoracic level and derived from the upper thoracic and cervical dorsal spinal roots, is lateral to the fasciculus gracilis. Some of its axons are secondary, from neurons in laminae III and IV of the ipsilateral dorsal grey column.

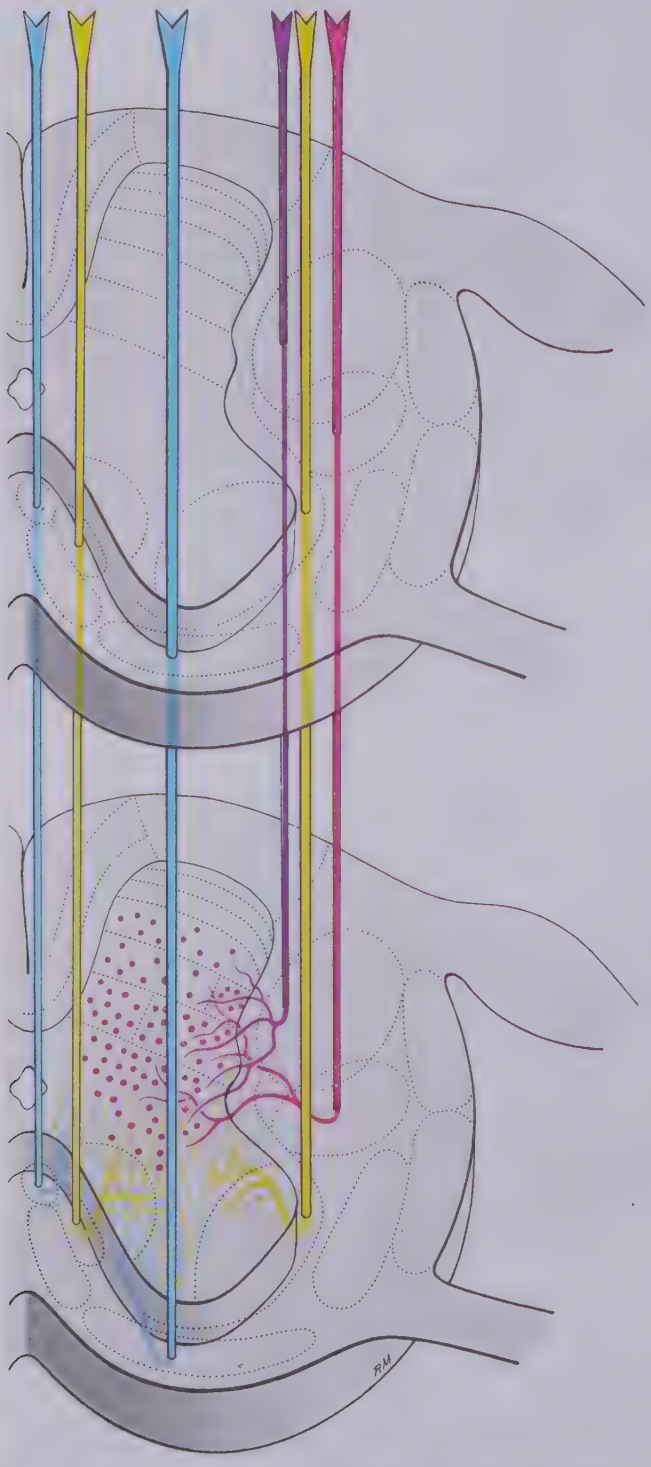


Both fasciculi are myelinated, the cuneate fibres being larger probably because proprioceptive fibres (of great diameter) remain in the cuneate but leave the gracile fasciculus at lumbar levels (vide infra). Both contain central processes of neurons in spinal ganglia, i.e. *primary afferent* neurons, some of which ascend *without synapse* or *decussation* to the medulla oblongata, ending in *gracile* and *cuneate nuclei*, in which secondary neurons begin; most of their secondary fibres sweep ventrally round the central grey matter (7.89) as *internal arcuate fibres* and part of the *lemniscal decussation*. Thereafter, as *medial lemnisci*, they ascend on each side to the ventral thalamic nucleus (p. 1002) and are relayed there to the post-central gyrus (areas 3, 1 and 2). Some secondary neurons form *posterior external arcuate fibres* (p. 953), entering the cerebellum. Presynaptic dendrites, making dendro-dendritic connections, have been described in the cuneate nucleus of macaques (Wen et al 1977) but their origin remains obscure.

These two tracts, almost filling the posterior funiculus, mediate proprioception, including vibration, pressure and some exteroceptive *tactile* information, fibres for which all reach the medulla oblongata in their ipsilateral posterior funiculi, with fibres concerned with posture and movement, active and passive. In the cord some fibres ascending in the dorsal white columns send collaterals into the dorsal grey column.

The somatotopic lamination of gracile and cuneate tracts is more intricate than the segmental pattern described above; fibres are also segregated by modality: those from hair receptors being the most superficial, those from tactile and vibrational receptors in the deeper layers (Uddenberg 1968). Experiments show that this pattern reaches the nuclei gracilis and cuneatus; these contain numerous interneurons, unit recording from which indicates a high specificity in fibres of both tracts. Stimuli just outside the

7.71 The lamination of the fibres in the posterior funiculus. The spinal cord is viewed from the dorsal aspect. The drawing shows that the posterior funiculus is formed (in part) by the long ascending fibres of the dorsal roots and that the sacral fibres adjoin the median plane, the lumbar to their lateral side, the thoracic more laterally and the cervical most lateral of all. For dorsal fibres arising elsewhere see p. 935.



7.72A Simplified scheme of some of the major ascending tract systems of the spinal cord and some features of grey matter organization. Within the grey matter the dotted lines show the laminar pattern; within the white matter they are an approximate guide to the topography of the tracts. Attempts have been made to indicate in a simplified manner the overlapping of dendritic fields described in the text. An alpha and a gamma motor neuron (grey) are included, together with some of the structural features of the substantia gelatinosa which are described and illustrated more fully in 7.75. Some of the small substantia gelatinosa neurons are uncoloured, as are some interneurons in the deeper laminae. The larger substantia gelatinosa neurons are solid black. Large lamina IV cells and associated ascending and descending intersegmental fibres are green. Primary sensory afferent fibres, including a fibre in the fasciculus gracilis, are purple. Spinotectal fibre—orange; anterior spinothalamic fibre—yellow; lateral spinothalamic fibre—magenta; and dorsal and ventral spinocerebellar fibres—blue. Compare with 7.73.

receptive field of a single unit may inhibit. Fibres from pre- and post-central cerebral cortex, descending in corticospinal projections, may facilitate or inhibit gracile and cuneate interneurons. Similar projections originate in brain-stem reticular nuclei (pp. 988-996). Such effects probably contribute to discrimination in the dorsal funicular paths; these tracts, like others, are not simple sensory routes (p. 944).

2. Descending Tracts

Confusingly numerous small descending tracts have been described in the dorsal funiculi, chiefly in the late nineteenth century, in accounts based on pathological appearances in human spinal cords; e.g. in cervical and upper thoracic levels, medial in the cuneate tract, is the *comma tract* (Schultze), *semilunar tract* or, more recently, *interfascicular fasciculus*. In the lower thoracic segments a superficial strand, almost certainly the upper end of the *septomarginal tract*, has been ascribed to a deeper site near the posterior median septum. The so-called '*oval field of Flechsig*' and '*triangular field of Gombault and Philippe*' are also different levels of the septomarginal tract, which alters in shape and position remarkably as it descends from the lower thoracic segments. Continuity of the interfascicular fasciculus and septomarginal tract seems likely, but remains uncertain. The former is said to consist only of descending branches of entering dorsal root fibres; the latter may also contain many intersegmental fibres. Almost all reports on these descending dorsal column fibres are clinical (Nathan & Smith 1959).

7.72B A simplified scheme of some of the major descending tract systems of the spinal cord including their overlapping zones of termination in the grey matter. The significance of the dotted lines is the same as for 7.72A. Corticospinal tract—mauve; rubrospinal tract—magenta; reticulospinal tracts—yellow; vestibulospinal tracts—blue.

3. Intersegmental Tracts

Deepest in the posterior funiculus is a small **posterior intersegmental tract**, crescentic in section and just posterior to the grey commissure (7.68, 69A,B). Most obvious in the lumbar region, it can be traced to thoracic and cervical levels. Its fibres, from neurons in the posterior grey column, divide into ascending and descending branches which re-enter and ramify in grey matter.

Further Aspects of Spinal Organization

The preceding introduction to organization of the spinal cord must now be expanded and partly modified in the light of re-investigation by old and new techniques, both neuroanatomical and neurophysiological (Eccles & Schadé 1964a, b, Lissák 1967, Ralston 1974). These intensive researches include comparisons in many vertebrates, alternative plans of spinal grey matter based on cytoarchitectonics and precise analyses of dendritic and axonal arborizations by modified Golgi techniques. Newer tracing techniques have also augmented our knowledge of the terminations of dorsal root afferents and collaterals, and of descending supraspinal projections. Minute focal lesions have been placed to unravel the intricacies of spinal cord circuitry, while light microscopial techniques have been improved by quantification and detailed ultrastructural studies of synapses. Distribution of putative transmitters has also shown much progress.

This renewed neuroanatomical attack, combined with refined 'unit' and other recording physiological techniques, has proved most stimulating (in both directions, as is apparent in the following brief account).

LAMINAR ARCHITECTURE

The *general outline* of spinal grey regions, as seen in transverse section, has long provided a useful but arbitrary basis for morphology and experiment. Dorsal, lateral and ventral columns and arbitrary subdivisions have been recognized (p. 926) and named. Such entities as the substantia gelatinosa, thoracic nucleus and subgroups of anterior grey column neurons have been named, with a terminology which, if arbitrary, is still used. Much basic work has been carried out within this topographical scheme but increasing analysis, structural and functional, reveals a lack of precision, prompting attempts to re-describe cordal structure (Rexed 1952, 1954, 1964). The currently adopted scheme stems initially from studies in thick and thin sections, stained for neuronal somata in feline spinal cords, neonatal, young and adult. Based on neuronal size, shape, cytological features and density in different regions, nine *laminae* have been distinguished, arrayed more or less parallel with the dorsal and ventral limits of the grey matter, at all levels, with a distinctive pericanalicular region. These laminae, as they appear in the transverse section of a fifth lumbar segment, are shown in 7.74. General confirmation of the laminar pattern in *human* material has been provided by Schoenen (1973). Briefly the structure of laminae is as follows:

Lamina I, a very thin layer with an ill-defined boundary, adjoins the white matter (which outlying neurons invade) and has a reticular appearance due to bundles of coarse and fine nerve fibres

intermingling in many directions. It contains small, intermediate and large neuronal somata, many fusiform. Alternative names are *lamina marginalis* or *layer of Waldeyer* (who recognized a similar zone in 1888).

Lamina II contains densely arrayed small neurons crossed, especially medially, by numerous bundles of fibres from the dorsal funiculus. An outer (dorsal) zone, darkly stained due to its high density of the smallest somata, contrasts with an inner (ventral) pale zone.

Lamina III consists of somata mostly larger, more variable and less closely arrayed than those in lamina II.

Lamina IV, a thicker layer, is a loosely packed, heterogeneous zone permeated by fibres. Neuronal somata vary much in size and shape, from small and round, through intermediate triangular, to very large stellar types.

Laminae I–IV correspond to the dorsal column's *head*. Lamina II (including part or all of lamina III) corresponds to the *substantia gelatinosa*; the ill-defined *nucleus proprius* of the dorsal grey column corresponds partly to laminae III and IV.

Lamina V, a thick layer including the dorsal column's *neck*, is divisible into a lateral third and medial two-thirds. Both have a mixed population but the former contains many prominent well-stained somata interlaced by numerous bundles of transverse, dorsoventral and longitudinal fibres: hence the term 'formatio reticularis' for this region, particularly prominent at cervical levels and recognized for over a century (Deiters 1865). (The term is now used more widely, pp. 988-996.)

Lamina VI is most prominent in the limb enlargements, particularly in young animals; it has a medial third of small densely packed neurons and a lateral two-thirds containing larger, more loosely packed, triangular or stellate somata. The medial hence stains more heavily, in contrast to lamina V, where the converse applies. Lamina VI corresponds approximately to the *base* of the dorsal column.

Laminae VII–IX show a variety of complex forms in limb enlargements (7.74A); to assist explanation, the simpler arrangement at thoracic levels is included for comparison (7.74B).

Lamina VII includes much of the intermediate grey column. It contains prominent neurons of the *thoracic nucleus* and *intermediomedial* and *intermediolateral columns* at their spinal levels (p. 927). Remaining areas (between these columns and, in limb enlargements, between lamina VIII and groups of IX) contain a uniform array of medium-sized triangular or stellate somata.

Lamina VIII spans the base of the thoracic ventral column but is restricted in limb enlargements to its medial aspect. It contains a mixture of somata.

Lamina IX is a complex array of columns (p. 927) including very large somata of α motor neurons and numerous smaller ones. Smaller somata include motor neurons with small-diameter efferent fibres (γ efferents) for muscle spindles and numerous interneurons, some perhaps being inhibitory Renshaw cells (vide infra). The location of γ motor neurons was long in doubt but studies of the retrograde changes following peripheral trauma (Nyberg-Hansen 1965) and intracellular recording (Eccles et al 1960) show them to be dispersed among α neurons in the motor columns. The sites and features of Renshaw cells remain uncertain. Intracellular recordings indicate inhibitory interneurons in the ventral extension of lamina VII, insinuated between VIII and IX (Willis & Willis 1966). Golgi staining in this region (Scheibel & Scheibel 1966) has not revealed typical Golgi type II neurons, long assumed to be the basis of 'Renshaw loop' inhibition. Nevertheless, Szentágothai (1967) considers that neurons with longer axons are not incompatible with inhibitory function and that the extension of lamina VII receives most initial collateral branches from axons of α motor neurons (assumed to synapse with Renshaw cells).

Lamina X surrounds the central canal, including the *dorsal* and *ventral grey commissures* and the *substantia gelatinosa centralis*.

FURTHER ASPECTS OF SPINAL LAMINAR ARCHITECTURE

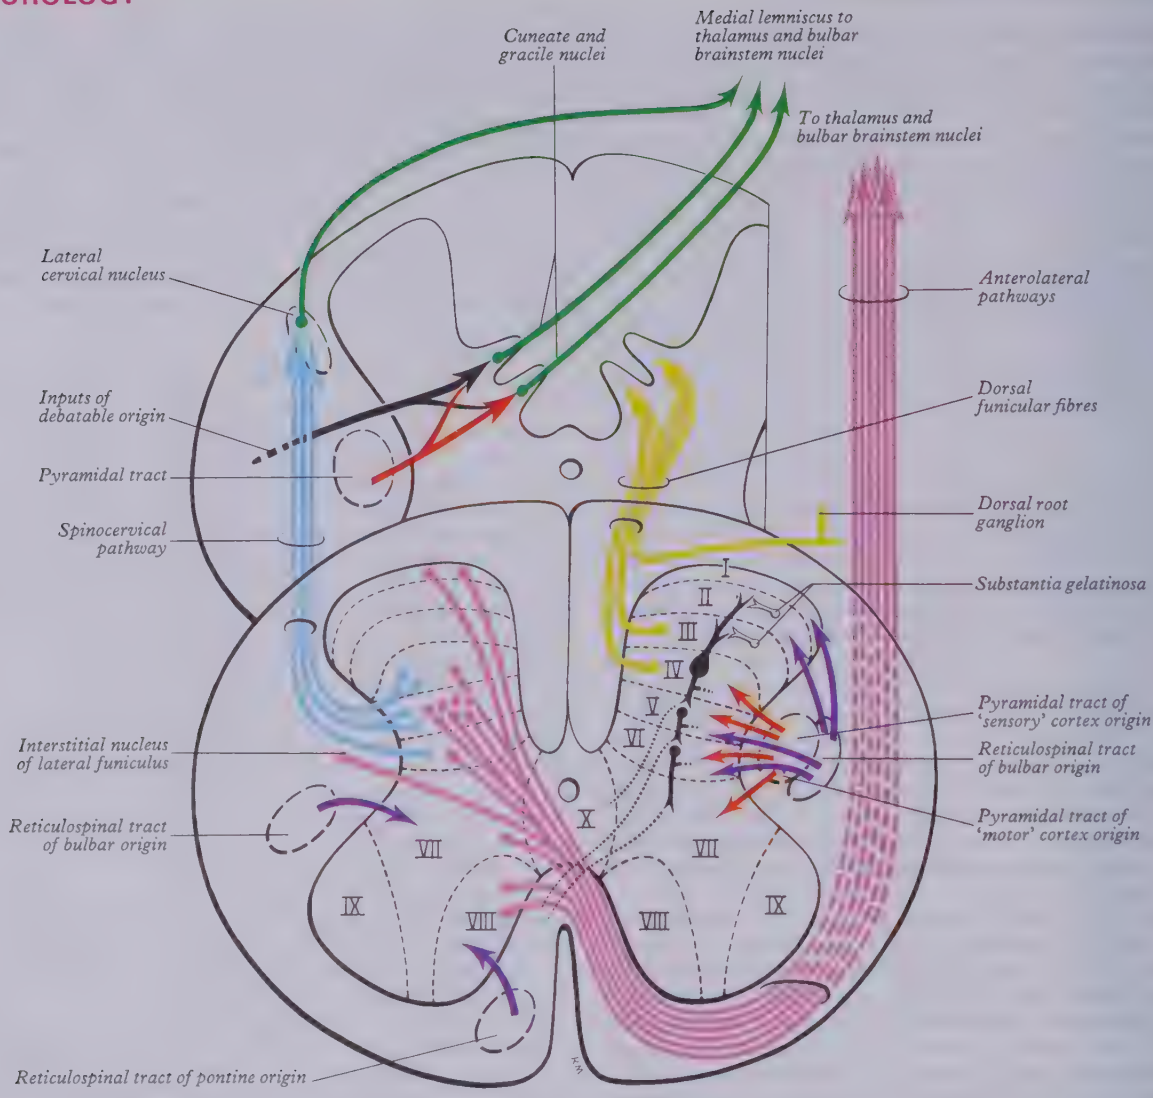
The preceding description outlines a new scheme of topography; further details will be found in the original papers quoted. (The scheme was originally applied only to feline spinal cords, with limited confirmation in mankind (Schoenen 1973). Similar laminar organization is *expected* to apply to the spinal cords of *all* higher mammals (Rexed 1964). The originator proposed the following tentative functional analysis (though some conclusions have been revised, vide infra).

Laminae I–IV are the main receiving areas for cutaneous primary afferent terminals and collateral branches (vide infra). From this region start many complex polysynaptic reflex paths, ipsilateral and contralateral, intrasegmental and intersegmental; and from it many long ascending tracts to higher levels are considered to arise (but vide infra).

Laminae V and VI receive most of the terminals of proprioceptive primary afferents and profuse corticospinal projections from the motor and sensory cortex and subcortical levels, suggesting intimate involvement in the regulation of movement.

Lamina VII (lateral part) has extensive ascending and descending connections with the midbrain and cerebellum (via the spinocerebellar, spinotectal, spinoreticular, tectospinal, reticulospinal and rubrospinal tracts) and is hence involved in the regulation of posture and movement. Its medial part has numerous propriospinal reflex connections with the adjacent grey matter and segments concerned both with movement and autonomic functions (p. 1011). Its ventral extension may contain inhibitory interneurons (p. 865, Renshaw 1941, 1946).

Lamina VIII, a mass of propriospinal interneurons, receives terminals from the adjacent laminae, many commissural terminals from the contralateral lamina VIII and descending connections from the interstitiospinal, reticulospinal and vestibulospinal tracts and the medial longitudinal fasciculus. Their axons influence motor neurons of both sides, perhaps directly but more probably by excitation of small neurons supplying γ-efferent fibres to muscle spindles.



Lamina IX contains α and γ motor neurons and many interneurons. Large α *motor neurons* supply motor end-plates of extrafusal muscle fibres in the *motor units* of striated muscle (p. 556); they vary in size. Recording techniques have demonstrated *tonic* and *phasic* α neurons (Granit et al 1956). The former, with a lower rate of firing and lower conduction velocity, are assumed to be smaller. Attempts to correlate these varieties with structural and functional types of striated muscle fibre, e.g. *slow* and *fast* (p. 555) have been frustrated by lack of histological differentiation. Some large motor neurons (β *motor neurons*) have been held to supply extrafusal *and* intrafusal fibres.

There are also several functionally distinct types of γ *motor neuron*, fusimotor fibres of which innervate the intrafusal fibres in muscle spindles. The 'static' and 'dynamic' responses of muscle spindles (p. 556) have separate controls mediated by *static* and *dynamic fusimotor fibres* distributed variously to *nuclear chain* and *bag* fibres; but it is impossible histologically to differentiate types of γ motor neuron somata, though *plate* and *trail endings* have been recognized and two varieties of γ-efferent myelinated nerve fibre (γ *1* and γ *2*) in nerves to muscle (Boyd 1962). Correlation of these varieties is disputed (Barker 1974).

GEOMETRY OF SPINAL NEURONS

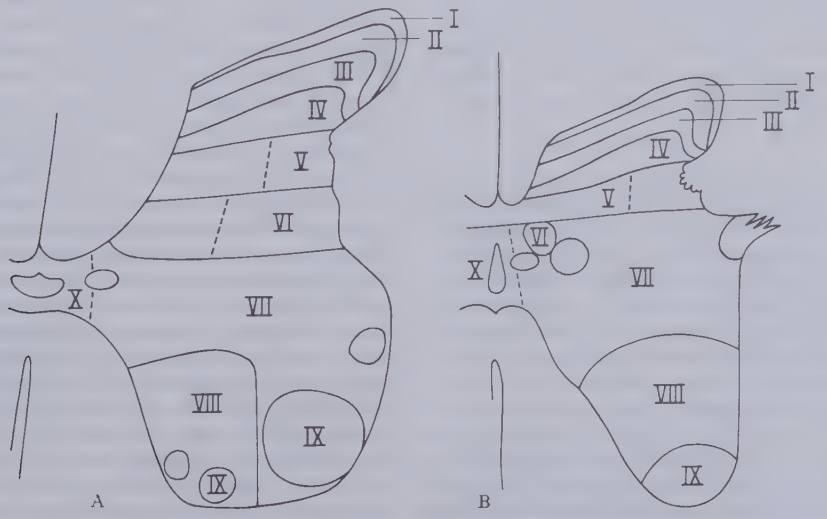
Since Cajal's classic investigations (1908), foreshadowing so much and still a primary source of information, increasingly precise data on spinal neurons have accumulated: on sizes, shapes, distribution, packing density and the cytological features of neuronal *somata*, as shown by the Nissl technique or its modifications. However, such techniques are limited, requiring complementary techniques permitting analyses, preferably quantitative, of the ramifications, arborizations and terminations of axons, dendrites and collateral branches. Degenerative and other techniques (p. 870) are also necessary for the precise determination of connections.

Quantitative analyses of lumbosacral regions of feline spinal cord were made by Aitken & Bridger (1961) and Schadé (1960), who found that in the *anterior zone* of the ventral grey column of one spinal segment (lumbar 6) the neuronal population totalled about 7000; 700 were considered small neurons of γ-efferent fibres to muscle spindles; 3276 larger ones were propriospinal

7.73 A more detailed analysis of the principal somaesthetic pathways. Descending corticospinal and reticulospinal tracts involved in sensory modulation are also indicated. Modified from data provided by K E Webster, King's College, University of London.

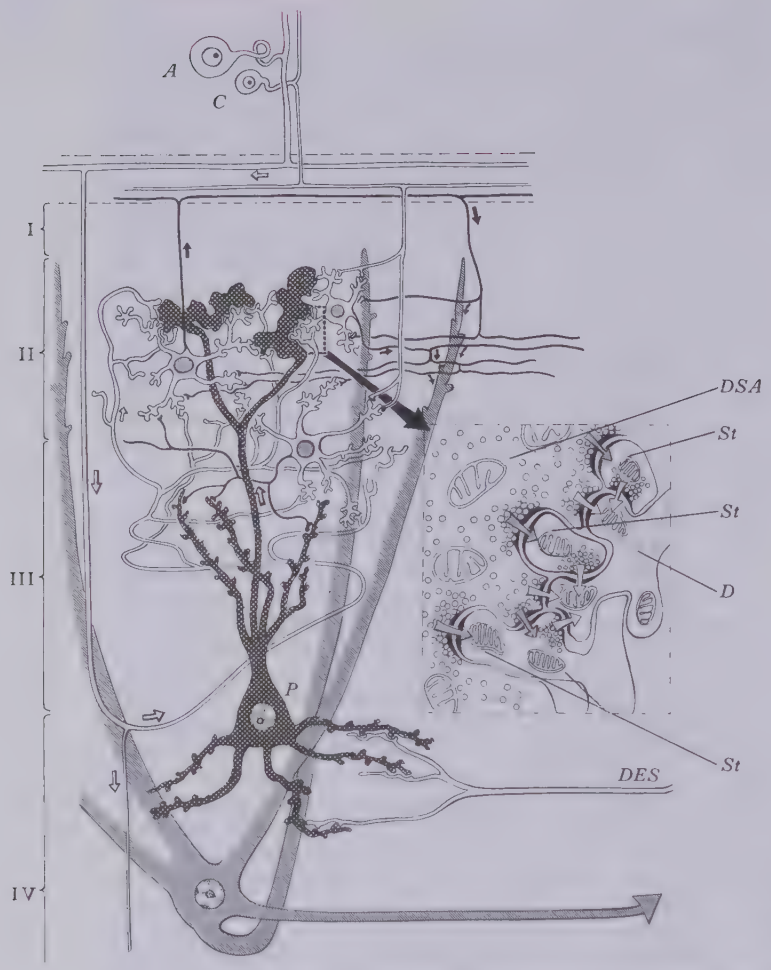
(interneurons), 126 were 'spinal border' cells and 2898 α motor neurons. Thus, about half were interneurons and half motor neurons; in the whole ventral column, the ratio was about seven interneurons to one motor neuron and, with the intermediate zone and base of the dorsal column included, the ratio rises to 13 to 1. Neuronal density was highest in the intermediate zone (7 cells per 100 μm cube of tissue), lowest in the ventral column (1–2 cells per 100 μm cube). The *total* surface area of cell somata and their dendrites ranged from 11 000 to 97 000 μm^2, the surface area of *cell somata* alone ranging up to 25 000 μm^2; stem dendrites varied to a maximum of 13, *dendritic* surface area ranged up to about 76 000 μm^2. Dendritic surfaces formed about 80% of the total *receptive* neuronal surface (i.e. excepting axonal surface), dendrites sometimes extending as far as 1000 μm from the parent soma, where terminal dendrites *entered* the adjacent white matter; as much as 50% of the estimated receptor surface was more than 300 μm from the parent soma. The latter figure is especially interesting; many types of neuron have very wide dendritic trees, but neurophysiological evidence (Eccles 1957) has cast doubt on the possible effectiveness of synapses situated more than 300 μm from the soma; their functional role remains to be determined. Schadé (1964) estimated separate percentages of grey matter occupied and the surface areas of somata and dendrites. A mean value of 7500 μm^3 was estimated for the volume of international soma and 29 000 μm^3 for a motor neuron. The surface area of the 'average' soma ranged from 4.4 to 5.9×10^3 μm^2 and that of the 'average' dendritic tree from 59 to 73×10^3 μm^2.

Other investigations (Romanes 1964, Sprague & Ha 1964) have also examined the complex dendritic patterns of ventral column motor neurons and interneurons in adjacent cell laminae, emphasizing the wide dendritic trees of motor neurons, better appreciated in transverse *and* particularly longitudinal sections. Not only do dendrites of the adjacent *cells* interweave *horizontally* in complicated patterns, but they also spread even more widely, overlapping the territories of other motor neuronal *columns*; some penetrate adjacent cell laminae (VII and VIII), interweaving with dendrites and somata, others pass deeply into the white matter between its longitudinal myelinated nerve fibres, ending at varying depths (sometimes traversing one-third to one-half of the white matter). Even more marked is the *longitudinal* spread of dendrites from α motor neurons *in* their own column, overlapping the territories of hundreds of adjacent motor neurons. Such data again call in question the functional role of axodendritic synapses remote from a neuron's soma. The causes of circumscribed grouping of motor neuron *somata* contrast with those involved in their *dendritic* interlacing. The latter's significance is obscure but interpretation of the patterns of overlap has been attempted in relation to the arrays of primary afferent terminals from muscle and to interneurons in the adjacent cell laminae, both of which spread longitudinally in three or four segments (Sprague & Ha 1964, Sterling & Kuypers 1967). Scheibel & Scheibel (1968) have analysed the dendritic fields in spinal grey matter, Szentágothai & Albert (1955) and Bohme (1962) have similarly examined Clarke's column, and Szentágothai (1964) and Ralston (1965) have analysed the substantia gelatinosa. Ralston (1974) has reviewed the field.



The general neuronal arrangement in the **substantia gelatinosa** is as follows: neurons of thin lamina I usually have large dendritic trees spreading tangentially across the dorsal aspect of the posterior grey column, mixing with the deepest fibres of the dorsolateral tract and some dorsal nerve root afferents; their axons mainly ramify in the subjacent laminae, but longer ones decussate and ascend to the brain stem and diencephalic levels in the ventrolateral white columns (p. 935). Dendrites of small neurons in lamina II and larger ones in lamina III are predominantly radial, occurring in longitudinal 'sheets' perpendicular to the dorsal column; a few may pass ventrally to the deeper laminae but most remain in the substantia gelatinosa (vide infra). These fine axons ascend or descend a little in lamina II or pass into the dorsolateral tract and return to either lamina II or III before ramifying. Between the radial dendrites of small neurons are two other radial components: the terminal parts of long dendrites of larger, more deeply sited neurons in lamina IV and terminals of many primary cutaneous dorsal root fibres. The fine non-myelinated afferents approach the substantia gelatinosa from its dorsal aspect, their terminal branches travelling ventrally; afferents of larger diameter curve round the substantia to its ventral aspect.

Another detailed study of the substantia gelatinosa (Réthelyi & Szentágothai 1969) was based on Golgi technique and ultrastructure combined with dorsal root transection or isolation of the dorsal grey columns. Neurons in laminae II and III were examined with special reference to the larger pyramidal neurons at the junction between laminae III and IV; these have recurrent axons entering lamina II, where they expand as cores of large *glomerular synaptic complexes*, containing axodendritic synapses between axons of pyramidal neurons and dendrites of small gelatinosal somata, and axoaxonic contacts between 'pyramidal' axons and terminals of dorsal root afferent fibres. Features of these synapses, with details of inputs from primary dorsal root afferents, axonal ramifications and terminals of gelatinosal neurons, main output channels via lamina IV neurons and terminals of fibres from supraspinal sources, are summarized in illustration 7.75. Further researches show that the detailed roles of the substantia gelatinosa in part remain obscure (Nathan 1976, Wall 1978), but also vide infra.



TERMINATIONS OF DORSAL ROOT AFFERENT FIBRES

The formation, topography and division of dorsal spinal roots have been described (p. 927) and confirmed in man (Sindou et al 1974). Terminations of these in spinal grey matter must now be detailed. Approaches to this problem have been anatomical and neurophysiological. In the former terminations at different levels have been followed by such techniques as those of Glees, Nauta and Fink-Heimer after the severance of individual dorsal roots. In the latter, the focal electrical potentials generated in spinal grey matter have been explored by microelectrodes to record the results of stimulation of the muscle, cutaneous nerves and dorsal roots. Most of the informative studies of dorsal root terminals (Sprague 1958, Sprague & Ha 1964) were on feline spinal cords; similar arrays probably exist in other mammals but *details* cannot be transferred without reserve to the human spinal cord. The findings were related to laminar architecture (p. 938), with the proviso that the degenerating terminals seen are only those near cell somata and dendrite trunks, although the branches of many dendrites radiate widely (p. 940). Dendrites are covered by synaptic contacts along all their course (Armstrong et al 1956, Wyckoff & Young 1956, Rasmussen 1957, Young 1958, Illis 1964, Gelfan & Rapisarda 1964), numbering thousands in large neurons, but these are *not* revealed by the degeneration techniques used and such studies must be combined with others, including Golgi techniques.

The fields of termination, after section of cats' sixth right lumbar dorsal roots, are shown at three levels (lumbar 5, 6 and 7) in 7.76A,B,C. All large dorsal funicular fibres (except some placed medially) have collaterals traversing the medial two-thirds of laminae I, II and III, many curving around their medial aspects to form a dense plexus of degenerating fibres of passage and terminals round most neurons in lamina IV. Many fibres of passage recurve into the substantia gelatinosa from its ventral aspect, showing as degenerating terminals between the radial dendrites of small neurons in laminae II and III and terminal segments of long dorsally directed dendrites from lamina IV. Degeneration also occurs in some fine fibres of the dorsolateral tract through three segments in both directions; from these, collaterals pass into laminae I, II and III, appearing in all as degenerating terminals. From lamina IV many larger fibres pass to the medial zones of V and VI (containing commissural interneurons), many others forming a mass of degenerating terminals in the central zones of these laminae. From this concentration 'fingers' of degenerating terminals radiate into laminae VII and VIII; running with them are fibres of passage converging on motor neuron pools and their interneurons in lamina IX. Sprague (1958) demonstrated degenerating synaptic terminals from dorsal root afferents terminating on the somata and dendrites of large multipolar motor neurons, interspersed between numerous terminals from interneurons in other laminae and levels. In cats such monosynaptic terminals (of dorsal root afferents) on motor neurons extended two segments above and below a severed root; terminals on interneurons in other laminae were identified one or two segments beyond this. Similar studies in rhesus monkeys (Shriver et al 1968, Carpenter et al 1968) show similar findings but differ in detail.

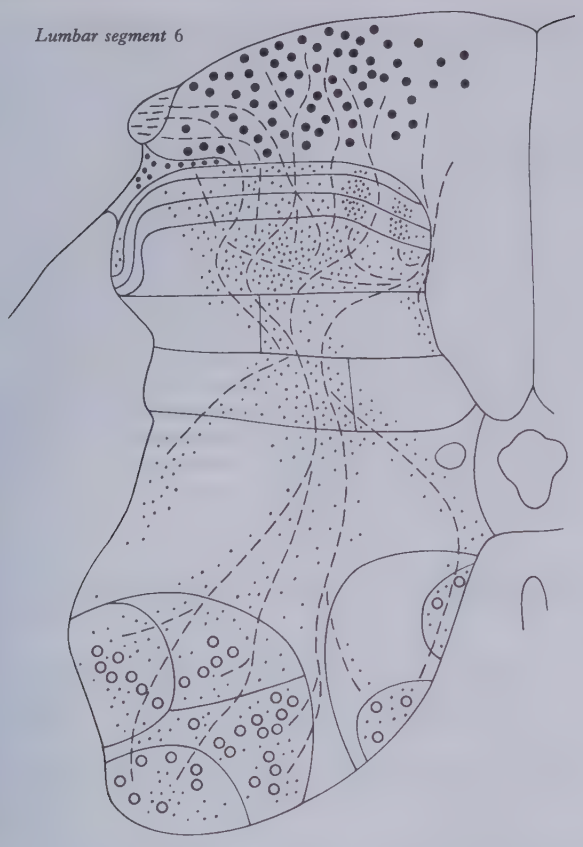
7.74 The pattern of lamination proposed by B Rexed (1964) for the spinal cord grey matter of the cat, viewed in transverse section: A. the fifth lumbar segment, B. the third thoracic segment. Reproduced with the permission of B Rexed and Elsevier.

7.75 The arrangement of neurons and their interconnections in a longitudinal section through the dorsal grey column of the spinal cord, which includes the substantia gelatinosa and adjacent neuronal laminae (Roman numerals I–IV). Inset (right) shows synaptic detail of the area indicated. Two primary sensory afferent fibres are shown: a cutaneous afferent of large calibre (A) and a small calibre non-myelinated afferent (C). Small substantia gelatinosa interneurons are in white with black outline; their axons are single black lines. A pyramidal cell with dendrites and spines and a recurrent axon expanding into synaptic complexes is shown in black with white dots. A large multipolar neuron of lamina IV with long radial dendrites and initial axon is in cross-hatch. DES = axon descending from a supraspinal source. Arrows on main diagram show presumed direction of impulse conduction. Note (1) the different sites of synaptic termination of primary afferents A and C, (2) the axonal pattern and terminals of substantia gelatinosa interneurons, (3) the synaptic complexes formed between the recurrent axon expansions of the pyramidal cell, the small gelatinosa interneuron dendrites and the primary sensory axon terminals. See inset for details. DSA = pyramidal cell axon terminal; D = dendrite of gelatinosa interneuron; St = primary afferent fibre axon terminal; white arrows = axo-dendritic synapses; cross-hatched arrows = axoaxonic synapses. Consult text for a discussion of the 'gate' theory and structural details. From Szentágothai 1975.

In recent years many attempts to correlate architectonics of spinal cord grey matter have been based on classic degeneration techniques and the use of tracers (p. 870), with more critical assessment of the terminations of tracts and complexities of propriospinal neurons, combined with neurophysiological experiments. Findings by Eccles (1957), Eccles & Schadé (1964a, b), Ralston (1974) and others are summarized below.

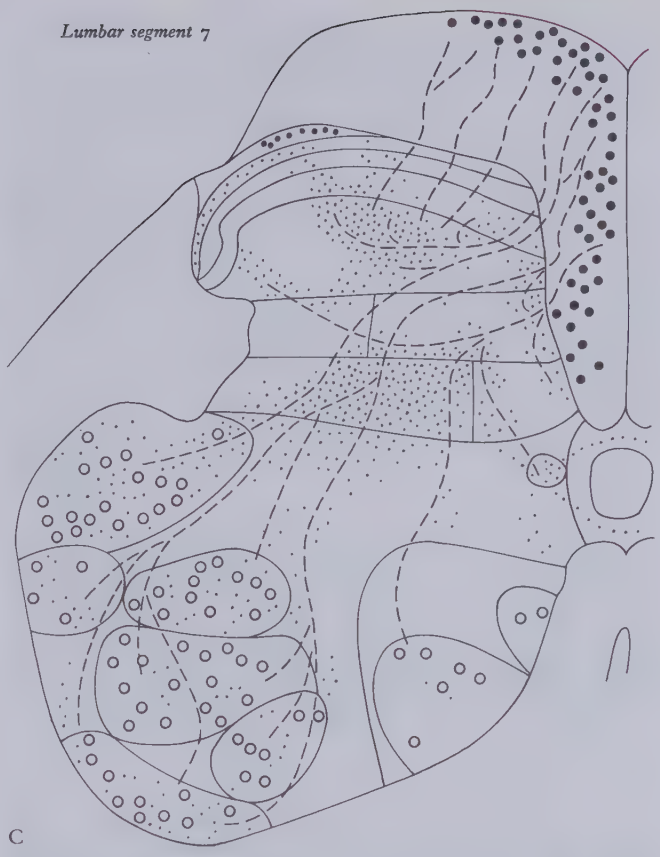
NEUROPHYSIOLOGICAL CORRELATIONS

In addition to being a prime site for degeneration studies (p. 870), large multipolar neurons of motor columns in lamina IX were the targets for classic studies of reflex responses (Sherrington 1906), from which emerged the first clear evidence of *integration* of contacts between neurons, and concepts of *excitation* and *inhibition*.



A

7.76 The pattern of degeneration of nerve fibres and their terminals, demonstrated with the Nauta-Laidlaw technique in the ipsilateral half of the spinal cord at various segmental levels, five days after surgical division of the *sixth* lumbar dorsal spinal nerve root of the cat. A. The fifth lumbar



Much later their large size made them most suitable for microelectrode recording; also they can be excited *orthodromically* by stimulation of the peripheral nerves or dorsal spinal roots and invaded *antidromically* by stimulation of the ventral roots. Thus detailed analyses are possible of electrical and ionic events at synapses during the generation of *excitatory* and *inhibitory postsynaptic potentials* (EPSPs and IPSPs). Similarly, recognition of adjacent inhibitory interneurons (Renshaw 1941, 1946) has prompted enquiry into *lateral* and *feedback* inhibitory phenomena.

Since 1940 evidence of *presynaptic inhibition* has grown; in this spinal neurons have also been a major experimental field (Eccles 1964). Synaptic terminals (A) impinging on a neuron (B) are themselves subject to synaptic terminals (C) from a nearby interneuron, i.e. these are axoaxonic synapses. When active, inhibitory terminals (C) are said to cause relative depolarization of terminals (A), reducing their power to cause postsynaptic change in the neuron (B). Usually two or more interneurons are thought to exist in a presynaptic inhibitory pathway. Like postsynaptic excitation and inhibition, presynaptic inhibition may be effected by descending fibres from supraspinal sources.

Once regarded as uncommon, *presynaptic inhibition* has been revealed in relation to many, possibly all primary afferent terminals. Thus sensory information entering the central nervous system does not simply reflect environmental changes but is continually modified at the first synapses depending on local conditions in the grey matter. A much investigated site of presumed presynaptic effects is in laminae II and III, the substantia gelatinosa (Wall 1964, Mendell & Wall 1964, Melzack & Wall 1965, Mendell 1966, Heimer & Wall 1968, Ralston 1974, Nathan 1976, Wall 1978, 1984). As noted elsewhere (p. 944) it has been proposed that impulses from cutaneous (and other) afferents are here subjected to *tonic control* involving the relative depolarization and hyperpolarization of primary afferent terminals, mediated by small and pyramidal neurons of the substantia gelatinosa; but precise

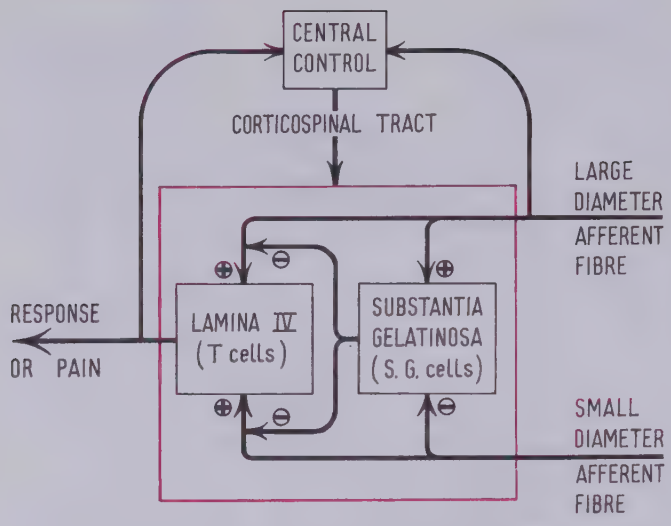
segment; B. the sixth lumbar segment; C. the seventh lumbar segment. The large dots indicate degeneration of fibres in the dorsal funiculus; smaller dots = degenerating fibres in the dorsolateral tract of Lissauer; smallest dots = degenerating nerve terminals; dashed lines = degenerating fibres of passage; circles = neuronal somata of motor neurons. From Sprague & Ha 1964, with the permission of the authors and Elsevier.

synaptic events are still under investigation (Réthelyi & Szentágothai 1969). A *gate control theory*, first proposed by Melzack & Wall (1965) as a possible gelatinosal mechanism providing a 'gate' to inflow along nociceptive and other afferents, has promoted much discussion. The *mechanisms initially* envisaged are summarized in 7.77.



It *was* proposed that large-diameter afferents (e.g. from hairs and touch corpuscles) are excitatory to gelatinosal interneurons (SG) and larger neurons (T cells) of lamina IV (from which spinothalamic fibres arise), whereas fine non-myelinated afferents are excitatory to T cells but inhibitory to SG cells; axons of the latter were presumed to inhibit presynaptically terminals of all afferents synapsing with T cells. In such a system, low activity in fine afferents inhibits SG cells so that they are prevented from inhibiting T cells; hence the 'gate' to T cells in lamina IV is *open* to transmit intermittent volleys from large fibres. A prolonged high-frequency volley in large-diameter afferents, however, is transmitted to lamina IV T cells initially, but this soon ceases as activity in SG cells *closes* the gate. Conversely, persistent high activity in fine afferents opens the gate to massive bombardment of neurons of lamina IV, which include some neurons of high threshold activated only by such bombardment; it is presumed that onward transmission in the lateral spinothalamic tract will evoke pain at supraspinal levels. Pain would thus result from an *imbalance* between the varieties of afferent impulses when there is abnormally large traffic along the fine afferents, which should perhaps not be regarded as '*specific pain afferents*' but as information mediators of the *state of the tissues* innervated. Thus, in addition to *interaction* and *comparison* of traffic along different fibres, other features of gate control theory involve the *presynaptic inhibition* of primary afferent terminals. Overall 'sensitivity' of the gate may be varied by *descending supraspinal control systems* (vide infra and p. 945).

Since its origin the theory has been progressively refined (Melzack 1973, Wall 1973, 1974, 1976). Nevertheless, Nathan (1976) was prompted to write a lengthy criticism. Subsequently Wall (1978) presented a *re-statement* of the gate control theory of pain mechanisms: 'In 1965, we proposed that transmission of information about injury from the periphery to the first central neurons was under control. The setting of this control or gate was influenced by peripheral afferents, other than those which signalled injury. The gate was also influenced by impulses descending from the brain. Subsequent work has fully supported and enlarged this view. All the cells so far discovered which transmit information from nociceptors are inhibited by low threshold afferents and by descending controls. The mechanism by which this control is achieved remains completely unknown. Pre-synaptic inhibition as a phenomenon isolated from post-synaptic inhibition is in doubt. Whether the inhibitions and facilitations are pre-synaptic or post-synaptic or both is unknown. The role of the substantia gelatinosa in any function is unknown. That a gate control exists is no longer open to doubt but its functional role and its detailed mechanism remain open for speculation and for experiment.'

The Endogenous Analgesia System

Since the above was written many data have accumulated concerning a descending pain control system (for an extensive review see Basbaum & Fields 1979, 1984). Three principal, interconnected regions are involved and each receives a variety of afferents and contains an array of neuromediators.

In the midbrain the *periaqueductal grey matter* (PAG) together with the nucleus raphes dorsalis, and part of the nucleus cuneiformis comprise neuron populations containing serotonin, GABA, substance P, CCK, neurotensin, enkephalin and dynorphin. The PAG receive afferents from the frontal somatosensory and cingulate neocortex, the amygdala, numerous local reticular nuclei and the hypothalamus (afferents from the latter are separate bundles carrying histamine LHRH, vasopressin, oxytocin, ACTH, γ-MSH, endorphin, and angiotensin II). From the PAG fibres descend to rhombencephalic centres (and possibly some direct to the spinal cord).

7.77 The sensory 'gate' mechanism as *originally* proposed by R Melzack and P D Wall for the modus operandi of the dorsal laminae of grey matter of the spinal cord. See text for a discussion of the effects of an imbalance in the sensory inflow along the large and small diameter afferent fibres. From an illustration in Melzack & Wall 1965, with permission of the authors and publishers. Consult references for a critical review of the gate theory by Nathan (1976) and a comprehensive reappraisal of the evidence and subsequent re-statement of the theory by Wall (1978).

In the rhombencephalon, nucleus raphes magnus and the medial reticular column is an important multineuromediator centre, containing serotonin, substance P, CCK, TRH, enkephalin and dynorphin. Some neurons contain two or even three neuromediators. Descending bulbospinal fibres pass to the nucleus of the spinal tract of the trigeminal nerve and its continuation, the substantia gelatinosa, throughout the length of the cord. Again there are populations of neurons containing many different neuromediators: GABA, substance P, neurotensin, enkephalin and dynorphin.

There is now abundant physiological and pharmacological evidence that these regions are intimately concerned with nociceptive (and probably other modality) input controls. Their highly complex interactions are, however, under constant reinvestigation and theoretical reappraisal.

Other general electrophysiological investigations have involved the exploration of spinal grey matter by microelectrodes during stimulation of muscle and cutaneous nerves (Eccles et al 1954, Coombs et al 1956) and during 'natural' stimulation of peripheral receptors (Kolmodin 1957, Kolmodin & Skoglund 1960). The focal extracellular potentials thus evoked correlate with the specific laminar regions and terminations of dorsal spinal afferents determined by degeneration techniques.

UNIT RECORDING WITH INTRACELLULAR MICROELECTRODES

Recordings from microelectrodes in neurons deep in the spinal grey matter have provided much information, often unexpected, leading to radical reappraisal of many views. Examples are recorded here of data from cells in laminae IV–VI during natural dermal stimulation, passive limb movements, stimulation of cutaneous, muscular and visceral nerves in various combinations, sometimes with the simultaneous stimulation of tracts from supraspinal sources or after their removal (Wall 1967, Pomeranz et al 1968, Wall 1970, 1978). Earlier experiments confirmed a *functional lamination* corresponding largely to cytoarchitectonic findings (p. 939). Neurons in all three laminae responded to cutaneous stimulation, only lamina VI to movement. Neurons in lamina IV had small receptive fields and responded as if *different* specific cutaneous afferents *converged* upon an *individual neuron* (e.g. to hair movement, touch, skin cooling, etc.). Lamina V neurons responded as if many in lamina IV converged upon each of them, having larger and more diffuse receptive fields. Many in lamina VI responded to passive movement and cutaneous stimulation. Simultaneous corticospinal stimulation affected the neurons in all three laminae, sometimes facilitating, sometimes inhibiting responses. Brain-stem activity inhibited responses to cutaneous stimulation, but enhanced responses to movement, even *switching the 'modality'* of some lamina VI neurons from cutaneous to proprioceptive. In later investigations the findings were refined. In lamina V *fine myelinated afferents* from *three* sources (cutaneous, muscular, visceral) converged on *individual cells* and interacted. They had large, non-discriminative receptive fields, perhaps in some way signalling information concerning the general 'state' of the tissues. These results were summarized by Wall (1970); cells in laminae IV–VI were compared with those in nuclei gracilis and cuneatus. These laminae are now considered to provide a source of crossed spinothalamic fibres (Dilly et al 1968), a principal sensory path receiving some terminals of fasciculi gracilis and cuneatus, a second major sensory path. Their respective roles have long been debated and comparison emphasizes the important aspects of sensory function.

COMPARISON OF THE DORSAL COLUMN—MEDIAL LEMNISCUS COMPLEX WITH THE SPINOTHALAMIC PATH

It is instructive to compare, in these two 'systems', the size of the receptive fields, somatotopy, specificity of channels or convergence and interaction among them, and forms of control of transmission.

Neurons of dorsal column nuclei (Mountcastle 1968, Norton 1968) receive terminals of long, ipsilateral fibres of fasciculi gracilis and cuneatus (p. 936), the primary afferents for deformation of skin, movement of hairs, joint movement and vibration. In cats fibres from hair receptors are superficial, those for touch and vibration deeper. The localization of fibres in dorsal white columns has been noted (p. 936); the connections of dorsal column nuclei are further detailed with the medulla oblongata (p. 936).

Unit recording in the neurons of dorsal column nuclei shows that tactile *receptive fields* (i.e. excitable skin areas) vary in size, being mostly small and smallest in the digits. Some fields have *excitatory centres* and *inhibitory surrounds*; stimulation just outside its field inhibits a neuron. Neurons in the nuclei are spaced to represent the periphery accurately (in accord with their localization in the dorsal columns). *Specificity* is high; each neuron responds only to *one type* of stimulation; some respond to movements of a hair or joint, never to both; and fibres converging to one neuron are always modally alike.

Conduction from the dorsal columns to the medial lemniscus is controllable (Jabbur & Towe 1961, Anderson et al 1964). The adjacent dorsal column fibres may be presynaptically inhibited by depolarization of the presynaptic terminals. Stimulation of sensorimotor cortex modifies transmission by pre- and postsynaptic inhibition, sometimes by facilitation, mediated by the corticospinal tracts. The reticular formation exerts like effects. Dorsal column nuclei are not merely 'relay nuclei', as long supposed. They have been pictured as a highly reliable telephone system in which afferent information is separated in channels, discrete for spatial origin and stimulus specificity. In this the dorsal columns strongly contrast with the spinothalamic tracts (p. 941).

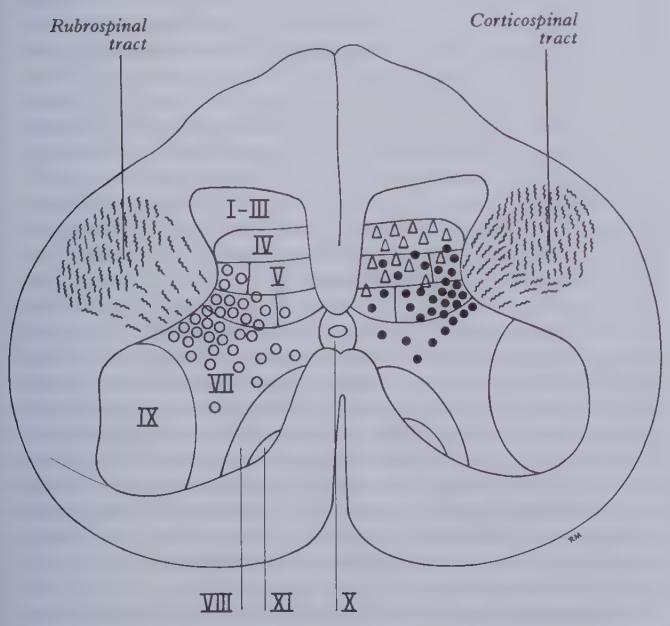
Neurons in spinal laminae IV–VI have different receptive fields. Those in IV have small fields and somatotopy is marked; those in V have large diffuse fields and respond to variable strength of stimulus. *Specificity* of channels, such as that present in dorsal column nuclei, is absent in the spinal laminae. The *convergence of different functional types* of afferent fibres to common neurons is usual in the cord, its degree varying among laminae. Lamina IV neurons receive large cutaneous afferents, lamina V fine afferents from the skin, muscle and splanchnic nerves, and lamina VI large afferents from muscle and skin. Convergence from different sources results in *interaction* between excitation and inhibition, summating to determine neuronal output. Transmission is variously modified. Firstly, cutaneous afferents may be influenced by the tonic mechanism in the substantia

gelatinosa previously discussed. Transmission is also much affected by tracts from the sensorimotor cortex and brain stem (vide supra). Control varies from altered excitability in lamina IV to reversed modality in lamina VI.

The roles of dorsal columns and spinothalamic tracts, have been much debated. A classic view (Mountcastle 1968) regards the dorsal columns as the *essential discriminatory pathway*, without which mechanical stimulus is recognized but assigned no specific location, intensity or pattern, a view strongly challenged (Wall 1970) because complete section of the dorsal column does not abolish discrimination of weight, texture, two-point stimulation, vibration or position. Environmental stimuli may be classified into those 'passively impressed' and those which 'must be actively explored by motor movement or sequential analysis' for successful discrimination.

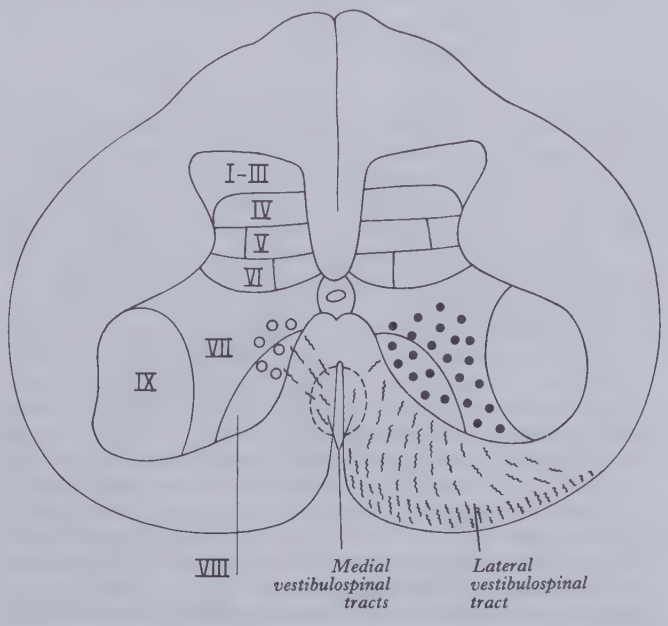
The former is considered the spinothalamic role, that of the dorsal columns is to *initiate and plan exploration* of the stimulus for the subsequent transmission of information.

SPINAL TERMINATIONS OF TRACTS DESCENDING FROM SUPRASPINAL SOURCES



Degeneration techniques such as Nauta's have much illuminated the spinal terminations of descending tracts (Nyberg-Hansen 1964a, b, 1965, 1966a, b, 1969, Nyberg-Hansen & Brodal 1963, 1964, Nyberg-Hansen & Mascitti 1964, Brodal 1969). Most investigations have been in cats, rarely primates. Results, while probably generally applicable, cannot be transferred in toto to human structures. The principal results are summarized in Figure 7.78, in which the distributions of terminals are related to laminar architecture. The following points, some already briefly mentioned, are noteworthy.

Corticospinal fibres almost all terminate, in cats, on interneurons in laminae IV–VII; but because of the widespread dendrites of multipolar neurons in lamina IX, some penetrating lamina VII, the existence of a few axodendritic contacts with motor neurons cannot be ignored. Corticospinal fibres from the 'sensory' cortex terminate chiefly in laminae IV and V, those from the 'motor' cortex in V–VII, with the densest concentration laterally in lamina VI. Thus, despite some overlap, corticospinal fibres from these two regions end differently—findings of interest in view of increasing evidence involving corticospinal tracts in the supraspinal *modulation of sensory inflow*; this may be mediated by presynaptic inhibition of primary afferent terminals or the postsynaptic inhibition or facilitation of subsequent neurons. In contrast there is evidence, anatomical (Hoff & Hoff 1934, Kupyers 1960, Liu & Chambers 1964) and physiological (Bernhard et al 1953, Preston & Whitlock 1961, Landgren et al 1962), that in monkeys some corticospinal fibres end monosynaptically on large α motor neurons. Less is known, quantitatively, about human synaptic terminals; most end on interneurons but some (Kuypers 1958) may end directly on motor neurons. Physiological studies (Corazza et al 1963) indicate that feline corticospinal tracts influence α and γ motor neurons, both via interneurons. The *increased* flux of impulses in corticospinal axons is excitatory to motor neurons of flexors and inhibitory to those supplying extensors. *Converse* effects of *decreased* flux are equally essential in normal function.

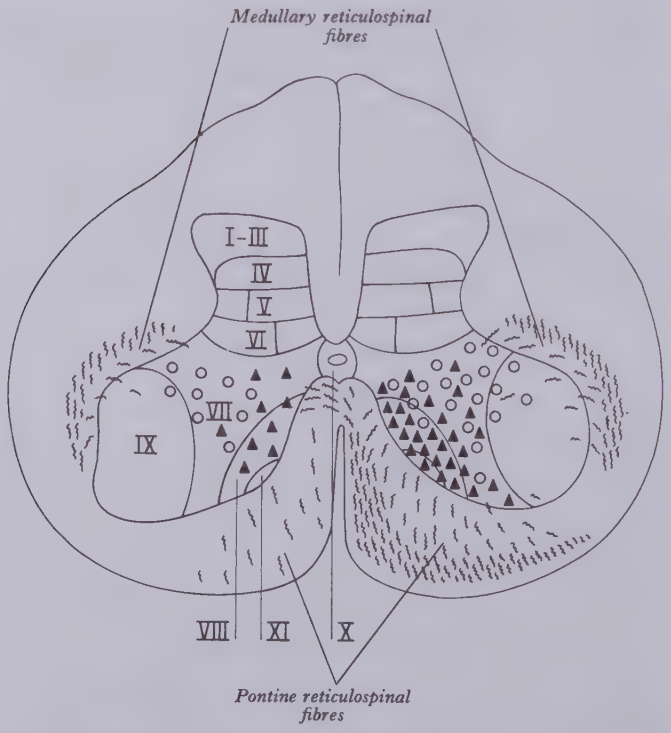


Rubrospinal fibres arise from large and small neurons in the contralateral red nucleus, with some degree of somatotopic order. Degeneration after nuclear lesions in cats shows the tract descending to lumbosacral levels, with terminals on interneurons in laminae V–VII. Its terminal zones correspond to those of corticospinal fibres from the 'motor' cortex, with similar effects on α and γ motor neurons. In some animals a somatotopic *corticorubral projection* has been demonstrated from the sensorimotor cortex, suggesting dual routes from cortex to cord, *direct corticospinal* and *indirect corticorubrospinal*, with similar spinal terminations and common functions. But the origin, localization, termination and functions of human rubrospinal connections are not defined, though often stated to be rudimentary.

The vestibulospinal tracts, medial and lateral, much investigated in other animals, are less clarified in man. The lateral, from the ipsilateral *lateral vestibular nucleus*, descends the whole cord, ending at successive levels largely in laminae VII and VIII and less so in lamina IX. The medial tract, mainly from *both* medial vestibular nuclei, descends perhaps only to mid-thoracic levels, terminating less widely in parts of laminae VII and VIII.

7.78 The spinal terminations of various descending tracts of the spinal cord determined experimentally in the cat and referred to the laminar pattern of the grey matter which is described elsewhere in the present section. Redrawn from Brodal 1969, by courtesy of the author and publishers. The original papers and illustrations stemmed from the numerous publications by R Nyberg-Hansen and his collaborators to whom we are grateful. Consult bibliography under 'Spinal Terminations of Descending Tracts from Supraspinal Sources'.

A. Termination of corticospinal fibres from 'motor' areas of the cerebral cortex—black dots; corticospinal fibres from 'sensory' areas of the cerebral cortex—white triangles; rubrospinal fibres—white dots.



B. Terminations of vestibulospinal fibres; those from the lateral vestibulospinal tract—black dots; those from the medial vestibulospinal tract are shown on the opposite side of the cord as white dots.

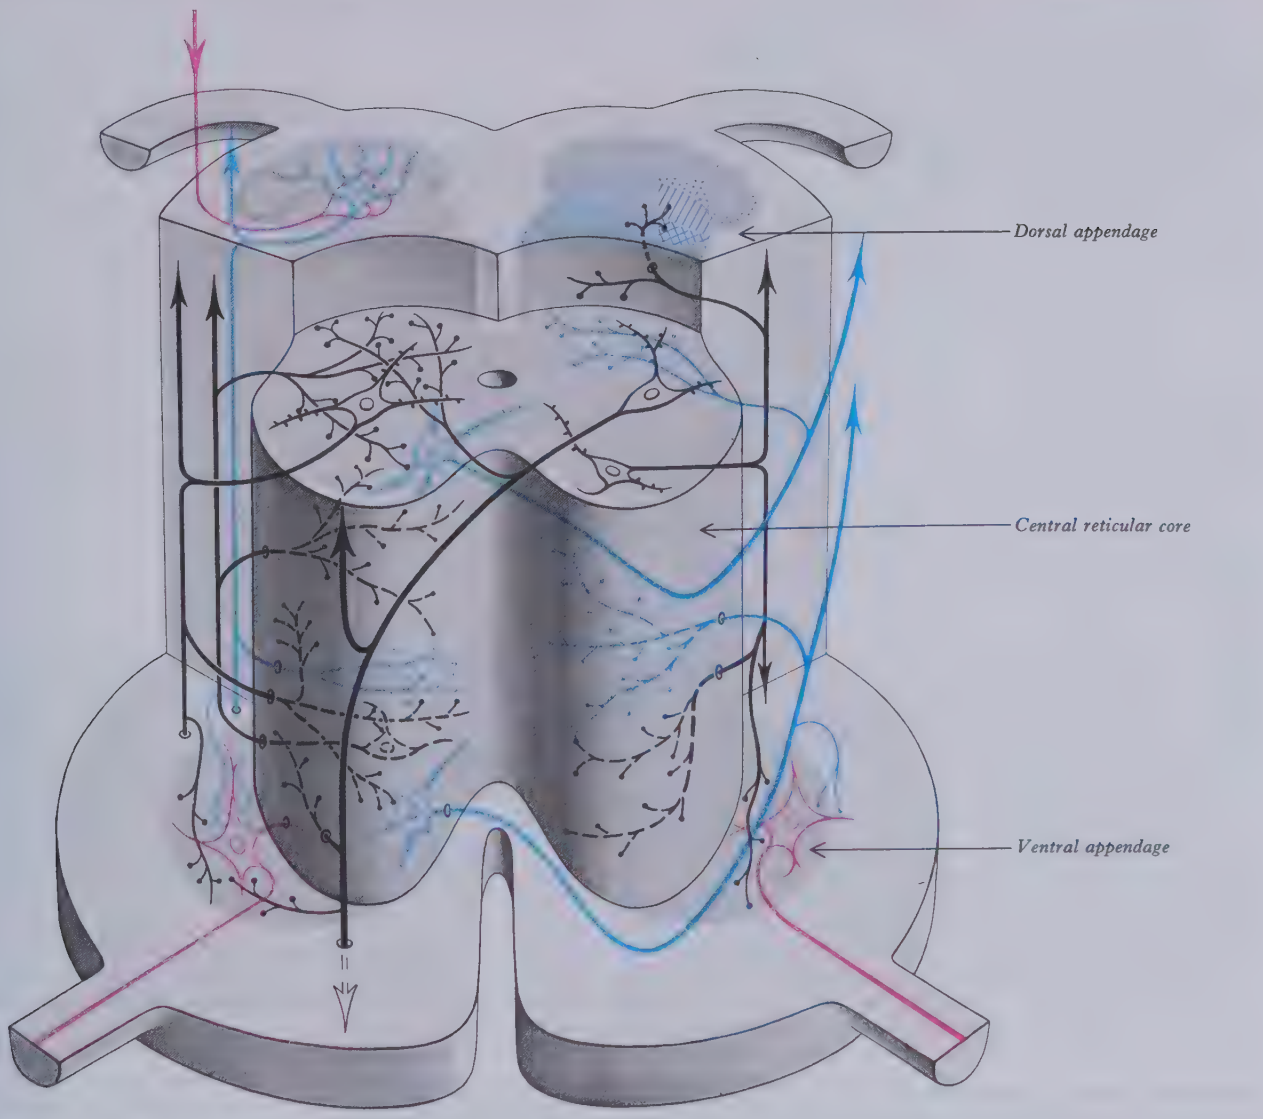
Activation of the lateral tract excites extensor and inhibits flexor motor neurons. Excitation is monosynaptic, indicating that vestibulospinal terminals synapse with the extensive dendrites of some motor neurons penetrating laminae VII and VIII. Gamma motor neurons are also probably facilitated; the inhibitory effect on flexors is presumably by inhibitory interneurons in their laminae of termination.

The reticulospinal tracts, notably difficult to evaluate in human spinal cords, have been mainly examined in cats, by retrograde degeneration in spinal neurons after spinal trauma and by anterograde effects following brain-stem lesions. Pontine and medullary reticulospinal fibres from one side apparently pass to *both sides* of the spinal cord; pontine fibres are ipsilaterally more concentrated; medullary fibres have also a substantial contralateral component. The zones of termination are summarized in 7.78c. (For non-aminergic, noradrenergic, serotonergic, enkephalinoid and other neuromediator substances associated with reticulospinal fibres, see pp. 992, 995, 996.) Similar experiments indicate that **tectospinal** and **interstitiospinal tracts** both terminate in laminae VI–VIII.

SUMMARY OF SPINAL ORGANIZATION

Szentágothai (1967) has considered spinal grey matter as a *central core* with paired *dorsal* and *ventral appendages*, each with distinctive features (7.79), terms which of course cut across the usual description but are held to be less arbitrary. The core has a diffuse, non-discriminative, reticular organization, with great divergence and convergence of paths; most interneurons connect with hundreds, perhaps thousands of others distributed in a substantial length of cord. In contrast dorsal and ventral appendages are more discriminatively organized in terms of somatotopy and functional localization. The precise limits to core and appendages are indefinable. The concept will undoubtedly need revision and perhaps lose relevance as knowledge increases. The central core includes interneurons of laminae VII and VIII (i.e. the intermediate zone and the areas between the motor neuron columns). But interneurons of dorsal columns and in motor neuron columns may be later included in this postulated reticular core. The ventral appendage corresponds to the neuronal columns of lamina IX, the dorsal appendage includes laminae I–VI.

7.78c Terminations of reticulospinal fibres; those originating in the medulla oblongata (white dots) are in general more dorsally placed than those originating in the pons (black triangles).



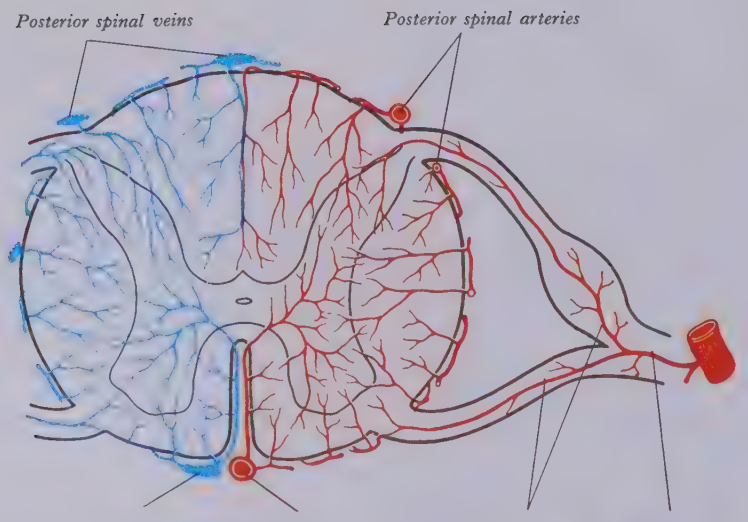
The dorsal appendage (p. 941) is a main receptive zone of exteroceptive, proprioceptive and interoceptive dorsal spinal root fibres. Laminae I–IV are the main cutaneous receptive areas; lamina V receives fine afferents from the skin, muscle and viscera; lamina VI receives proprioceptive and some cutaneous afferents. But few appropriate investigations have yet been made; hence the functional boundaries are uncertain and interneuronal complexities are postulated but as yet undemonstrated. Intracellular recording has its difficulties; some neurons may long remain out of technical reach.

Nevertheless the available recordings suggest that neurons in the dorsal appendages abstract data from internal and external environments. Neuronal groups show varying somatotopic array, size and response of receptive fields, specificity, convergence and interaction. Clearly, simple views of spinal neurons as merely relays in invariant, discrete, 'unimodality' channels, transmitting a punctate replica of the environment to the spinal cord or brain, are inadequate. Complex transformations of input occur in the dorsal appendage, whose output spreads to many destinations: directly to the ventral motor neuron columns, or indirectly via laminae including complex interneurons of the reticular core, to both sides of the cord, cranial and caudal to the input. Neurons in the dorsal appendage and reticular core contribute to the ascending tracts, reaching many brain-stem centres.

Transmission to and through the dorsal appendage may be modified by mutual interaction and control. Facilitatory and inhibitory effects, due to simultaneous activity in various afferent fibres converging on a single neuron, have been noted (p. 944), as has tonic modulation by the substantia gelatinosa. Much evidence suggests that transmission in all laminae is influenced by supraspinal sources, with excitation or inhibition provided by a wide array of neuromediators. The functional significance of these mechanisms is obscure; they may elminate redundancy, reduce confusion or be linked to central 'states of readiness' or temporary 'preoccupation' with immediately significant transformations. Such hypothecation is fortunately complemented by continuing investigation. It is increasingly clear, however, that most descending tracts which influence motor behaviour do so by modifying transmission in the primary afferents, and in interneurons in the spinal laminae, less often than by direct influence on motor neurons.

Interneurons of the reticular core form an intricate net in which each neuron receives from and transmits to large numbers of others (pp. 988-996) and is characterized by one or more neuromediators. The core receives some axons from the dorsal appendage, proprioceptive dorsal root fibres and some descending fibres. This plethora of connections makes investigation difficult but an earlier view of *random nerve networks* is receding with newer methods, which include minute stereotactic lesions, intracellular recording, the inspection of thousands of Golgi-stained sections (Brazier 1969) and the mapping of somata or terminals by their content of established or putative neuromediators (p. 995). An aspect of organization has emerged that concerns the quantitative analysis of connectivity ('transmitting power') of different interneurons and some descending tracts. Some axonal terminals have very long courses in the grey matter and through successive branches give two or three synaptic end bulbs to each of many hundreds of interneurons encountered; others concentrate many end bulbs on one neuron or on a small group; yet others have widespread paracrine effects. Diffuse, '*non-discriminative*' connections hence contrast with '*discriminative*' ones. Many proprioceptive terminals in the core are 'segmentally' localized in *transverse* 'sheets' of grey matter. (Dorsal appendage cutaneous afferents terminate in *longitudinal* sheets.) In such complex interneuronal congeries, sensory input probably interacts with supraspinal influences to set in train the multivarious locomotor response. This analysis is largely speculative but the modern technical armamentarium will doubtless effect some progress.

The ventral appendage (pp. 927, 929, 939), is a columnar array of α amd γ motor neurons and interneurons. Evidence points to 'tonic' and 'phasic' types of α neurons innervating striated muscle and to different types of γ neurons for 'static' and



7.79 A highly simplified stereodiagram illustrating the concept of the spinal cord as consisting of a central 'reticular' core of grey matter, with related dorsal and ventral 'appendages' of grey matter. Many structural features are omitted and only a few examples, relevant to the concept, are included. A dorsal column neuron and others, more ventrally placed, which give rise to descending, long ascending and local collateral branches, are shown in blue. Varieties of interneuron are in black. Two motor neurons are shown in red; also in red is a single example of a fibre descending from a supraspinal source. See text for a more detailed description; see also 7.73 for the origin and termination of some tracts and 7.75 for one view of the fine structure of the substantia gelatinosa. Redrawn from Szentágothai 1967 by courtesy of the author and publishers.

'dynamic' responses in muscle spindles and their independent controls; but their detailed synaptic patterns remain uncertain.

The main connections of the *motor neurons* are: (1) direct monosynaptic terminals of proprioceptive dorsal root afferents in the same or nearby segments, (2) terminals from axonal collaterals from dorsal appendage interneurons, (3) terminals of interneurons of the reticular core: 'discriminative' from the same segment, 'non-discriminative' from adjacent segments, and (4) direct monosynaptic terminals from the vestibulospinal and (in man) corticospinal tracts. The interaction of such converging channels for integrated motor behaviour is obscure. A few generalizations can be made; descending paths can be grouped into those wherein impulses are excitatory to flexors, inhibitory to extensors (cortico-, rubro- and medullary reticulospinal tracts) and those with the opposite effect (vestibulo- and pontine reticulospinal tracts). But this simple dualistic view ignores much investigation reported on the complex modification of reflex activities by descending tracts.

Muscle is made to contract or relax by *two routes*: the α pathway produces a direct, immediate change in the excitatory level of α motor neurons innervating motor units, but probably acts infrequently, in sudden forceful responses; usually a γ *pathway* also operates by sequential activity in local interneurons and activity (or inhibition) of the γ efferents to muscle spindles which, via local muscle 'servo-loop' mechanism (p. 916), causes the appropriate change in tonic and phasic α motor neurons. How this so-called α–γ *linkage* is maintained or broken in different conditions is under investigation (Granit 1970). Available reports indicate that during voluntary actions initiation of activity in the α system may be more frequent than previously recognized (p. 916).

Applied Anatomy. The segmental level of spinal injury may be determined from clinical data and accurate anatomical knowledge. Complete division above the fourth cervical level causes respiratory failure by loss of activity in the phrenic and intercostal nerves. Lesions between C_5 and T_1 paralyse all four limbs (quadriplegia), effects in the upper limbs varying with the site of injury: at the fifth cervical segment paralysis is complete; at the sixth the arms are between abduction and lateral rotation, with elbows flexed and forearms supinated, due to unopposed activity in the deltoids, spinati, rhomboids, bicipites and brachiales (all supplied by the fifth cervical spinal nerves). In lower cervical lesions upper limb paralysis is less. Lesions of the first thoracic segment paralyse small muscles in the hand and damage sympathetic outflow, resulting in contraction of the pupil, recession of the eyeball, narrowing of the palpebral fissure and loss of sweating in the face and neck (Horner's syndrome); sensation is retained in areas innervated by segments above the lesion; cutaneous sensa-

7.80 The intrinsic blood vessels of the spinal cord. The position of the veins is quite variable.

tion is retained in the neck and chest down to the second intercostal space, because this area is innervated by the supraclavicular nerves (C_3 and C_4). At thoracic levels division paralyses the trunk below the lesion's level and both lower limbs (paraplegia). The first sacral *neural* segment is approximately level with the thoracolumbar vertebral junction; injury, commonly occurring here, paralyses the urinary bladder, rectum and muscles supplied by the sacral segments; cutaneous sensibility is lost in the perineum, buttocks, the flexor aspect of the thighs, legs and feet. The roots of lumbar nerves descending to join the cauda equina may be damaged, causing complete paralysis of both lower limbs. Lesions below the first lumbar vertebra may divide or damage the cauda equina; severe damage is uncommon and usually confined to the spinal roots at the level of trauma. Neurological symptoms may be due to interference with the spinal blood supply, particularly in the lower thoracic and upper lumbar segments.

Vertebral Levels of Spinal Cord Segments

The level of spinal segments relative to the vertebrae is clinically important. A useful approximation is: at cervical level a vertebral spine's apex corresponds to the succeeding segment (i.e. the *sixth* cervical spine is opposite the *seventh* spinal segment); at upper thoracic levels a vertebral apex corresponds to the cord two segments lower (i.e. the *fourth* spine is level with the *sixth* segment); in the lower thoracic region there is a difference of three segments (i.e. the *tenth* thoracic spine is level with the *first* lumbar segment). The *eleventh* thoracic spine overlies the *third* lumbar segment, the *twelfth* is opposite the *first* sacral segment. The neonatal spinal cord extends to the upper border of the third lumbar vertebra; Barson (1970), in a series of 258 pre- and postnatal subjects, found the perinatal level at the third lumbar vertebra, rising during the first two postnatal months; variation was marked: first to fourth lumbar at birth, first to third in children (three months to 15 years of age).

Vasculature of the Spinal Cord

Blood reaches the spinal cord along spinal branches of the vertebral, deep cervical, intercostal and lumbar arteries; these, with the anterior and posterior spinal arteries, form longitudinal anastomotic channels along the cord (pp. 751, 765, Gillilan 1972). Spinal arteries send anterior and posterior radicular branches to the spinal cord along ventral and dorsal roots. Most anterior radicular arteries are small, ending in the ventral nerve roots or the cord's pial plexus. Posterior radicular arteries supply the dorsal root ganglia; according to Somogyi et al (1973) ganglionic ramules enter at both ganglionic poles and are distributed around ganglion cells and nerve fibres; the same authors and Undi et al (1973) have described the arterial supplies of spinal roots. Some radicular arteries (usually four to nine), mainly in the lower cervical, lower thoracic and upper lumbar regions, are large enough to reach the anterior median sulcus, dividing into slender ascending and large descending rami, which anastomose with the anterior spinal arteries to form a single or partly double, longitudinal vessel of uneven calibre along the anterior median sulcus. The largest anterior radicular artery, *arteria radicularis magna*, varies in level; it arises from an intersegmental aortic branch at the lower thoracic or upper lumbar level; about 65% arise on the left. Reaching the spinal cord, it sends a branch to the anterior spinal artery below and another to anastomose with a ramus of the posterior spinal artery anterior to the dorsal roots. It is sometimes the main supply to the lower two-thirds of the cord. Central rami of the anterior spinal artery enter the anterior median fissure, turning right or left to supply the ventral grey column, the base of the dorsal grey column, including the dorsal nucleus and adjacent white matter (7.80).

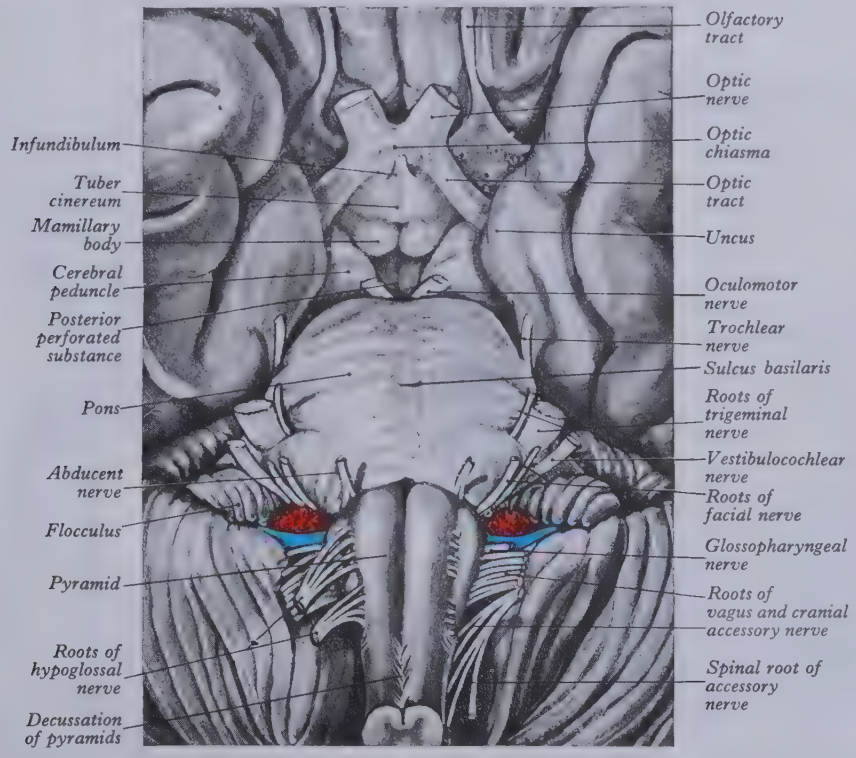
Each posterior spinal artery contributes to a pair of longitudinal anastomotic channels, anterior and posterior to the dorsal spinal roots. These are reinforced by posterior radicular arteries, variable in number and size but more numerous than the anterior radicular. The anterior channel is also joined by a ramus from the descending branch of the arteria radicularis magna. Lazorthes et al (1971) have largely confirmed this description but emphasize the uneven calibre and interruptions in longitudinal spinal arteries, which are conjoined at the conus medullaris by anastomotic loops. They also emphasized anastomoses other than those between the pial or peripheral spinal arterial branches, such as a posterior spinal series of anastomoses between rami of the dorsal divisions of segmental arteries near spinous processes.

Central branches of the anterior spinal artery supply about two-thirds of the cross-sectional area of the cord. The rest of the dorsal grey and white columns and peripheral parts of lateral and ventral white columns are supplied by numerous small radial vessels from posterior spinal arteries and the pial plexus (Torr 1957, Gillilan 1958). In a microangiographic study of human spinal cord at cervical levels (Turnbull et al 1966) there were 1–6 anterior and 0–8 posterior radicular spinal arteries. From each centimetre of anterior spinal artery arose 5–8 central branches. No internal anastomoses were seen but overlapping of territories of central arteries was confirmed; similar longitudinal overlap was also emphasized.

Spinal veins drain into six tortuous, often plexiform longitudinal channels, one each in the anterior and posterior median fissures and four others, often incomplete, one pair being posterior, the other anterior to the ventral and dorsal nerve roots. These vessels connect together freely and above with the cerebellar veins and cranial sinuses. Veins with the anterior spinal artery receive large venules from the central grey matter; much blood from the cord's periphery enters the pial veins (p. 812).

THE RHOMBENCEPHALON OR HINDBRAIN

The rhombencephalon includes the medulla oblongata, pons and cerebellum; its cavity is the fourth ventricle. The medulla and pons contain tracts connecting all parts of the central nervous system and also nuclei of several cranial nerves and many other groups of neurons. Emerging superficially from the pons and medulla are: the trigeminal, abducent, facial, vestibulocochlear, glossopharyngeal, vagus, cranial accessory and hypoglossal nerves. Among the nuclei and tracts is the *reticular formation* (p. 988), a mass of neurons and axons continuous with its spinal counterpart; some of its nuclei are concerned in cardiac, respiratory and alimentary control, others in some aspect of all other neural activities (p. 995 et seq.).



THE MEDULLA OBLONGATA

The medulla oblongata is arbitrarily defined as extending from the lower pontine margin to a transverse plane above the first pair of cervical spinal nerves, which is at a level corresponding dorsally with the upper atlantal border and ventrally with the centre of the dens; but the medulla is uninterruptedly continuous with the pons and spinal cord. Its internal structure is similar to the spinal cord below but changes *gradually* with increasing distance from the spinal cord. Its anterior surface is separated from the basilar part of the occipital bone and apex of the dens by the meninges and occipito-axial ligaments. Dorsally it is in the cerebellar notch, between its hemispheres; in its upper part it forms the lower half of the fourth ventricle's floor. It is somewhat piriform (7.81, 82), its broad (superior) end merging into the pons and its narrow lower end continuous with the spinal cord. It is about 3 cm in length, 2 cm transversely at its widest and sagittally some 1·3 cm thick. The spinal central canal is prolonged into its lower half, expanding above as the fourth ventricle. The medulla is hence divided into a *closed part* containing the central canal and an *open part* containing the lower half of the fourth ventricle. Its anterior and posterior surfaces have median fissures.

The anterior median fissure, containing a shallow fold of pia mater, extends throughout but is partly obscured; it is continuous below with the spinal anterior median fissure, ending above at the lower pontine border in a small triangular *foramen caecum*. Inferiorly it is interrupted by fascicles crossing obliquely, the *pyramidal decussation*. *Anterior external arcuate fibres* emerge from the fissure above this and curve laterally over the medullary surface.

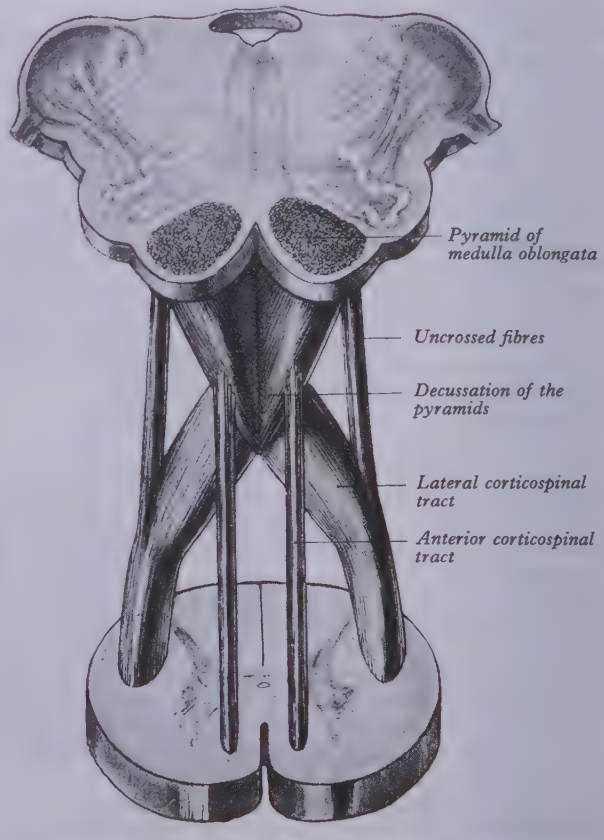
The posterior median sulcus exists only in the closed part, continuous below with the spinal posterior median sulcus; it rapidly shallows above, ending at the mid-level of the medulla, where the central canal expands into the fourth ventricle. (The external posterior median sulcus must be carefully distinguished from the median sulcus on the floor of the fourth ventricle; they are, of course, neither continuous nor homologous.)

Cranial nerves emerging from the medulla appear in line with *both* roots of the spinal nerves. Hypoglossal rootlets are in line with the ventral spinal roots, emerging from an *anterolateral sulcus*. The accessory, vagus and glossopharyngeal nerves are in line with the dorsal spinal roots (p. 924), passing through a *posterolateral sulcus*. These features are used to divide each half medulla into anterior, middle and posterior regions. Though these *appear* to be continuous with the corresponding spinal funiculi, they do not contain precisely the same fibres; some spinal tracts end or begin in the medulla, with others altering course in it.

7.81 The ventral aspect of the brain stem and the interpeduncular fossa. The wall of the lateral recess of the fourth ventricle is shown in blue and the choroid plexus, which protrudes through the foramen of the lateral recess into the subarachnoid space, is coloured crimson. Note that the lateral recess covers the medial part of the flocculus and is itself partially obscured by a rootlet of the glossopharyngeal nerve.

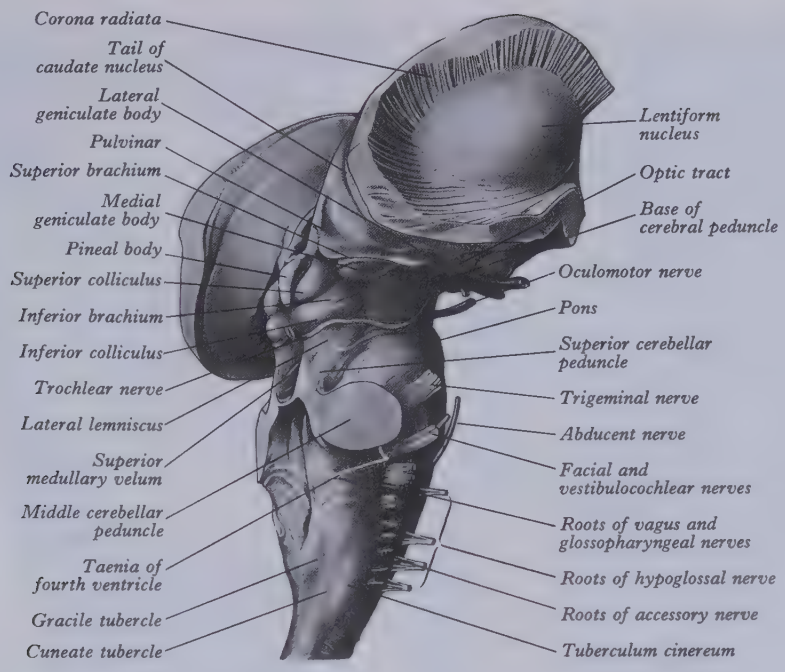
7.82 The ventral aspect of the brain stem, interpeduncular fossa and adjacent parts of the cerebellar and cerebral hemispheres. For identification of the various structures, compare with 7.81. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Department of Anatomy, Guy's Hospital Medical School, London.

The anterior region (7.81, 82), between the anterior median fissure and the anterolateral sulcus, shows an elongated surface inappropriately named the *pyramid*. At its slightly narrowed pontine end the abducent nerve emerges; below it tapers into the spinal anterior funiculus, superficially continuous with it. The two pyramids contain corticospinal fibres, approximately 70–90% of which leave the pyramids in successive bundles and which cross in and deep to the anterior median fissure as the *pyramidal decussation*. They then descend dorsally in the spinal lateral funiculus as the crossed lateral corticospinal tract. The remaining fibres, lateral in the pyramids, do not cross; some descend as the anterior corticospinal tract (7.83) into the ipsilateral anterior funiculi, others incline posterolaterally to join the lateral corticospinal tracts as their lesser uncrossed component (p. 832). The corticospinal tracts display somatotopy at almost all levels; in the pyramids the arrangement is like that at higher levels, the most lateral fibres being concerned with the legs, the most medial with the arms and neck. How far this pattern is carried into the anterior corticospinal tracts or decussating fibres is unknown; but similar somatotopy is usually ascribed to the lateral corticospinal tracts as they traverse the spinal cord.



The lateral region (7.84A,B) is between the anterolateral sulcus (with the hypoglossal roots) and the posterolateral sulcus (with roots of the accessory, vagus and glossopharyngeal nerves). Its upper part is largely a prominent, oval *olive*; its lower part matches the spinal lateral funiculus and appears to be its direct continuation, but only part of the latter continues into this region; the lateral corticospinal tract is mainly from the contralateral pyramid and the posterior spinocerebellar tract mostly leaves it to enter the inferior cerebellar penduncle. The lateral intersegmental and anterior spinocerebellar (and other) tracts continue into the lateral region.

The olive, a smooth, oval elevation between the anterolateral and posterolateral sulci, is due to the subjacent *inferior olivary* complex of *nuclei* (p. 956). Lateral to the pyramid, separated by the anterolateral sulcus and hypoglossal fibres, it is about 1·25 cm long; dorsolateral to its upper end is a slight depression at the lower pontine border; in this, roots of the facial nerve appear. Anterior external arcuate fibres emerge from the anterior median fissure, curving back across the pyramid and olive to the inferior cerebellar peduncle (7.93).



The posterior region (7.84A,B) dorsal to the posterolateral sulcus is, like the lateral, divisible into upper and lower levels. The *lower part*, limited behind the posterior median sulcus, is an upward continuation of the *fasciculi gracilis* and *cuneatus*. The former, with its fellow, flanks the posterior median sulcus, separated from the cuneate fasciculus by a cranial continuation of the posterointermediate sulcus and septum of the cervical spinal cord (p. 922). Both fasciculi are first vertical; but at the lower end of the fourth ventricle they diverge from their fellows, each developing an elongated swelling, the *gracile* and *cuneate tubercles*, produced by the subjacent **nuclei gracilis** and **cuneatus**. Most fibres in both fasciculi synapse with neurons in their respective nuclei. A *tuberculum cinereum* sometimes appears below (7.84A,B), between the fasciculus cuneatus and the roots of the accessory nerve; narrow below, it widens upwards and is produced by a nucleus continuous below with the substantia gelatinosa; the spinal trigeminal tract ends in it, separating it from the surface (pp. 953, 978). The upper posterior medullary region is the *inferior cerebellar peduncle*, a rounded ridge between the fourth ventricle and the glossopharyngeal and vagal roots. The two peduncles diverge and incline from the dorsolateral medulla into the cerebellum. Ascending, they form the inferolateral ventricular boundaries; above they curve dorsomedially into the cerebellar hemispheres, where they are crossed by the *striae medullares*, running to the median ventricular sulcus (7.115, 116). The inferior peduncle is not a continuation of the gracile and cuneate fasciculi, whose fibres end in the gracile, cuneate and accessory cuneate nuclei. The peduncle's composition is described on p. 965.

INTERNAL STRUCTURE OF THE MEDULLA OBLONGATA

Like other neuraxial levels the medulla has been much studied in transverse sections and also by experiment and reconstruction

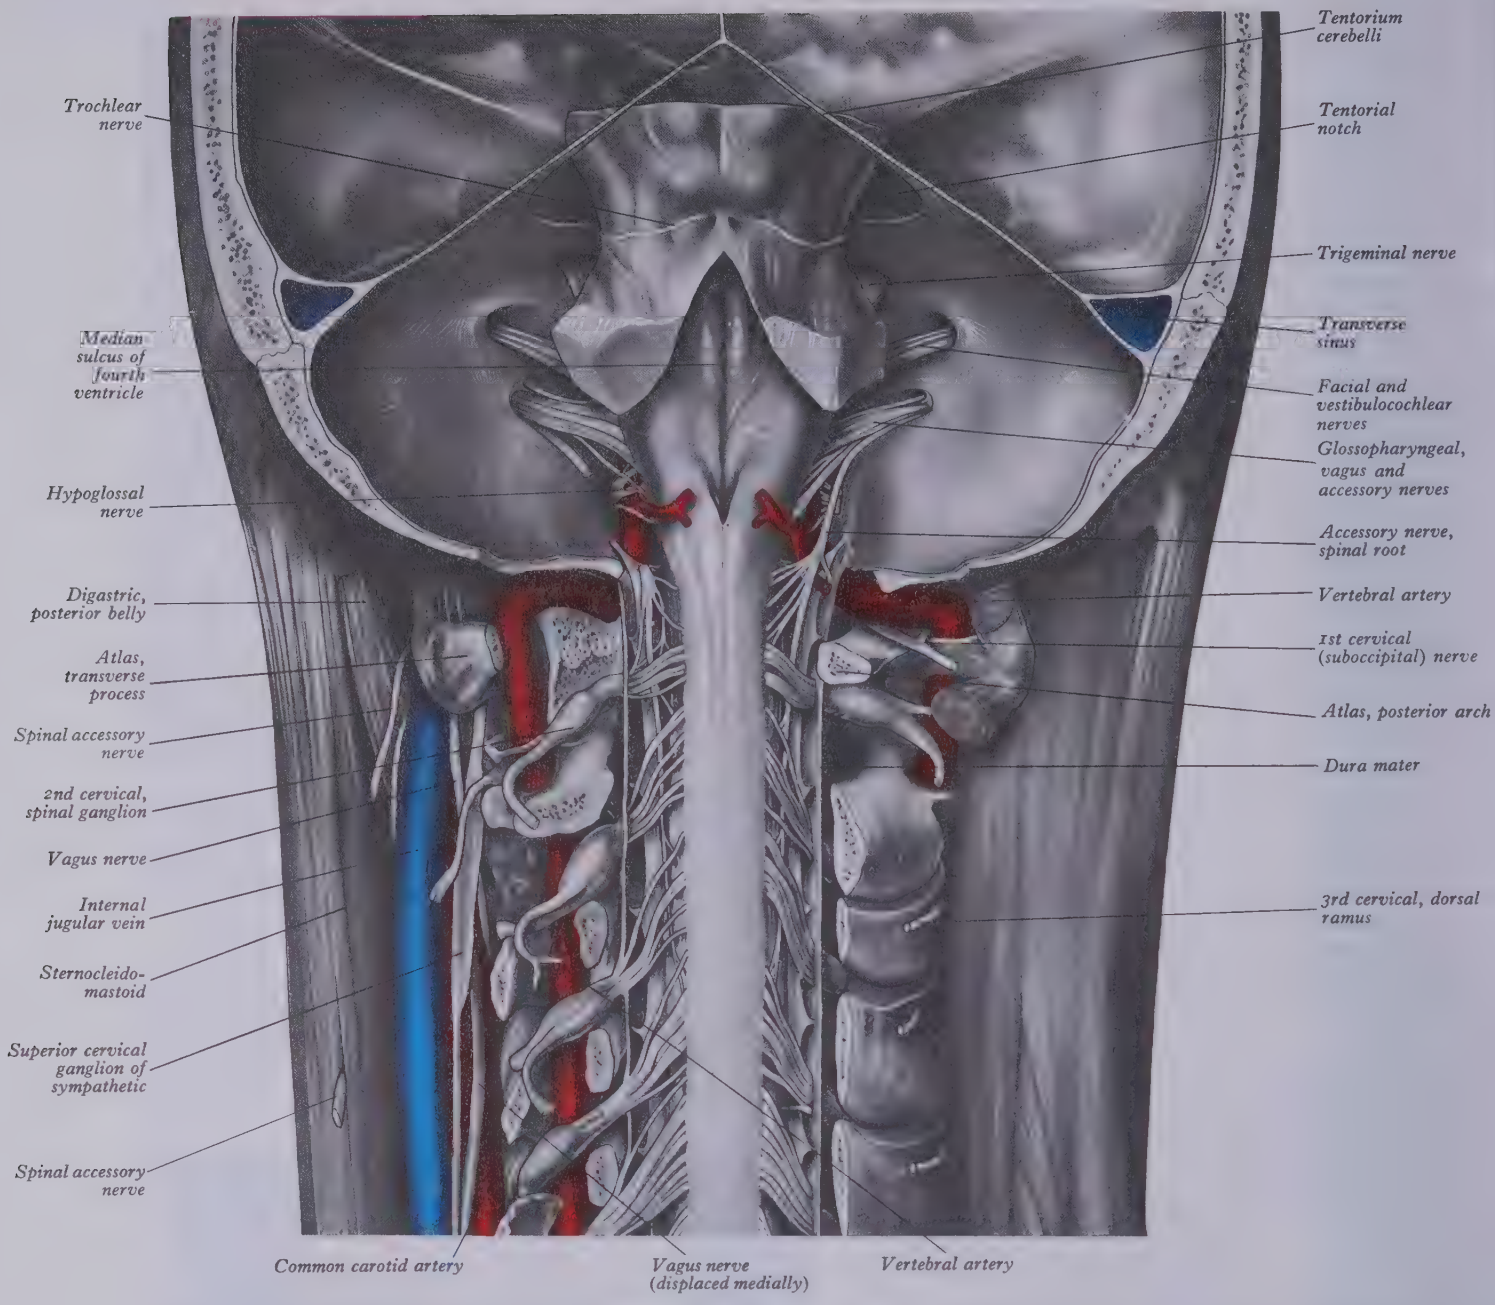
7.83 Schematic dissection to show the decussation of the pyramids.

7.84A The brain stem, posterolateral aspect.

(largely based on transverse sections). It is customary and convenient to describe it in sample transverse sections at several levels. In this account, both of the medulla and other brain-stem levels, this custom is followed, describing four successive medullary levels. The general disposition of some principal brain-stem nuclei is shown in Figures 7.86, 87, 122.

(1) **A transverse section in the lower medulla oblongata** is similar to the adjoining spinal cord, as would be expected (7.88). Dorsal, lateral and ventral funiculi exist and contain the same tracts; however, the grey matter shows two marked changes. Ventral grey columns are separated from the central grey matter by corticospinal fibres decussating dorsolaterally to the opposite lateral funiculus. In the upper medulla these fibres are ventromedial in the pyramids but below most cross, inclining dorsally (7.83) and decussating ventral to the central grey matter. The decussation is orderly: the fibres ending in the cervical segments decussate first. This *pyramidal decussation* is the most striking feature in caudal sections. Usually at least 75% of fibres cross and descend in the lateral funiculus as the crossed lateral corticospinal tract. Of the rest some descend ventromedially in the ipsilateral anterior funiculus as the anterior corticospinal tract; other uncrossed fibres descend with the crossed fibres in their *ipsilateral* lateral funiculus (7.83). The decussation displaces the anterior intersegmental tract towards the central grey matter, which, with its canal, becomes more dorsal. Continuity between the ventral grey column and central grey matter, maintained throughout the spinal cord, is severed; the column rapidly diminishes as it ascends, subdivided into a *supraspinal nucleus*, the efferent source of the first cervical nerve and a *spinal nucleus of the accessory nerve*, which is dorsolateral and, as its name indicates, provides some spinal accessory fibres. The supraspinal nucleus is continuous above with that of the hypoglossal. The spinal nucleus continues into the upper five cervical segments, where it is dorsolateral in the ventral grey column; rostrally it merges with the nucleus ambiguus (p. 956).

The dorsal grey column's outline is still recognizable, but modified. A narrow grey lamina appears in the fasciculis gracilis, continuous ventrally with the base of the posterior column, the lower end of the *nucleus gracilis*, which extends upwards to the caudolateral limit of the fourth ventricle, forming the gracile tubercle (p. 950). A second projection from the dorsal grey column, more laterally placed and beginning and ending at a higher level, invades the fasciculus cuneatus from its ventral aspect, as the *nucleus cuneatus*.



The substantia gelatinosa is prominent as an upward continuation of the apex of the dorsal grey column, becoming continuous with the inferior end of the *spinal trigeminal nucleus* (pp. 961, 1122); fibres of the *trigeminal tract* itself are between the nucleus and the surface (7.88) (cf. the dorsolateral tract at spinal levels).

(2) **A transverse section just above the pyramidal decussation** shows an increase in changes already noted and some new features (7.89).

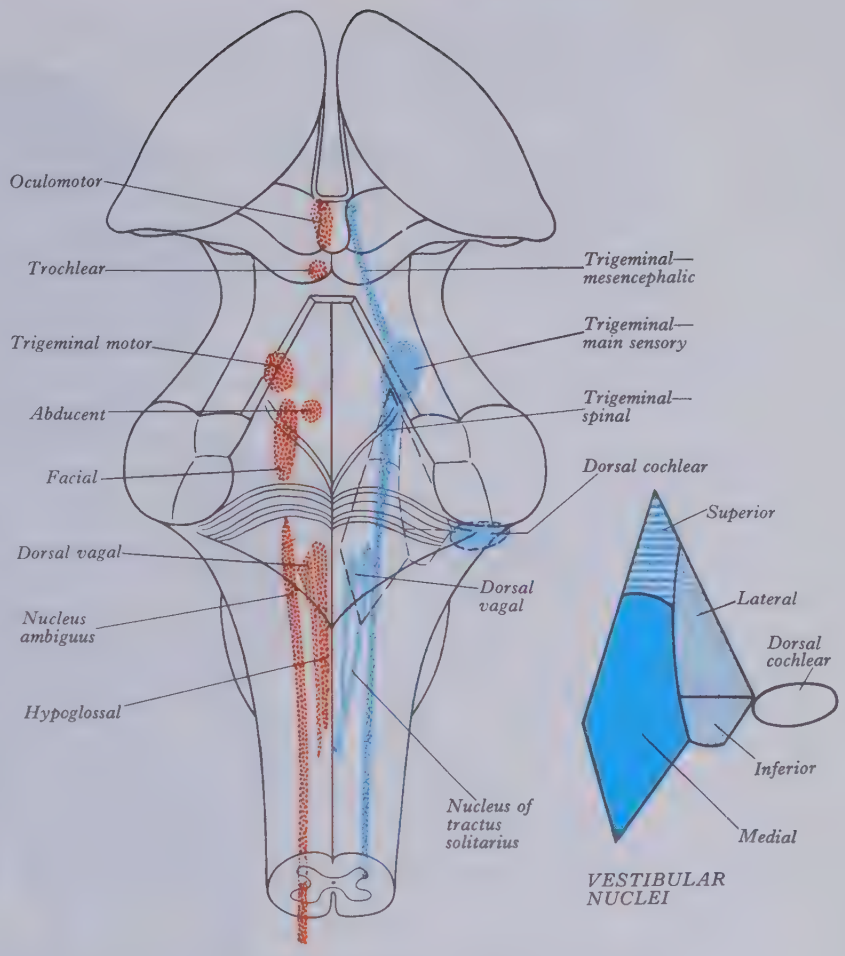
The nucleus gracilis is broader and the fibres of its fasciculus are groups on its dorsal, medial and lateral surfaces; the *nucleus cuneatus* is also larger. Both, here, retain continuity with the central grey matter but lose it at higher levels. Gracile and cuneate

7.84B The right lateral aspect of the brain stem, lentiform nucleus and corona radiata. For identification compare with 7.84A. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Department of Anatomy, Guy's Hospital Medical School, London.

7.85 Dissection exposing the brain stem and upper five cervical spinal segments after removal of large portions of the occipital and parietal bones and the cerebellum together with the roof of the fourth ventricle. On the left the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been removed.

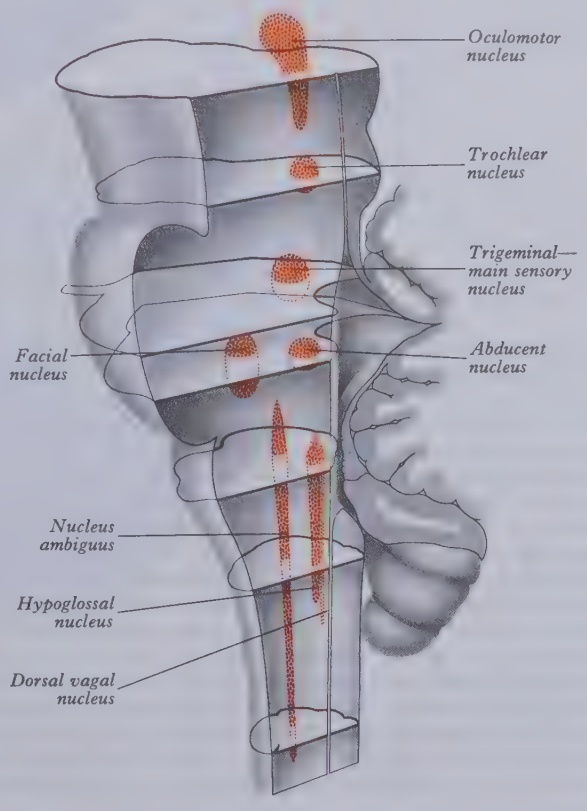
fascicular fibres (*uncrossed*) synapse in their respective nuclei at different levels. Axons (secondary) *from* the nuclei emerge ventrally *as internal arcuate fibres*, at first curving ventrolaterally around the central grey matter and then ventromedially to *decussate* (7.89), thereafter *ascending* near the median raphe as the *medial lemniscus*. This *lemniscal decussation* is dorsal to the pyramids, ventral to the central grey matter and thus the latter is even more dorsally displaced. Internal arcuate fibres sweep ventrally between the trigeminal spinal tract and the central grey matter. The gracile and cuneate nuclei are not simple sensory relay stations on a path widely considered the major route for the discriminative aspects of tactile and locomotor sensation. Much evidence has changed such concepts. The nuclear neuronal populations have long been considered uniform, despite the early distinction of types among them by Cajal (1900). Many are multipolar but vary in size and distribution. Taber (1961) and Kuypers & Tuerk (1964) have described several types of neurons in the nuclei and Biedenbach (1972) defined two zones of contrasting cytoarchitecture. In all the species examined, including monkeys, the upper regions of both nuclei are *reticular*, containing small and large multipolar neurons with long dendrites, and large round neurons with short and profusely branching dendrites, the last predominating below in both nuclei in clusters of various form. These zones differ in their connections; both receive terminals from the dorsal spinal roots at all levels but inferiorly they have a denser input. Dorsal funicular fibres from neurons in the spinal grey matter terminate only in the superior, reticular zone. In all connections there is variable ordering of terminals on the basis of spinal root levels, like the dorsal funiculi; but variable overlap has been observed (Millar & Basbaum 1975). In monkeys, the hind leg and tail are represented medially, the trunk ventrally and digits dorsally. There is also modal specificity; lower levels respond to low threshold cutaneous stimuli, reticular (upper) levels to inputs from fibres serving receptors in

the skin, joints and muscles. Both nuclei contain interneurons (Andersen et al 1964, Rustioni & Sotelo 1974), many are inhibitory. But primary spinal afferents synapse with multipolar neurons forming the major nuclear efferent projection, as a relay between the spinal cord and higher levels. Descending afferents from the somatosensory cortex (p. 1003), reaching the nuclei through the corticospinal tracts, appear restricted to the upper, reticular zones; they may inhibit or enhance activity at nuclear level, clearly a region of sensory modulation. The reticular zones also receive connections from the reticular formation proper (Spacek & Lieberman 1974). It is probable that 'feed back' from the gracile and cuneate nuclei to the spinal cord also exists. By antidromic stimulation (Dart 1971), retrograde horseradish peroxidase (Kuypers & Maisky 1975) and anterograde isotopic transport (Burton & Loewy 1977), it has been shown in cats and monkeys that neurons of these nuclei project to the ipsilateral spinal dorsal appendage, by fibres presumably involved in the observed depression of dorsal column activity (Hillman & Wall 1969).



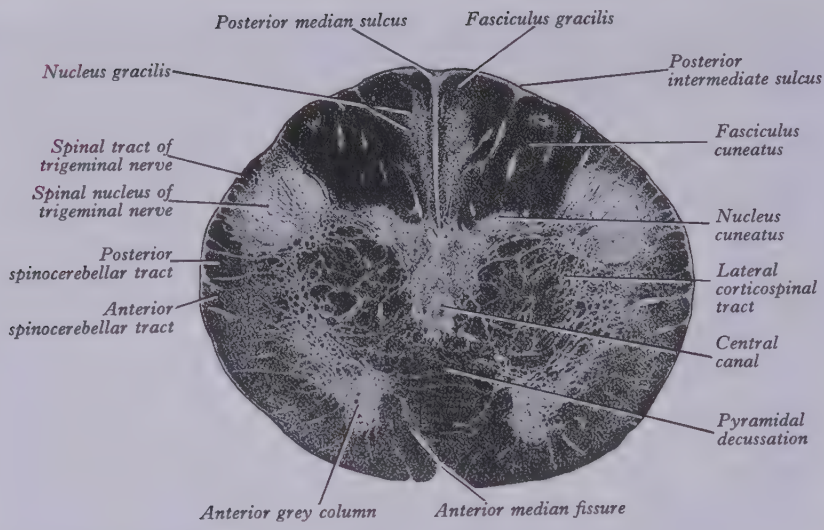
The *accessory cuneate nucleus*, dorsolateral to the cuneate, contains large neurons like those in the spinal thoracic nucleus; these form the *posterior external arcuate fibres* (p. 966), which enter the cerebellum by its ipsilateral inferior peduncle. The nucleus receives lateral fibres of the fasciculus cuneatus, derived from cervical segments. It provides the *cuneocerebellar tract* for proprioceptive impulses from the upper limb which enter the spinal cord above its thoracic nucleus. A group of neurons, '*nucleus Z*', was identified in cats by Brodal & Pompeiano (1957) between the upper pole of the nucleus gracilis and the inferior vestibular nucleus and said to be present in the human medulla (Webster 1977). Its input is probably from the dorsal spinocerebellar tract (Rustioni 1973); it may be a separated part of the gracile reticular zone, which it resembles; it is concerned in proprioception from the ipsilateral hind limb (Landgren & Silfvenius 1971).

The *nucleus of the spinal tract of the trigeminal nerve* (7.86) is separated from the central grey matter by internal arcuate fibres and from the lateral medullary surface only by the trigeminal spinal tract, which ends in it, and by some dorsal spinocerebellar tract fibres; the latter progressively incline dorsally and at a higher level enter the inferior cerebellar peduncle (p. 965).

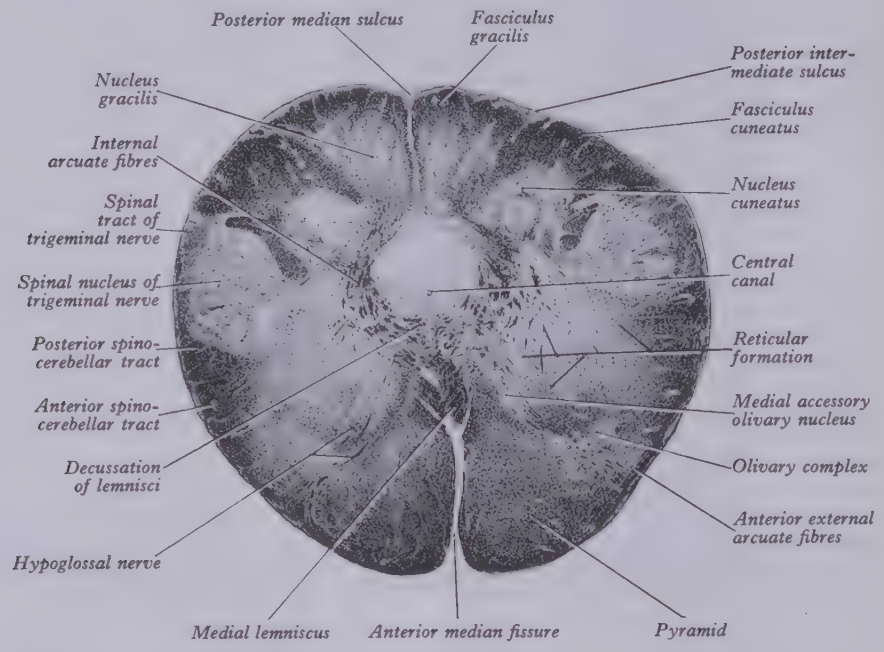


Two other nuclei occur at this level. One is dorsolateral to the pyramid, the other medial to it and near the median plane; these are parts of the *medial accessory olivary nucleus*, described with the inferior olivary nuclear complex (p. 956).

The central grey substance, at this level near the dorsal medullary surface, contains three bilateral nuclei. The prominent *hypoglossal nucleus*, of large motor neurons interspersed with myelinated fibres, is ventromedial in the central grey matter. It extends into the open part of the medulla, subjacent to the *trigonum hypoglossi* in the fourth ventricle's floor. Near it are several smaller groups, perhaps misnamed '*perihypoglossal complex*' or '*perihypoglossal grey*', for none is known to be connected with the hypoglossal nerve or nucleus. (However, the location of hypoglossal-related interneurons remains to be clarified.) These small groups include the *nucleus intercalatus*, *sublingual nucleus*, *nucleus prepositus hypoglossi* and *nucleus paramedianus dorsalis (reticularis)*, all containing neurons suggestive of reticular connections, definitely ascribed to the paramedian nucleus (Brodal 1957). Gustatory and visceral connections are attributed to the nucleus intercalatus; there is more convincing evidence that the perihypoglossal nuclei project to the cerebellum, at least in cats (Torvik & Brodal 1954) and monkeys (Mehler et al 1960). Representation of lingual musculature has been described in the hypoglossal nucleus (p. 1119).



Dorsolateral to the hypoglossal is the *dorsal vagal nucleus* containing neurons of at least two types, the larger with fine fibres innervating non-striated muscle and smaller fusiform neurons possibly concerned with visceral afferents. But many believe that



7.86 *Surface projection* of some cranial nerve nuclei on the dorsal aspect of the brain stem. Motor nuclei are in red, sensory in blue. The vestibular nuclei are indicated in the main diagram by interrupted lines and are shown in detail in the small diagram. The olfactory and optic centres are not shown.

7.87 Motor nuclei of the cranial nerves. The sectional planes shown correspond to those depicted elsewhere in the text.

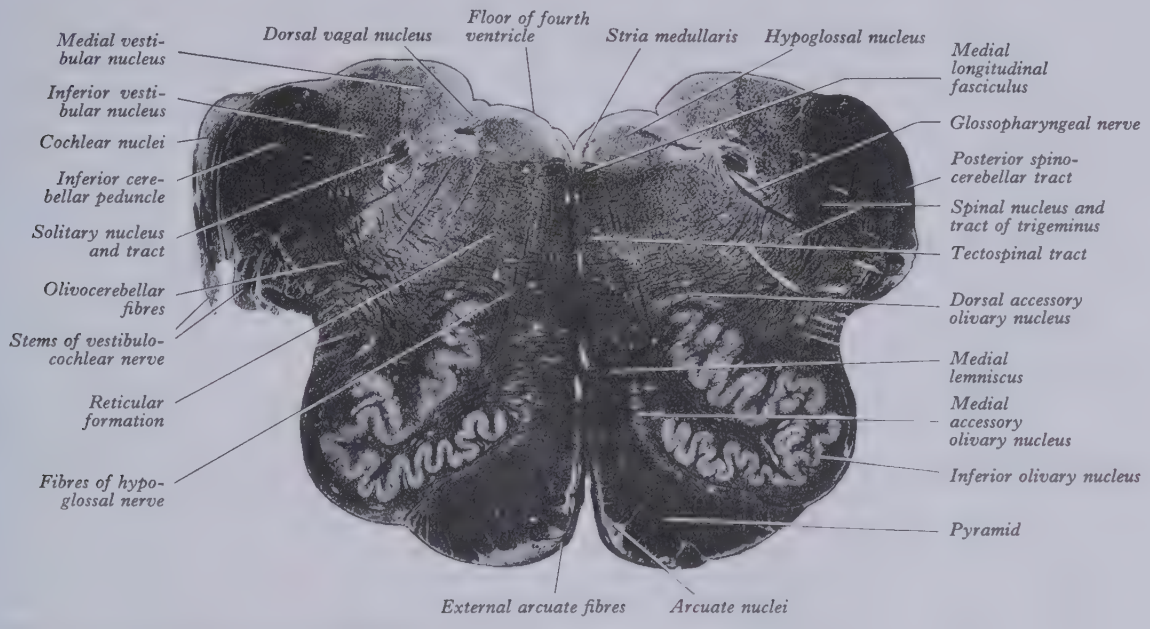
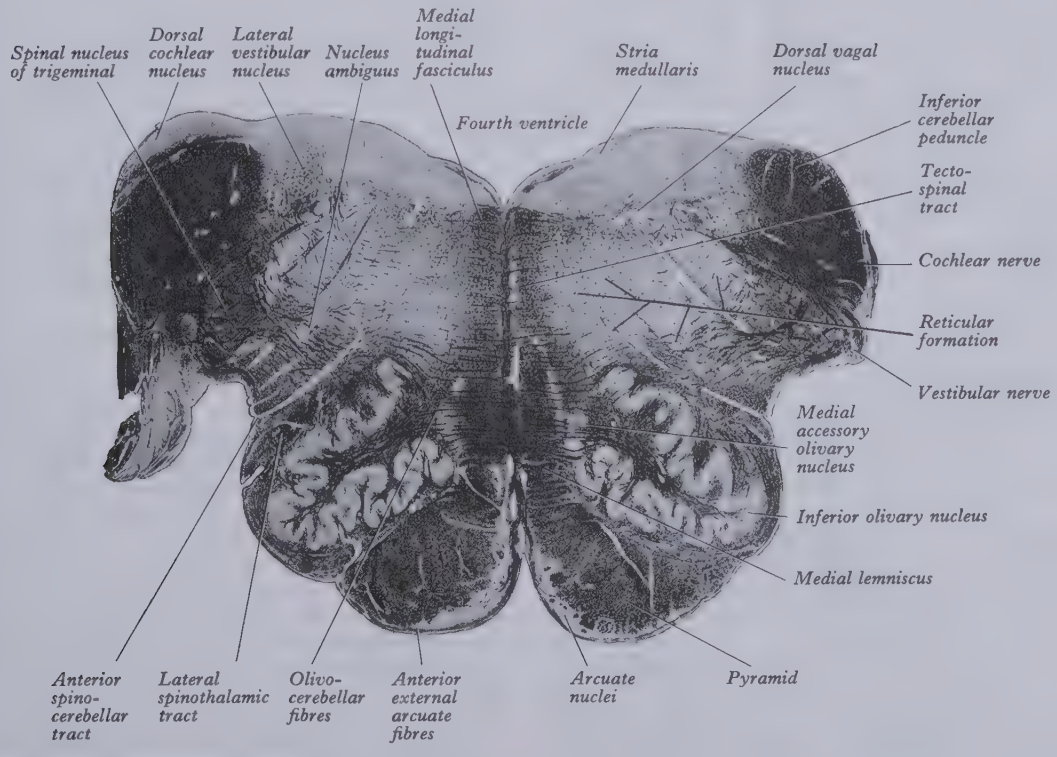
7.89 Transverse section through the medulla oblongata at the level of the decussation of the lemnisci. Weigert Pal preparation. Magnification ×6.

all vagal visceral afferent fibres end in the nucleus solitarius (vide infra). Superiorly the dorsal vagal nucleus is lateral to the hypoglossal, in the fourth ventricle's floor subjacent to the *trigonum vagi*. Dorsolateral to it at this level is the *nucleus solitarius* (strictly: *nucleus of the tractus solitarius*) (7.92), intimately related to the descending *tractus solitarius*. At the medulla's lower end these nuclei fuse dorsal to the central canal. As the nucleus solitarius ascends it lies deeper in the medulla, ventrolateral to the dorsal vagal nucleus and almost co-extensive with it. The tractus solitarius receives afferent fibres from the facial, glossopharyngeal and vagus nerves, entering it in descending order and conveying gustatory information from the lingual and palatal mucosa and, according to many, visceral impulses from the pharynx (glossopharyngeal and vagus) and from the oesophagus and abdominal alimentary canal (vagus). In this vertical representation there is some overlap (Schwartz et al 1951, Kerr 1962). Neurons in the solitary nucleus are smaller than those in the dorsal vagal nucleus; their axons may project to the thalamus and thence to the cerebral cortex, but attempts to establish this in cats have failed (Morest 1967). The dorsal vagal nucleus and nucleus ambiguus are connected. The solitary nucleus may project to the upper levels of the spinal cord through a *solitariospinal tract* (p. 932) in man (Collier & Buzzard 1903) and cat (Torvik 1957). This nucleus is considered to receive fibres from the spinal cord, cerebral cortex and cerebellum (Angaut & Brodal 1967). A neuronal group ventrolateral to the solitary nucleus has been termed the *nucleus parasolitarius* (Crosby et al 1962).



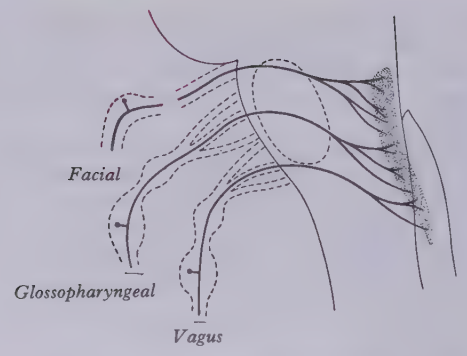
Numerous islets of grey matter are scattered centrally in the ventrolateral medulla, an area intersected by nerve fibres in all directions and hence termed the *reticular formation*. It exists at all medullary levels, extending to the pontine tegmentum and midbrain. The reticular formation at all brain-stem levels is considered in continuity (p. 988).

The medullary white matter is rearranged above the corticospinal decussation. The *pyramids* contain corticospinal and corticonuclear fibres, the latter distributed to nuclei of cranial nerves



and other medullary nuclei; they form two large ventral bundles flanking the anterior median fissure; dorsal are the accessory olivary nuclei and lemniscal decussation.

The *medial lemniscus* (p. 952) ascends from the lemniscal decussation on each side as a flattened tract, near the median raphe. The tracts ascend to the pons, increasing as fibres join from upper levels of the decussation. Ventral are the corticospinal fibres and dorsal the medial longitudinal fasciculus and tectospinal tract. In the decussation fibres are rearranged; those from the gracile are ventral to those from the cuneate nucleus; above this the medial lemniscus is also rearranged (p. 983): gracile fibres *become lateral*, cuneate fibres *medial*. At this level medial lemniscal fibres in monkeys (Ferraro & Barrera 1936) and chimpanzees (Walker 1937) show a laminar somatotopy on a segmental basis. This is almost certainly present in mankind.



The *medial longitudinal fasciculus*, a small compact tract near the midline and ventral to the hypoglossal nucleus, is continuous with the ventral spinal intersegmented tract; at this medullary level it is displaced dorsally by the pyramidal and lemniscal decussations. It ascends in the pons and midbrain in the *same* relation to the central grey matter and midline and is therefore

near the somatic efferent column. Its fibres have short courses in it, being from a variety of sources, and are detailed on p. 985.

The *spinocerebellar, spinotectal, vestibulospinal, rubrospinal and lateral spinothalamic (spinal lemniscal)* tracts are all in the ventrolateral area, limited dorsally by the spinal trigeminal nucleus, ventrally by the pyramid.

(3) **A transverse section level with the fourth ventricle's lower end** (7.90) shows some new features with most of those already described. The total of grey matter is increased by the large olivary nuclear complex, arcuate nucleus and nuclei of the vestibulocochlear, glossopharyngeal, vagus and accessory nerves.

7.93 Some of the afferent components of the inferior cerebellar peduncle; the efferent components have been omitted. See text for further details.

The *inferior olivary nucleus* is hollow, irregularly crenated, with a longitudinal medial hilum and surrounded by myelinated fibres forming the *olivary amiculum*. Dorsolateral to the pyramid, it underlies the olive but ascends to the pons. It contains small neurons, most of which form the *olivocerebellar tract*, emerging from the hilum or through the adjacent wall to run medially, intersecting the medial lemniscus (7.90, 91). Its fibres *cross the midline*, decussate and sweep dorsal to or traverse the opposite olivary nucleus, intersecting the lateral spinothalamic and rubrospinal tracts and spinal trigeminal nucleus to enter the contralateral inferior cerebellar peduncle. The afferent olivary connections are ascending and descending; ascending fibres, mainly crossed, arrive from all spinal levels in the *spino-olivary tracts*; ascending connections also arrive via the dorsal white columns (Hand & Liu 1966). Descending fibres come from the cerebral cortex, thalamus, basal nuclei, red nucleus and central grey of the midbrain (Walberg 1960), some perhaps in the *central tegmental fasciculus* (Jansen & Brodal 1950).

The *medial accessory olivary nucleus* is a curved grey lamina, concave laterally, between the medial lemniscus and pyramid and the ventromedial aspect of the inferior olivary nucleus. The *dorsal accessory olivary nucleus* is a similar lamina dorsomedial to the inferior olivary nucleus. Both nuclei are connected with the cerebellum. The accessory nuclei are phylogenetically older than the inferior, connecting with the paleocerebellum (p. 963); the inferior nucleus occurs only in mammals, enlarging caudally during its evolution. In all connections, cerebral, spinal and cerebellar, olivary nuclei sometimes display very specific somatotopy, particularly in their cerebellar connections, detailed later (pp. 974, 975, 978). The *arcuate nuclei* are curved, interrupted bands, anteromedial to the pyramids; they are said to be displaced nuclei pontis (Rasmussen & Peyton 1946). Anterior external arcuate fibres are derived from them.

The central grey matter, at this level spread over the ventricular floor, contains the *hypoglossal* and *dorsal vagal nuclei* and the *nucleus solitarius* ventrolateral to the vagal; these and the inferior cerebellar peduncle are near the lower ends of the *inferior and medial vestibular nuclei* (p. 958). Between the hypoglossal and dorsal vagal nuclei is the *nucleus intercalatus* (p. 954).

A group of large motor neurons, *the nucleus ambiguus*, is isolated deep in the reticular formation and descends as far as the upper end of the dorsal vagal nucleus. Fibres emerging from it above join the glossopharyngeal nerve, those at a lower level join the vagus and cranial accessory nerves. Below, it continues into the spinal accessory nucleus (p. 951). It has large motor neurons, whose fibres innervate striated muscle of branchial origin (p. 1113). These first pass dorsomedially, then curve laterally to join the emerging fila of the cranial accessory, vagus and glossopharyngeal nerves. The nucleus displays several groups of neurons in man and other mammals; some representation of the muscles innervated has been established (Lawn 1966, and p. 1114). At its upper end, between this and the facial nucleus, is a small *retrofacial nucleus*; though in line with the special visceral efferent nuclei, it is a reputed source of general visceral efferent vagal fibres.

The gracile and cuneate nuclei, diminishing and irregular, fill the dorsolateral region; ventral is the *spinal trigeminal* tract and *nucleus*. The *cochlear nuclei* are superficial to the inferior cerebellar peduncle (pp. 958, 963). The white matter shows little change except for the development of the inferior cerebellar peduncles lateral to the fourth ventricle. The pyramid, medial lemniscus, tectospinal tract and medial longitudinal fasciculus are unchanged in position. Olivocerebellar tracts sweep across the midline, turning dorsally to join the inferior peduncles (p. 965). *Anterior external arcuate fibres*, bilateral in origin, arising from both arcuate nuclei, emerge from the anterior median fissure to pass dorsolaterally over the surface of the pyramid, olive and spinal trigeminal tract to reach the posterior spinocerebellar tract, then together ascending into the inferior cerebellar peduncle (7.93).

Hypoglossal radicles emerge ventrally from their nucleus, traverse the reticular formation lateral to the medial lemniscus and medial to (sometimes through) the olivary nucleus and curve laterally to emerge superficially through the ventrolateral sulcus.

A small lesion in the ventral medulla at this level may involve the corticospinal tract and hypoglossal nerve, causing characteristic paralyses in ipsilateral lingual muscles and contralateral limbs. The reticular formation is traversed dorsally by vagal radicular fibres and their dorsal nucleus, the nucleus ambiguus and nucleus solitarius, all emerging at the dorsolateral sulcus.

The *spinal lemniscus* (p. 935), dorsal to the inferior olivary nucleus, is separated from the surface by the anterior spinocerebellar and spinotectal tracts. Clinical and experimental evidence indicates somatotopy among its fibres: those for the lower limb are superficial, for the upper limb deep and for the trunk intermediate. At it ascends in the medulla, the lemniscus is near the nucleus ambiguus; a ventral lesion in the reticular formation may hence paralyse the ipsilateral vocal fold and soft palate, with contralateral loss of pain and temperature sensibility.

(4) **A transverse section of the medulla at its upper limit** shows little change. The dorsal surface is relatively flat but undulant and may show a few fibres of the stria medullaris (p. 960). The inferior olivary nucleus is unchanged, but accessory olivary nuclei are diminishing (7.91). The medial vestibular nucleus is wider and dorsolateral to the dorsal vagal nucleus, separating the latter from the floor of the rhomboid fossa. The inferior vestibular nucleus is between the medial vestibular nucleus and the inferior cerebellar peduncle. At the pontomedullary junction the *lateral vestibular nucleus* (p. 958) replaces the inferior vestibular nucleus and the *cochlear nuclei* usually appear. The nucleus solitarius, spinal trigeminal tract and nucleus and the nucleus ambiguus are almost unchanged in position.

The white substance at this level is also little changed: the lateral spinothalamic tract (spinal lemniscus) ascends dorsal to the olivary nucleus, its fibres retaining their somatotopic arrangement (p. 935). The *inferior cerebellar peduncle* (p. 965) is a large dorsolateral bulge. The *medial lemniscus* widens ventrally and moves between the pyramid and the narrowing olivary nucleus (7.97), its dorsal part receding from the tectospinal tract and medial longitudinal bundle. Entering the pons, it spreads coronally (7.96) in the ventral tegmentum (p. 959). It contains fibres for proprioceptive and tactile sensibility. As it ascends in the medulla it is probably joined by the anterior spinothalamic tract (p. 932). In the pons, therefore, it contains fibres serving proprioception, tactile and pressure sense from the contralateral lower limb, trunk and upper limb; fibres from the lower limb are lateral, from the upper limb intermediate and from the neck medial in position.

The medullary reticular formation is described on pp. 988–996.

THE PONS

The pons lies ventral to the cerebellum, below the midbrain and above the medulla with which it is continuous, but superficially demarcated from it by a transverse ventrolateral sulcus in which the abducent, facial and vestibulo-cochlear nerves appear. Its *ventral surface* (7.81, 82) is markedly convex transversely, less so vertically. Its transverse fibres 'bridge' the midline, converging on each side into a large but compact *middle cerebellar peduncle*. It adjoins the sphenoid's dorsum sellae and basilar occipital bone. The surface has a shallow vertical median *sulcus basilaris*, usually containing the basilar artery and bounded bilaterally by prominences due partly to the corticospinal fibres descending in the pons. Lateral to these, near mid-pontine level, the trigeminal nerves emerge, each with a superomedial motor root and a larger, inferolateral sensory root; verticals just lateral to these roots are arbitrary boundaries between the ventral pontine surface and middle cerebellar peduncles. The *dorsal surface*, hidden by the cerebellum, contributes to the rostral half of the rhomboid fossa (p. 980). Transverse sections show a dorsal *tegmentum* and a *ventral (basilar) part*, the former a continuation of the medulla, excluding its pyramids. The ventral pons contains bundles of *longitudinal fibres*, some continued into the pyramids, some ending in many pontine or medullary nuclei; also present are many *transverse* fibres and scattered *nuclei pontis*.

('Pons' is commonly used in two senses: to denote the external protuberance of the ventral pons, or to include both this and the tegmentum, i.e. the whole brain stem between the medulla and midbrain.) In mammals, the degrees of development of the cerebral hemispheres, ventral pons and cerebellum (neocerebellum, p. 963) are correlated. The ventral pons is absent in non-mammalian vertebrates, present in all marsupials (*Metatheria*) and mammals (*Eutheria*) and possibly present in monotremes (*Prototheria*). It enlarges *pari passu* with the cerebrum and cerebellum, ascending the mammalian evolutionary scale.

INTERNAL STRUCTURE OF THE PONS

The ventral (basilar) pons is similar in structure at all levels. Its longitudinal fascicles (7.97) contain corticopontine, corticonuclear and corticospinal fibres, descending from the midbrain's crus cerebri (p. 981), which enter the pons compactly but rapidly disperse into fascicles, separated by *nuclei pontis* and transverse pontine fibres. *Corticospinal fibres* traverse the pons to the medullary pyramids, converging again here into compact tracts (p. 950); *corticonuclear fibres* accompany them, some diverging to both contralateral (and some ipsilateral) nuclei of cranial nerves and other nuclei in the pontine tegmentum, the rest reaching the pyramids. Clinical evidence supports the contention that the facial and other nuclei (p. 961) also receive ipsilateral corticonuclear fibres. *Corticopontine fibres*, from the frontal, temporal, parietal and occipital cortex, end in the nuclei pontis (7.94); axons from the latter are the *transverse pontine fibres* (pontocerebellar) which after midline decussation continue to form the contralateral middle cerebellar peduncle. Frontopontine axons end in the nuclei pontis above the level of the emerging trigeminal roots and are relayed to the contralateral cerebellum forming the upper transverse pontine fibres. A few pontocerebellar fibres do not cross and end as mossy fibres in the cerebellar cortex (p. 971). A degree of somatotopy is maintained in these connections. Axons from the midbrain tectum (*tectopontine fibres*) may also relay in the nuclei pontis (Pearce 1960), perhaps some also from the spinal levels (*spinopontine fibres*).

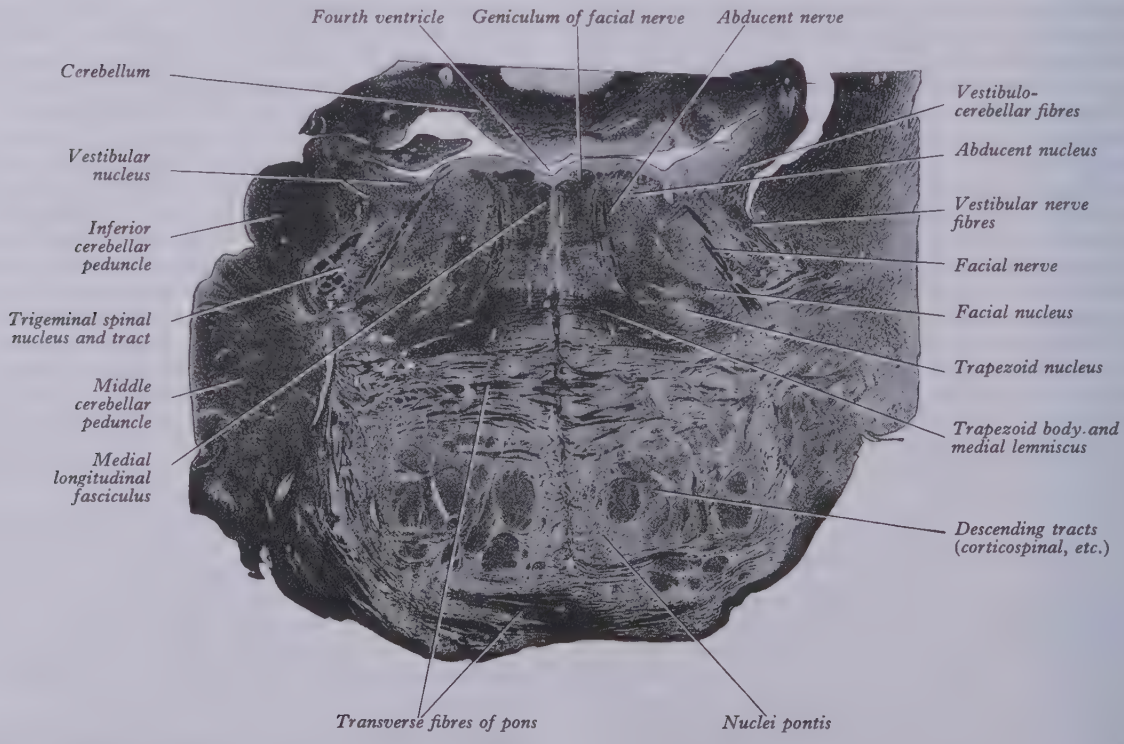
The *nuclei pontis* include all the neurons scattered in the ventral pons. Varying in size and shape, they are, as indicated, relays on paths from the cerebral cortex to the cerebellum; they migrate ventrally and upwards from the rhombic lip (p. 980) but do not all reach the ventral pons; some remain as an oblique dorsolateral ridge across the inferior cerebellar peduncle, forming the *nucleus of the circumolivary bundle* (corpus pontobulbare), whose axons are said to ascend vertically on the surface between the emerging facial nerve and eighth cranial nerve on its lateral side (p. 981). Afferents to the nucleus have been claimed to traverse the pons descending longitudinally with the corticospinal fibres, leaving in the medulla to *ascend*, recurving dorsally over the olive to the nucleus, as part of the *fasciculus circumolivaris pyramidis* (7.103).

The tegmental pons varies at different levels, especially in its cytoarchitecture but is adequately described for general purposes by examples of the lower and upper sections.

Transverse section through the pontine lower tegmentum transects the facial colliculus (7.94), containing the motor nucleus of the abducent and the geniculum of the facial nerves. More deeply placed is the facial nucleus, the nearby vestibular and cochlear nuclei and other isolated neuronal groups. The *medial vestibular nucleus* thus continues a little from the medulla into the pontine tegmentum, with the *lateral vestibular nucleus* between it and the inferior cerebellar peduncle.

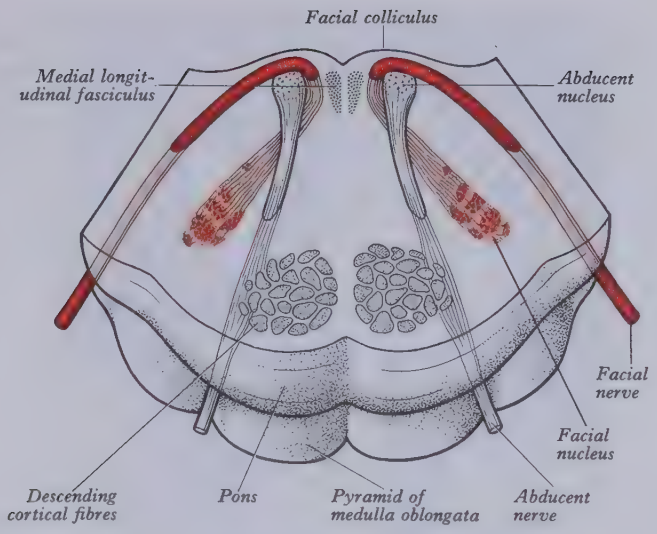
The vestibular nuclei, subjacent to the roughly rhomboid vestibular area (p. 980), are laterally placed in the fourth ventricle's rhomboid fossa. They comprise medial, lateral,

superior and inferior vestibular groups receiving fibres from the eighth cranial nerve's vestibular part and sending axons to the cerebellum, medial longitudinal fasciculus, spinal cord and lateral lemniscus. The *medial vestibular nucleus* broadens, then narrows as it ascends from the upper olivary level into the lower pons, separating the dorsal vagal nucleus from the fourth ventricle's floor. It is crossed by the striae medullares nearer the floor. Below, it is continuous with the nucleus intercalatus. The *inferior vestibular nucleus* (the smallest) lies between the medial vestibular nucleus and inferior cerebellar peduncle, from the level of the upper end of the nucleus gracilis to the pontomedullary junction. It is traversed by descending fibres of the vestibular nerve and the vestibulospinal tract. The *lateral vestibular nucleus* is just above the inferior, ascending almost to abducent nuclear level, and is composed of large multipolar neurons, which are the main source of the vestibulospinal tract. The *superior vestibular nucleus* is small and lies above the medial and lateral nuclei.



Vestibular fibres of the vestibulocochlear nerve enter the medulla between the inferior cerebellar peduncle and the trigeminal spinal tract and approach the vestibular area, separating into ascending and descending fascicles. Fibres ending in medial, lateral and inferior vestibular nuclei descend medial to the inferior cerebellar peduncle and mingle with neurons of the inferior nucleus. Ascending fibres enter the superior or medial nuclei; a few enter the cerebellum directly via its inferior peduncle (superficially in the *juxtarestiform body*), to end in the nucleus fastigii, flocculonodular lobe and uvula (p. 965). Vestibular nuclei project extensively to the cerebellum (p. 966) and also *receive* axons from its cortex and fastigial nuclei (p. 975). Their spinal projections via the vestibulospinal tracts have been described (p. 945); vestibular axons also reach the spinal cord in the medial longitudinal fasciculus (p. 939) and some also reach cerebral levels, possibly for bilateral cortical representation. The vestibular nuclear complex also projects to the pontine reticular nuclei (p. 990) and, via the medial longitudinal fasciculus, to motor nuclei of the ocular muscles.

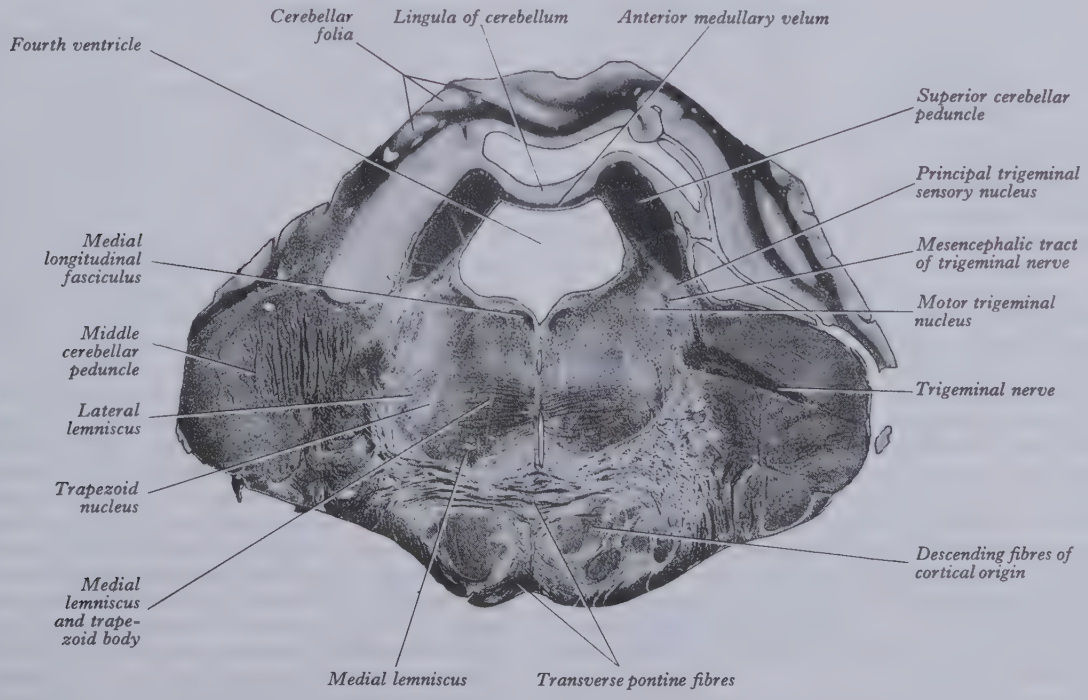
Minor neuronal groups near the vestibular nuclei have been observed; only the *interstitial nucleus* is known to receive primary vestibular axons. The *nucleus parasolitarius* (p. 954) may be linked to the vestibular complex by afferent fastigial connections (p. 975). Nuclear vestibular neurons much exceed afferent fibres in the nerve, which reach only limited regions of the nuclei; many cells may therefore be interneurons and many also sources of the projections already mentioned. Evidence favours spatial representation of the vestibular apparatus in the nuclei (p. 1111). For appraisal of earlier experimental research on vestibular paths see Rasmussen & Windle (1960) and Brodal et al (1962).



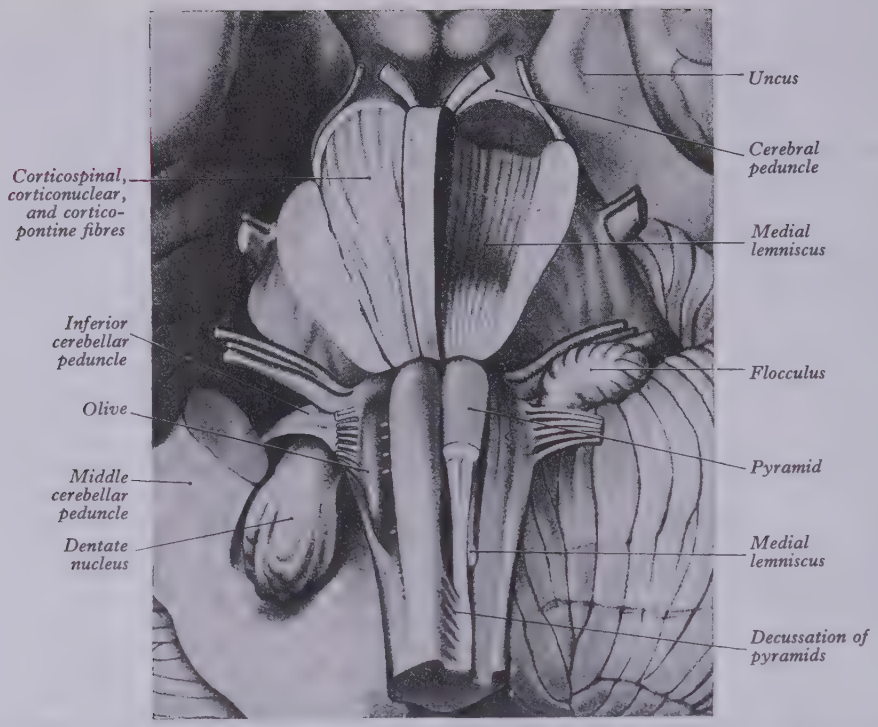
Fibres of the vestibulocochlear nerve's cochlear division partially encircle the inferior cerebellar peduncle laterally and end in *dorsal* and *ventral cochlear nuclei*, projecting slightly on its surface. The *dorsal cochlear nucleus*, or auditory tubercle (p. 959), is posterior on the peduncle and continuous medially with the rhomboid fossa's vestibular area. The *ventral cochlear nucleus* is on its ventrolateral aspect, between the cochlear and vestibular fibres of the eighth cranial nerve, both parts of which, with the cochlear nuclei, are usually at the level of the pontomedullary junction.

The ventral cochlear nucleus, complex in cytoarchitecture, contains many neuronal types (e.g. giant, large and small spherical, multipolar, granular), the variants being segregated in separate nuclear regions (Cajal 1909, Lorente de No 1933 and p. 1112). Marked topographical order has been demonstrated in cochlear nerve terminals within the nucleus, different parts of the spiral organ and differing stimulation frequencies being related to neurons serially arrayed antero-inferiorly in the ventral nucleus (Schuknecht 1960, Whitfield 1960). All cochlear nerve fibres enter the nucleus, bifurcating into ascending branches which end in the ventral nucleus and descending ones traversing it to reach the dorsal nucleus (vide infra). Human cochlear fibres are estimated at about 25 000; since the ventral nucleus alone contains at least three times as many neurons in cats, whose cochlear fibres are half the human complement, cochlear neurons greatly exceed these fibres. Ferraro & Minckler (1977) also found fibre numbers in the lateral lemniscus much more numerous (p. 1112). A minor fraction of the cochlear neurons receive terminals from the nerve, though each fibre may connect with several (Lewy & Kobrak 1936). Terminals are limited to the antero-inferior region of the ventral nucleus, whose elements are probably in large part local interneurons.

The dorsal cochlear nucleus is almost continuous with the ventral, separated only by a thin stratum of nerve fibres. It also



7.94 Transverse section through the pons at the level of the facial colliculus. Weigert Pal preparation. Magnification × 3·5.



7.95 Diagram of the central course of the fibres of the facial nerve, superior aspect, in a transverse section of the pons.

has a complex laminar pattern, with a range of cell types like those in the ventral nucleus but also a fusiform or pyramidal type peculiar to it. Again, the terminals appear limited in distribution, being, as mentioned, descending branches of cochlear fibres (Olsen 1969).

Though, quantitatively, their cellular origins are not precisely known, axons of most neuronal types (all having efferent axons, with few confined to the nucleus) nevertheless leave to end at pontine levels in the superior olivary, trapezoid and lateral lemniscal nuclei (vide infra). They leave the cochlear nuclei by three routes. (1) A ventral contingent, the most numerous, decussates as the *trapezoid body*, level with the pontomedullary junction (7.96). These axons ascend slightly while decussating; a few, however, do not cross, synapsing in the ipsilateral superior olivary nuclei. Those decussating relay in the contralateral nuclei; and in both the next order of axons ascend in the corresponding *lateral lemniscus*. A few decussating fibres traverse the contralateral superior olive into the lateral lemniscus to relay in lemniscal nuclei. (2) Some axons from ventral cochlear neurons pass dorsally, superficial to the descending trigeminal spinal fibres, the cerebellar fibres in its inferior peduncle and to axons of the *dorsal* cochlear nucleus (vide infra). These ventral cochlear fibres, smaller than those in the trapezoid decussation, swerve ventromedially across the midline, ventral to the medial longitudinal fasciculus as *intermediate acoustic striae* (Held 1893); their further path is uncertain; they probably ascend in the opposite lateral lemniscus. (3) The most dorsal fibres, from the dorsal nucleus, curve dorsomedially round the inferior cerebellar peduncle towards the midline as *dorsal acoustic striae* (Monakow 1905), not to be confused with the striae medullares (p. 960), to which they are ventral. They incline ventromedially and cross the midline to ascend in the opposite lateral lemniscus, probably relaying in its nuclei.

7.96 Transverse section of the pons at the level of the trigeminal nerve. Weigert Pal preparation. Magnification × 2·5.

7.97 Ventral aspect of a dissection of the pons, the medulla oblongata and the right cerebellar hemisphere. In the pons and medulla, the dissection is deeper on the left (right side of figure). Note the spiralling of the medial lemniscus from sagittal (below) to oblique coronal (in pons).

The *superior olivary complex* is lateral in the reticular formation, level with the pontomedullary junction. Medial to it are the trapezoid nucleus and body, inferior to it the much larger inferior olivary group (p. 956). The superior complex includes several named nuclei and nameless smaller groups (Irving & Harrison 1967). The *lateral superior olivary nucleus* ('S-shaped segment' of the feline olivary complex) is small in primates. The *medial (accessory) superior olivary nucleus* (para-olivary nucleus of Minckler) is larger in man. Medial again to this is the trapezoid nucleus (vide infra). Dorsal in the complex is a *retro-olivary group*, the reputed origin of efferent cochlear fibres described below. Some internuclear connections have been described. Unit recording from the feline lateral nucleus (Warr 1966) demonstrated a tonotopical organization, adjoining neurons being connected to the ipsilateral cochlear fibres concerned with different but related frequencies. The medial superior olivary nucleus receives impulses from both spiral organs; evidence suggests its involvement in auditory sound source localization. With the trapezoid nuclei, superior olivary complexes are the main relay stations of the ventral and the largest cochlear projection. These intricate connections are not yet well established in man. Neuronal counts of certain human nuclei have been recorded by Ferraro & Minckler (1977).

The *trapezoid nucleus* has a ventral component of neurons scattered among the trapezoid fascicles and a more compact dorsal nucleus, medial to the superior olivary complex. Though usually regarded as auditory relays, human trapezoid nuclei remain in this an uncertain issue. Some trapezoid axons may enter the medial longitudinal fasciculus, ascending to end in trigeminal, facial, oculomotor, trochlear and abducent nuclei, mediating reflexes involving the stapedius, tensor tympani and extraocular muscles.

The *nucleus of the lateral lemniscus* consists of small groups of neurons among lemniscal fibres. Lateral and medial groups may receive afferent axons from both cochlear nuclei; their efferents enter the midbrain along the lemniscus, with further connections considered later (pp. 986, 1015). Total neuronal counts of 18 000–24 000 have been recorded in human lemniscal nuclei (Ferraro & Minckler 1977).

Efferent cochlear axons travel in the cochlear nerves to the spiral organ (Held 1983, Rasmussen 1967). Though few (about 500 in cats), they may be involved in hearing, perhaps by inhibitory and excitatory reflexes via cochlear nuclei (Allanson & Whitfield 1955). Lateral inhibition has been demonstrated by unit recording at trapezoid level. Efferent cochlear fibres appear to come from retro-olivary neurons in the superior olivary complex, fibres from both sides proceeding to both cochleae. Borg (1973) has confirmed projection to the cochlea, in rabbits, from neurons both dorsal and ventral to the superior olivary nucleus, describing also a descending connection from the inferior colliculus to the olivary complex (confirming Munzer & Wiener 1902). Since a descending projection from the medial geniculate body to the inferior colliculus has been demonstrated, a complete efferent corticocochlear pathway appears established (p. 1015).

Striae medullares of the fourth ventricle are *not* auditory nerve fibres; evidence suggests that they are an *aberrant cerebropontocerebellar* connection, in which arcuate nuclei (p. 956), the pontobulbar body (p. 957) and external arcuate fibres (p. 956) are involved. Disagreement exists regarding the pontobulbar body. This description merely presents a consensus of views, of variable reliability. Embryological evidence (p. 185) suggests that some neurons, migrating ventrally to the pons from the rhombic lip to form the nuclei pontis, remain near the fourth ventricle as the pontobulbar nucleus. Others migrate further, scattered ventrally over much of the surface of the pyramids as arcuate nuclei, just below the pons. Both groups may receive corticobulbar projections, descending to the arcuate nuclei in the pyramids with the corticospinal fibres. Axons from both arcuate groups spread round the medulla, above and below the inferior olive, their fascicles being superficially visible. All these fibres, collectively the external arcuate fibres, enter the inferior cerebellar peduncle. Some so-called '*external*' arcuate fibres pass dorsally from arcuate nuclei *through* the medulla near its midline; near the fourth ventricle's floor they decussate and then turn laterally under the ependyma, entering the cerebellum by its inferior peduncle. They are striae medullares, also known as the *arcuatocerebellar tract*. This may end in the flocculus (Szentágothai 1955); some fibres are said to end in the pontobulbar nucleus but may be confused with its projection fibres; some may travel ventrally in the *circumolivary fasciculus*, which skirts below the inferior olive and are usually visible on the surface. The fasciculus and pontobulbar nucleus have been found absent in pontine aplasia, a confirmation of

their pontocerebellar association (Baumgarten 1959). Efferent circumolivary fibres, passing ventrally, join the arcuatocerebellar tract, also reaching the striae medullares to enter the contralateral inferior cerebellar peduncle. However, as noted (p. 960), pontobulbar afferents have also been ascribed to the circumolivary fasciculus; the precise relation of efferent and afferent fibres to the fasciculus remains uncertain.

The abducent nucleus is paramedian in the central grey matter, in line with the trochlear, oculomotor and hypoglossal nuclei, it forms a *somatic motor column* (p. 185). It is near the medial longitudinal fasciculus, which lies ventromedial; via this fasciculus, vestibular and cochlear nuclei and those of other cranial nerves, especially the oculomotor, connect with the abducent, also related to the emerging facial nerve (vide infra). Efferent abducent axons pass ventrally, descending through the reticular formation, trapezoid body and medial lemniscus and traversing the ventral pons to emerge at its inferior border (p. 1107).

The facial nucleus is deeper, lying ventrolateral in the pontine reticular formation, posterior to the dorsal trapezoid nucleus; the trigeminal spinal tract and nucleus are dorsolateral. The facial nucleus receives both crossed corticonuclear fibres and a smaller ipsilateral number (p. 1111) and ipsilateral rubroreticular tract fibres. Axons of its large motor neurons form the facial nerve. At first they incline *dorsomedially* towards the fourth ventricle, below the abducent nucleus (7.95) and ascending medial to it near the medial longitudinal fasciculus, through which the facial may communicate with other cranial nerves. Its fibres now curve anterolaterally round the upper pole of the abducent nucleus, as the *geniculum of the facial nerve*, and descend anterolaterally through the reticular formation. Finally they pass between their own nucleus medially and the spinal trigeminal nucleus. This unusual course provided apparent evidence for neurobiotaxis (p. 185). In 10 mm human embryos the nucleus is in the fourth ventricle's floor, in the branchial (special visceral) efferent column, and is above the abducent nucleus. As growth proceeds, the facial nucleus migrates at first downwards, dorsal to the abducent, then ventrally to its final position. As it migrates its axons elongate, their subsequent course marking the path of migration.

The facial nucleus receives corticonuclear fibres for volitional control and (among other sources) afferents from its own sensory root (via the nucleus solitarius) and the spinal trigeminal nucleus. These infracortical afferents complete local reflex loops, as in the spinal segments. It is opined that the facial nucleus migrated to remain near the nucleus solitarius and the spinal trigeminal nucleus.

Facial neurons are grouped; those innervating muscles in the scalp and upper face are dorsal and believed to receive bilateral corticonuclear fibres (Papez 1927, Buskirk 1945). The groups may represent discrete motor pools (p. 1109).

The salivary nucleus is near the upper pole of the dorsal vagal nucleus, just above the pontomedullary junction (Lewis & Shute 1959) and near the inferior pole of the facial nucleus. It is customarily divided into *superior and inferior salivary nuclei*, sending secretomotor fibres to the salivary and, perhaps, lacrimal glands via the facial and glossopharyngeal nerves (pp. 1110, 1113).

The trigeminal spinal nucleus ascends in the lower pons, its tract still applied to its lateral aspect. It is ventral to the lateral vestibular nucleus and traversed by vestibular nerve fibres. The inferior cerebellar peduncle is lateral, but inclines dorsally as it ascends into the cerebellum; the trigeminal spinal tract and nucleus are then lateral to the middle cerebellar peduncle. The nucleus continues up to expand into the superior sensory trigeminal nucleus. The spinal 'tract' consists not of endogenous fibres but of descending axons from the trigeminal ganglion. Their collaterals and terminals enter the spinal nucleus, which is continuous below with the spinal substantia gelatinosa (p. 1099). It is mainly concerned with the mediation of pain and thermal sensibility in the trigeminal area and shows well-established topographical organization (p. 1099).

In addition to the tracts already noted at lower levels, the lower pontine tegmentum contains the trapezoid body, lateral lemniscus and emerging fibres of the abducent and facial nerves. The *medial lemniscus* is ventral; its now *transverse* outline, a flat oval, extends laterally from the median raphe (7.94); its vertical fibres are traversed by horizontal trapezoid axons; it is laterally related to the *lateral spinothalamic tract* and *trigeminal lemniscus*, which are from neurons of the contralateral spinal nucleus, serving pain and thermal sensibility in facial skin and mucosae of the conjunctiva, tongue, mouth, nose, etc. The lemnisci together here form a transverse band composed, in lateral order from the midline, of medial and trigeminal lemnisci, the lateral spinothalamic tract and lateral lemniscus.

The *trapezoid body* contains cochlear fibres, mainly from the ventral cochlear and trapezoid nuclei. These ascend transversely in the ventral tegmentum; traversing or passing ventral to the vertical medial lemniscal fibres, they decussate with the contralateral fibres in the median raphe. Below the emerging facial axons, the trapezoid fibres turn up into the *lateral lemniscus*, as an *ascending* auditory path.

The *medial longitudinal fasciculus* is paramedian, ventral to the fourth venticle, near the abducent nucleus and facial fibres ascending medial to this. Its proximity to many structures suggest its connections (p. 985). In the lower pons it receives fibres from vestibular and perhaps dorsal trapezoid nuclei (p. 960), through its peduncle. Vestibulocochlear contributions form its greater part (p. 960). It is the main 'intersegmental' tract in the brain stem, particularly for interactions between nuclei of extraocular muscles and the vestibular system.

A transverse section at an upper pontine tegmental level contains trigeminal elements (7.96), but otherwise shows no notable alteration.

The trigeminal motor nucleus is in the reticular formation, near the lateral part of the fourth ventricle's floor in line with trigeminal fibres traversing the ventral pons (7.96).

The principal (superior) trigeminal sensory nucleus is lateral to its motor nucleus, between it and the middle cerebellar peduncle, continuous below with the spinal nucleus. Secondary axons from it decussate to ascend in the medial lemniscus to the thalamus (p. 1099).

The small *lateral lemniscal nucleus* is medial to its tract in the upper pons, receiving some lemniscal terminals; some of its efferent fibres enter the medial longitudinal fasciculus, others return to the lemniscus. It is a relay station associated with the trapezoid nucleus.

Tegmental white matter in the upper pons contains the lateral lemnisci, replacing the trapezoid body; its dorsolateral parts are invaded by the superior cerebellar peduncles.

The *medial lemniscus* (7.97), ventral in the pontine tegmentum, is a little lateral to the median raphe and is joined medially by fibres from the principal trigeminal sensory nucleus serving proprioceptive, tactile and pressure receptors in its area. Dorsolateral are the trigeminal lemniscus and lateral spinothalamic tract, serving pain and thermal senses, and the lateral lemniscus and its nucleus. As the lateral lemniscus ascends it is near the brain stem's dorsolateral surface. Above, its fibres enter the inferior colliculus and medial geniculate body. The *medial longitudinal fasciculus* retains its paramedian position.

The *superior cerebellar peduncle*, a mass of fibres, many from the intracerebellar dentate nucleus (p. 975), ascends into the lateral part of the fourth ventricle's roof. It also inclines ventromedially into the dorsolateral tegmentum; the *ventral spinocerebellar tract* is intimately associated with it. In the medulla it is dorsal to the olivary nucleus, separated from the surface only by anterior external arcuate fibres. In the lower pons it inclines dorsally between the trigeminal sensory nucleus and middle cerebellar peduncle to the superior peduncle's lateral aspect. Its fibres then recurve to descend dorsally into the cerebellum.

The *reticular formation* is continuous throughout the pons and is considered on pp. 988–996.

THE CEREBELLUM

The cerebellum, the largest part of the hindbrain, is posterior to the pons and medulla, its median region being separated from them by the fourth ventricle. It occupies the posterior cranial fossa, covered by the tentorium cerebelli (p. 1086). Somewhat ovoid, it is constricted in its median region and flattened, the greatest diameter being transverse. Average weight in males is about 150 grams. In adults the ratio of cerebellum to cerebrum is about 1 to 8, in infants about 1 to 20.

GENERAL FORM OF THE CEREBELLUM

The cerebellum has two so-called *hemispheres* joined by a sagittal, transversely narrow median *vermis*. On its *superior surface* there is no deep grooving; the superior vermian surface, a slight median ridge, is continuous with the hemispheres (7.98). Ventrally the *superior vermis* projects beyond the free edge of the tentorium cerebelli and thence slopes postero-inferiorly below the straight sinus. The superior surface of each hemisphere adjoins the tentorium, sloping down laterally from the superior vermian aspect. Its ventrolateral *margin* corresponds to the tentorial attachment to the superior border of the petrous temporal bone; its curved dorsolateral margin adjoins the transverse sinus in its tentorial attachment.

Inferiorly the cerebellar hemispheres are separated by a deep *vallecula* (7.101). The inferior hemispheric surface is irregularly convex and adjoins the posterior surface of the petrous temporal bone, sigmoid sinus, mastoid temporal bone and occipital squama. The *inferior vermis* projects into the vallecula, limited on each side by a *vallecular sulcus*.

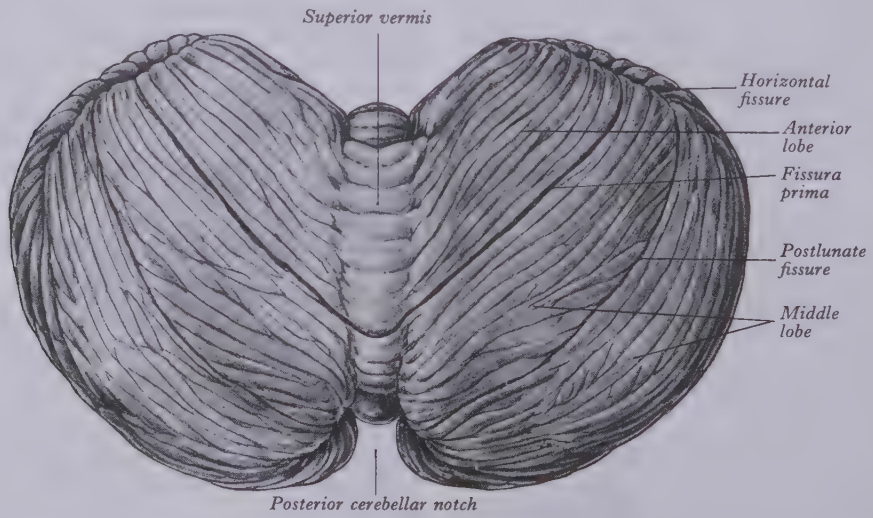
A wide, ventral, *anterior cerebellar notch* is adapted to the pons and upper medulla but separated by the fourth ventricle. In the notch's floor the peduncles enter the white core of the cerebellum.

Dorsally the hemispheres are separated by the *posterior cerebellar notch*, deep, narrow and containing the dural falx cerebelli.

SURFACE CEREBELLAR TOPOGRAPHY

The cerebellar surface is wholly occupied by numerous curved, transverse *fissures*, giving it a laminated appearance and separating its *folia*. Deeper fissures divide it into *lobules*, the most conspicuous being the *horizontal fissure* which extends around the dorsolateral border of each hemisphere from the middle cerebellar peduncle to the posterior cerebellar notch; it separates the superior and inferior surfaces.

Superior surface (7.98, 111). Deepest is the *fissura prima*, somewhat V-shaped, with a dorsal apex cutting into the superior vermian surface at the junction of the anterior two-thirds with the posterior. The fissure curves ventrolaterally around the superior surface to meet the horizontal fissures.

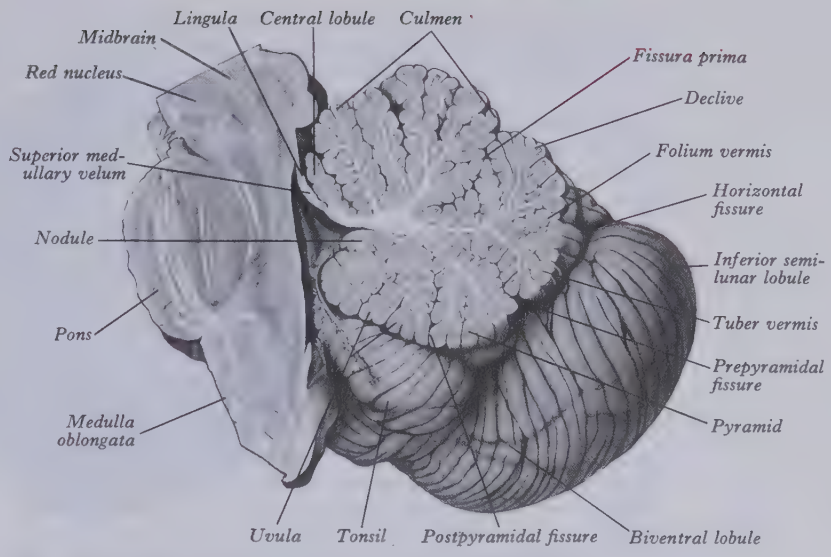


Deep fissures divide the superior vermian surface into *lingula, central lobule, culmen, declive* and *folium vermis* in ventrodorsal order. Each, except the lingula, is continuous bilaterally with an adjoining lobule in each hemisphere (7.100, 111). The fissura prima crosses between the culmen and declive. The lingula is a single lamina of four or five shallow folia, its white core continuous with the superior medullary velum. It is separated from the central lobule by a *postlingual fissure*, the lobule being bilaterally continuous with its *alae* and limited dorsally by the *postcentral fissure*. Between this and the fissura prima is the culmen and laterally the *quadrangular lobules*.

Superior hemispheric surfaces and the vermis *dorsal* to the fissura prima are divided by a curved *postlunate fissure* into a ventral region consisting of the *declive* and its lateral extensions, the *lobuli simplices*, and a dorsal region, the *folium vermis* with adjoining *superior semilunar lobules* limited dorsally by the horizontal fissure.

Inferior surface (7.101, 111). The inferior vermis is divided into the *tuber vermis, pyramid, uvula* and *nodule*, in dorsoventral order. The vermian tuber is continued laterally into *inferior semilunar lobules*, bounded dorsally by the horizontal fissure and ventrally by a *prepyramidal fissure*. The *pyramid* is separated from the *uvula* by a *postpyramidal fissure* (*fissura seconda*) and continuous laterally with a *biventral lobule* visible on each inferior hemispheric surface. Ventral to the uvula, separated by the median part of a *dorsolateral sulcus*, is the *nodule* (7.99, 101).

On each inferior hemispheric aspect, ventral to the biventral lobule, is a deep *retrotonsillar fissure*, passing laterally from the sulcus valleculae opposite the fissura secunda to curve forwards to the ventral surface. With the anterior part of the sulcus valleculae it bounds a circumscribed *tonsil*, connected to the uvula across the sulcal floor by a strip of cortex, the *furrowed band* (7.101). Above, the tonsil is close to the inferior surface of the inferior medullary velum.



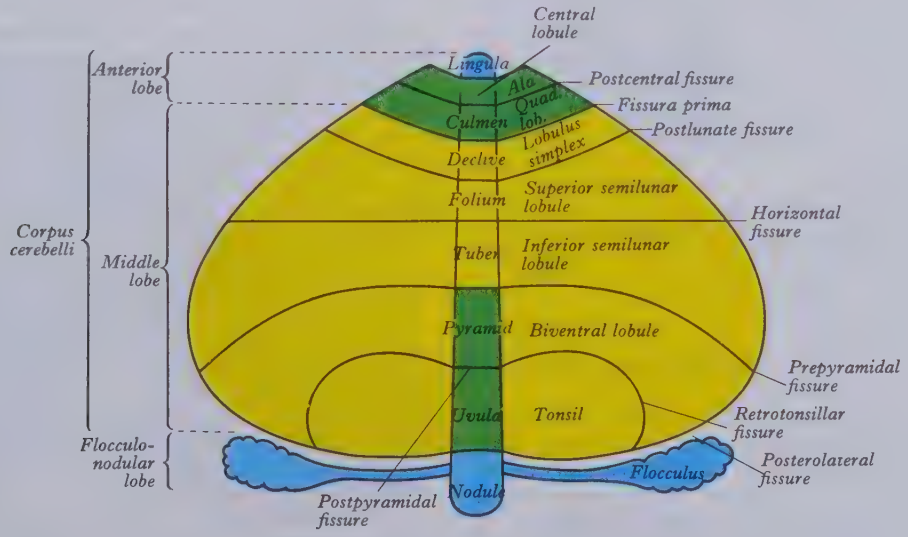
The *nodule*, most ventral on the inferior vermian surface, is separated from the uvula by the dorsolateral fissure and connected on each side to the flocculus and its hemispheric core by the inferior medullary velum. Its anterosuperior aspect faces the fourth ventricle. Ventrally, covered by grey matter, it is crossed by two or three shallow fissures, separated from the ventricle by

7.98 Superior aspect of the cerebellum to show major fissures and lobes. Compare with 7.100.

a double layer of pia mater, its choroid plexus and ventricular ependyma (7.115). Grey matter is dorsally deficient, the white surface being covered only by the neuroglia and ependyma (7.115). The nodule's sides are ventrally free and covered by grey matter; it is continuous dorsally with the inferior medullary velum.

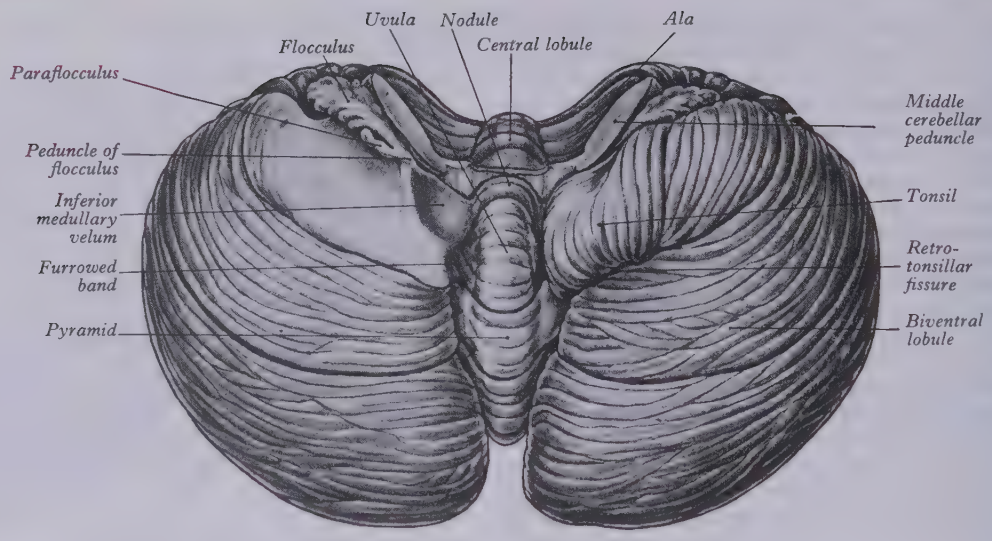
The small *flocculus* is partially detached and just below the vestibulocochlear nerve as it enters the brain stem; it is crossed ventrally by glossopharyngeal and vagal radicles near the jugular foramen. It is oval, with a crenated margin and from its medial end a narrow *peduncle* of fibres emerges; it is covered ventrally by the fourth ventricle's lateral recess and part of the choroid plexus projecting from its aperture (7.81). The peduncle contains afferent and efferent fibres; at the fourth ventricular lateral angle it forms dorsal and ventral parts, the former connecting the flocculus with the nodule and uvula; the ventral part passes medially, turning upwards near the lateral border of the pontine part of the ventricular floor, many of its fibres being afferents from vestibular nuclei and perhaps the medial accessory olivary nucleus; but others are efferent to vestibular nuclei and some may ascend to higher levels.

7.99 Median sagittal section of the cerebellum and brain stem.



LOBES OF THE CEREBELLUM

The cerebellum can be primarily divided into a flocculonodular lobe and the corpus cerebelli, the latter having anterior and middle lobes (7.100, 111A). Such division is embryological, morphological and functional. The *flocculonodular lobe* comprises the nodule, both flocculi and their peduncles. The remainder is the *corpus cerebelli*, separated from the flocculonodular lobe by the *dorsolateral fissure*, which is the first to appear in phylogeny and ontogeny. The corpus is subdivided by the *fissura prima* into *anterior* and *middle* lobes. The former is anterior to the fissure and includes the lingula, central lobule and its alae, the culmen and its quadrangular lobules. The rest, the *middle lobe*, includes the median declive, folium vermis, tuber vermis, pyramid, uvula and, serially, their bilateral lobuli simplices, superior and inferior semilunar lobules, biventral lobules and tonsils.



Some sectors are phylogenetically older. The flocculonodular lobe, mostly *vestibular* in connections, and lingula, with *spinocerebellar* and *vestibular* connections, form the oldest, the *archicerebellum*. The anterior lobe, except the lingula but including the pyramid and uvula of the middle lobe, largely *spinocerebellar* in connections, is the phylogenetically intermediate *palaeocerebellum*. At this evolutionary stage, this newer lobe separates the archicerebellum into the lingula (ventral and rostral) and the flocculonodular lobe (dorsal and caudal). With evolution of the neopallium in mammals, further cerebellar expansion with the addition of a larger middle lobe (excluding the pyramid and uvula), forms the *neocerebellum*, mainly *corticopontocerebellar* in its afferent connections. Like the palaeocerebellum, the neocerebellum expands between the anterior and flocculonodular lobes (7.100, 111A).

The superior medullary velum, a thin white lamina, stretches between the superior cerebellar peduncles (brachia conjuctiva), forming the upper part of the fourth ventricle's roof; its ventricular surface is covered by ependyma. The velum is narrow above between the inferior colliculi, broader below where it is continuous with the superior vermis. The lingula's folia are prolonged dorsally on its lower half; a median *frenulum veli* descends on it from between the inferior colliculi. The trochlear nerves emerge beside the frenulum (7.113).

The inferior medullary vela are bilateral, crescentic sheets flanking the nodule. Each is a thin layer of nerve fibres and neuroglia, surfaced internally by the ventricular ependyma, externally by the pia mater. The internal surface is the inferior limit of the lateral dorsal recess (p. 979); the external surface adjoins the tonsil's upper aspect. The convex peripheral velar limit is continuous with the cerebellar white core and sides of the pyramid, uvula and nodule; the ventral (sometimes inferior) border is free (7.113) and from it the ventricular ependyma is prolonged in apposition to the pia mater to form a thin part of the ventricular roof, reaching the taeniae. (The taeniae are narrow ridges of white

matter forming the inferolateral limits of the fourth ventricle; here nervous tissue and the tela choroidea of the ventricle's roof commences, p. 979.) At each ventrolateral corner it continues into the dorsal part of the floccular peduncle, from which most, if not all, its nerve fibres issue (7.101).

GENERAL CEREBELLAR DEVELOPMENT

For initial cerebellar development see p. 187. Early in the third month it is a mass across the roof of the hindbrain vesicle, soon becoming transversely bilobar; its narrow median part is the predecessor of the vermis, its expanded bilateral lobes becoming the hemispheres. As growth proceeds transverse dorsal grooves appear on this rudiment, forming superficial fissures (7.101, 102). The lateral parts of the *dorsolateral fissure* appear first, demarcating an inferior (caudal) region from the rest; by this flocculi can be identified. The right and left parts of this fissure then meet in the midline, demarcating the nodule. Flocculonodular lobes can now be recognized as the most inferior (caudal) at this stage; but by adjoining growth (massive radial expansion) they become *antero-inferior* in adults. They form near the attachment of the epithelial roof, i.e. the superior rhombic lip (p. 185). As the third month ends a transverse sulcus on the rudiment superior slope deepens to form the *fissura prima*, invading the vermis and both hemispheres and separating the uppermost (rostral) region as the anterior lobe. About the same time two transverse grooves appear on the inferior vermian surface dorsal to the postnodular fissure. Initially the *fissura secunda* demarcates the uvula, then the *prepyramidal fissure* demarcates the pyramid (7.100–102). The whole cerebellum expands dorsally, rostrally, caudally and laterally; the inferior aspects of the hemispheres enlarging much more than their adjacent vermian surface, which is buried in the *vallecula*. Numerous other transverse grooves develop, most having little taxonomic significance; the most extensive, being an exception, becomes the *horizontal fissure*.

In many mammals part of the hemisphere above the flocculus becomes demarcated, in some most markedly. This is the *paraflocculus*, but the term is topographical; unlike the flocculus, it has mainly afferent connections from the cerebral cortex. A paraflocculus is not identifiable in the human cerebellum; whether it is represented by occasional patches of grey matter on the inferior aspect of the middle cerebellar peduncle is uncertain. (Cerebellar *cellular neurogenesis* is summarized on pp. 187–189.)

7.102 Median sagittal sections through the developing cerebellum at four successive stages.

INTERNAL CEREBELLAR STRUCTURE

The cerebellum differs profoundly from the spinal cord, medulla and pons, the arrangement of its grey and white matter being reversed. A grey cortex covers the whole surface, following all fissures. Internal masses of grey matter also exist, but the core is predominantly white. In this the cerebellum resembles the cerebrum and this change has led to enormous evolutionary expansion of these parts in the human nervous system.

The Cerebellar White Core

The white core is thicker in the hemispheres than in the vermis, where it is a mere strip between the lateral parts. It is prolonged by many radially divergent primary laminae projecting towards the surface, with secondary laminae branching at very obtuse angles; these may divide again into shorter tertiary laminae, all covered by

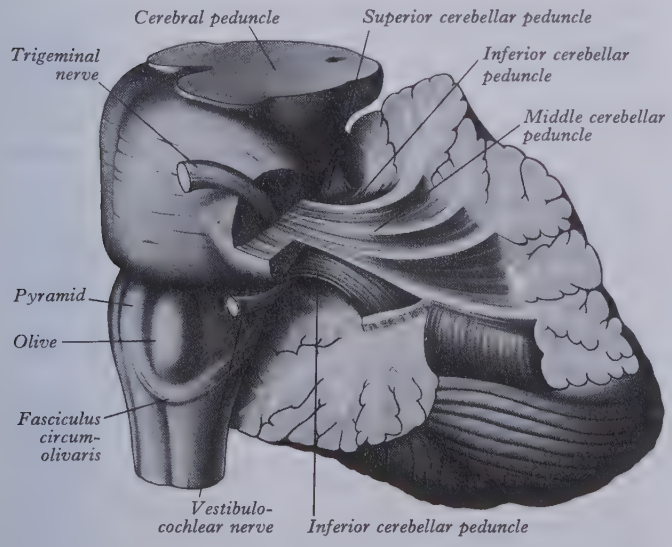
a grey stratum. Sagittal cerebellar sections cut across primary laminae at right angles; the cut surface has a highly branched pattern, the *arbor vitae* (7.99).

The white core contains: (1) fibrae propriae, (2) projection fibres, (3) myelinated axons of Purkinje neurons, (4) 'climbing' afferent fibres and (5) 'mossy' afferent fibres, requiring separate descriptions.

Fibrae propriae, intrinsic fibres, connect cerebellar regions. *Association fibres* connect the cortical folia, including the vermis; they do not decussate and most are short but some longer; they have been little studied (p. 969). Many *commissural fibres* connect the hemispheres, many being grouped in an *anterosuperior commissure*. A *posteroinferior commissure* also crosses near the fastigial nuclei (vide infra). Decussating spinocerebellar and cerebellovestibular are intermingled with intrinsic commissural fibres.

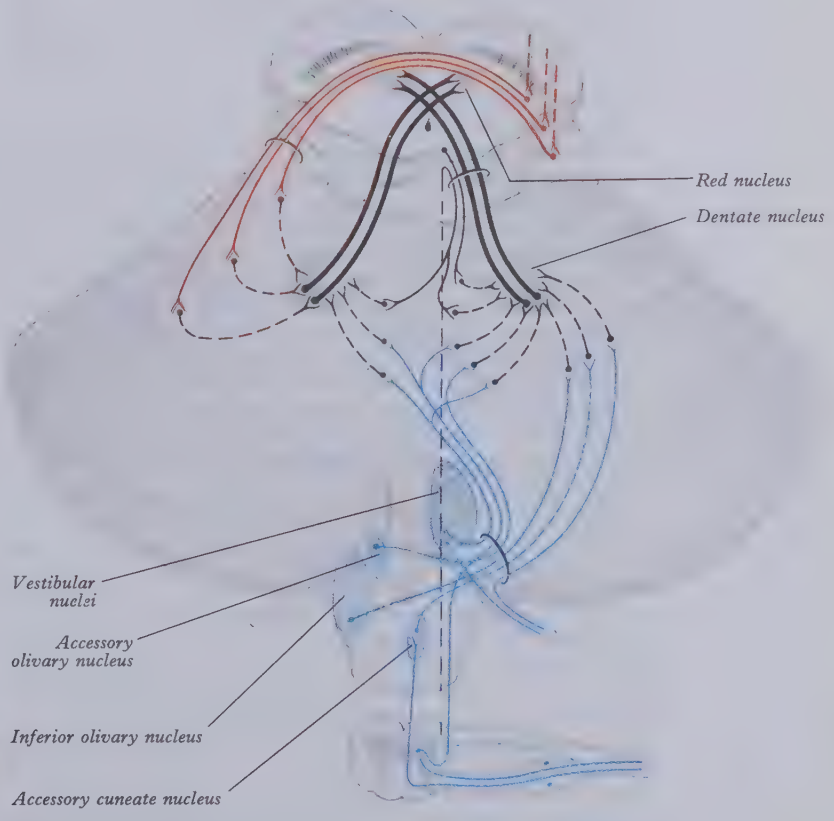
Projection fibres, connecting the cerebellum with many other regions, form three large *peduncles* (7.103) on each side, issuing from the ventral cerebellar notch. Superior peduncles connect the cerebellum to the midbrain, middle peduncles to the pons and inferior peduncles to the medulla. These connections are shown highly simplified in 7.104.

THE INFERIOR CEREBELLAR PEDUNCLES



Each inferior cerebellar peduncle is a thick mass of fibres, entering and leaving between many sources and destinations. As noted elsewhere (p. 957) it forms on the dorsolateral aspect of the upper medulla. The pair diverge as they ascend; at the ventral cerebellar notch each turns dorsomedially into its hemisphere, then curves dorsally between the middle peduncle on its lateral aspect and the superior peduncle on its medial aspect. Some investigators divide the inferior peduncle into a small, medial, *juxtarestiform body* and a large, lateral *restiform body*. The relation of the oblique *pontobulbar body* to the peduncle has been mentioned (p. 957).

Tracts enter the cerebellum via its inferior peduncle from many medullary and spinal sources, including the olivo-, parolivo-, vestibulo-, reticulo-, dorsal spino-, cuneo- and trigeminocerebellar tracts with the ventral external arcuate and other arcuatocerebellar fibres (striae medullares). Tracts *leaving* via the inferior peduncle include the cerebello-olivary, -vestibular and -reticular paths, with minor fascicles of cerebellospinal and cerebellonuclear fibres.



(1) **The posterior (dorsal) spinocerebellar tract** (p. 935) starts from neurons of the ipsilateral thoracic nucleus, shows somatotopic lamination and conveys impulses from cutaneous exteroceptors and proprioceptors of the hind-limb and lower trunk. Some are 'modality-specific', others carry impulses from multiple sources; transmission of both may be modified by descending brain-stem tracts. Fibres end in 'hind-limb' regions of the cerebellar cortex (vide infra) including the central lobule, culmen, part of the declive and nearby parts of adjacent lobules; some fibres end in the pyramid and uvula.

(2) **The cuneocerebellar tract** (dorsal external arcuate fibres) from the external (accessory) cuneate nucleus reaches the ventral and dorsal regions of the ipsilateral vermis. Tract and nucleus are somatotopically organized and functionally similar to the posterior spinocerebellar tract, but concern the fore-limb and upper trunk. Receiving areas of the cerebellar cortex and localization within them are illustrated in 7.111A,B.

(3) **The olivocerebellar tract** contains axons from the inferior olivary nucleus and (4) **the parolivocerebellar tracts** contain axons from dorsal and medial accessory olivary nuclei. A close correspondence between points in the inferior olive and contralateral cerebellar cortex has long been mooted. Degenerative changes and experimentation have confirmed this, showing a precise point-to-point interconnection between all parts of the olivary complex and opposite hemisphere. Dorsoventral and mediolateral correspondence exists, the inferior olive projecting to larger, more lateral hemispheric areas, accessory olives to vermian and paravermian regions. Illustration 7.111E simplifies largely clinical findings (Jansen & Brodal 1954, Brodal 1969). Most olivocerebellar fibres decussate but a few fascicles are said to terminate ipsilaterally. They end as *climbing fibres*, latterly regarded as functionally highly important (vide infra). Afferents converge on the olivary nuclei from the spinal cord, cerebral cortex and subcortical regions. The spino-olivary tracts (p. 936) convey tactile and proprioceptive afferents to accessory olivary nuclei, which project largely to 'spinal regions' of the contralateral hemisphere, completing a *spino-olivocerebellar* path. Cortico-olivary fibres descend largely from the motor cortex to end in inferior and accessory olivary nuclei (Sousa-Pinto & Brodal 1969) completing a *cortico-olivocerebellar path*. Other subcortical nuclei, including the corpus striatum, red nucleus and

7.103 Dissection of the left cerebellar hemisphere and its peduncles (by the late E B Jamieson, University of Edinburgh).

7.104 A simplified diagram of a few of the connections of the cerebellum showing some components of the peduncles: inferior (blue), middle (magenta) and superior (black). The important cerebellothalamic fibres and other efferent systems have been omitted, as have olivary, reticular and tectal connections.

brain-stem reticular formation, all project to restricted regions of the olivary complex and may modify cerebellar cortical activity.

Not all olivocerebellar fibres end as climbing fibres; some reach contralateral fastigial, emboliform, globose and dentate intracerebellar nuclei and are somatotopically organized. These nuclei are described below.

(5)**The reticulocerebellar tract** is mainly from large and small neurons of the medullary *lateral reticular nucleus (nucleus of lateral funiculus*, p. 990), but other *perihypoglossal* and *paramedian* reticular nuclei also contribute (p. 953). Parts of the latter, in particular neuron group A2 (in part *nucleus commissuralis*, a perihypoglossal component), but also part of group A6 (nucleus coeruleus) which are noradrenergic (p. 993), connect via the inferior peduncle with intracerebellar nuclei and wide areas (perhaps all) of the cerebellar cortex. Other *general* reticulocerebellar fibres end in the vermian 'spinal' regions mentioned above. Indirect connections to the cerebellum thus exist through the medullary reticular nuclei, by convergence on them of spino-, vestibulo- and corticoreticular tracts. (The fibres from groups A2 and A6 are the *noradrenergic reticulocerebellar tract*, in part, the *coeruleocerebellar tract*.)

(6) **The vestibulocerebellar tract** consists mainly of primary afferent fibres from the vestibulocochlear nerve (vestibular part); but some secondary fibres stem from medial and inferior vestibular nuclei. Fibres terminate ipsilaterally in the archicerebellar cortex, principally the flocculus and nodule, but a few may end in the uvula and lingula. Other fibres reach both fastigial nuclei. Stein & Carpenter (1967) held that primary vestibulocerebellar fibres are mainly those with sensory endings in the ampullae of their semicircular ducts; but the nuclei of origin of secondary fibres receive the terminals of the rather small spinovestibular tract (p. 933). Vestibulocerebellar fibres partly occupy the juxtarestiform body (vide supra).

Other paths to the cerebellum via its inferior peduncle are less well investigated.

(7) **Ventral external arcuate fibres** arise from arcuate nuclei of both sides and, with some superficial reticulocerebellar fibres, course over the inferior peduncle's surface into the cerebellum. Arcuate nuclei are possibly homologous with pontine nuclei and hence their fibres may be part of a *cortico-arcuatocerebellar* path, whose cerebellar terminations and functions remain uncertain.

(8) **Striae medullares** (p. 960) may also originate in arcuate nuclei; they partially decussate and reach the flocculus and are sometimes termed *the arcuatofloccular tract* (fibres of Piccolomini), probably to be grouped with ventral external arcuate fibres and those from the pontobulbar body (p. 957).

(9) **Trigeminocerebellar fibres**, crossed and uncrossed, enter the cerebellum from superior sensory and spinal trigeminal nuclei. Their human distribution and the status of other nucleocerebellar tracts are uncertain.

Tracts leaving the cerebellum via the inferior peduncle include the following:

(10) **Cerebello-olivary fibres**, of uncertain origin, leave to end around inferior olivary neurons.

(11) **Cerebellovestibular fibres**, from the ipsilateral flocculus, nodule and fastigial nucleus (and partly its antimer), run with other elements of the juxtarestiform body to end in all the vestibular nuclei. Others are axons of Purkinje neurons in the ventral and dorsal vermian regions which do *not* synapse in the intracerebellar nuclei, passing directly to the lateral vestibular nucleus. The ventral vermian projection is somatotopic, corresponding in this to the origin of the lateral vestibulospinal tract (p. 932). Other vermian projections pass to the fastigial and thence to the lateral vestibular nucleus via a fastigiovestibular tract, all showing somatotopic order (Brodal et al 1962).

(12) **Cerebelloreticular fibres**, from both but mainly from the contralateral fastigial nuclei, partially decussate and proceed as the *hook bundle of Russell*, curving round the cerebellar end of the superior peduncle before joining the inferior peduncle. These fascicles end mainly in the pontine and medullary reticular formation. Different zones of the nucleus fastigii (vide infra) and *fastigiovestibular* and *fastigiobulbar* tracts have hence been recognized. But the two tracts are partially mixed in the direct juxtarestiform route and less direct hook bundle, some of whose fibres may traverse the medulla to enter the ventral spinal funiculus as a *cerebellospinal tract*. Evidence for this and for direct *cerebellonuclear tracts* to brain-stem motor nuclei remains less than convincing.

THE MIDDLE CEREBELLAR PEDUNCLES

Each middle peduncle (brachium pontis), the most massive of the three, passes lateral to the others from the pons, curving dorsally to radiate into white laminae in the core of its cerebellar hemisphere (7.103); it is composed almost wholly of axons of secondary neurons in the *corticopontocerebellar path* which are distributed as nuclei pontis, scattered throughout the ventral pons. These fibres almost all cross, traversing the opposite middle peduncle to the contralateral cerebellar cortex. Much of the vermis probably receives fibres from both sides but the lingula, adjacent small regions of the anterior lobe and the flocculonodular lobe have no pontocerebellar projection.

The middle peduncle's fibres are arranged in superior, inferior and deep fasciculi. The *superior fasciculus* contains upper transverse pontine fibres; it passes dorsolaterally superficial to the others and is distributed mainly to inferior cerebellar lobules and to superior parts adjoining the dorsolateral margins. The *inferior fasciculus* contains inferior transverse pontine fibres; it passes inferomedial to the superior fasciculus, more or less parallel with it, to folia on the inferior cerebellar surface near the vermis. The *deep fasciculus* comprises most dorsal transverse fibres. At first covered by superior and inferior fasciculi, it crosses obliquely to appear medial to the superior, from which it receives a bundle; its fibres spread out to the superoventral cerebellar folia.

Distribution of pontocerebellar fibres from different pontine regions has been little investigated. In general, lateral and medial pontine nuclei project to the vermis, the intermediate to the contralateral hemisphere.

Pontine nuclei receive corticopontine terminal fibres from many, perhaps all parts of their ipsilateral cerebral cortex and also collaterals from some corticospinal fibres. Though corticopontine projection is extensive, quantification as to areas and possible somatotopy are unknown in primates. Somatotopy among corticopontine sensorimotor projection exists in cats (Brodal 1968a, b). Feline *spinopontine* and *tectopontine* connections are unconfirmed in primates. Another class of afferents in the cerebellum traverse the middle peduncle to reach cerebellar nuclei and wide areas (perhaps all) of the cortex. These aminergic fibres form a *cerebellar serotonergic path* (p. 994) derived from cell groups B_5 (part of nucleus raphe pontis) and B6 (part of central pontine reticular formation). Their terminations and functions are undetermined.

SUPERIOR CEREBELLAR PEDUNCLES

Superior cerebellar peduncles (7.103, 116) emerge from the ventral cerebellar notch, overlapped by the anterior lobes; displacement of these reveals the superior medullary velum connecting them and their ascent lateral in the fourth ventricular roof to disappear below the inferior colliculi. Some fibres *enter* the cerebellum via the superior peduncle (vide infra), but most are *leaving* and largely from nucleus dentatus. **Efferent dentate fibres** emerge from the nuclear hilum and, joined by some from emboliform, globose and fastigial nuclei, ascend ventromedially, at first covered by medial fibres of inferior and deep fibres of middle peduncles. Ascending in the ventricular roof, they turn into the tegmental midbrain medial to the lateral lemniscus, sweeping medially to decussate with their contralateral fibres. Some do not decussate, leaving a small ipsilateral component with the crossed majority on each side. Both divide into ascending and descending fascicles, a *crossed ascending bundle* being much more prominent and the descending one often ignored.

The uncrossed component, in part from the fastigial nucleus, mainly reaches the brain-stem reticular formation. *Ascending terminals* end in reticular nuclei of the tegmental midbrain and circumaqueductual grey matter, *descending ones* in reticular nuclei of the pons and medulla.

Crossed descending fibres end mainly in inferior and accessory olivary nuclei and adjacent reticular formation. Some may reach the spinal cord, accompanying the medial longitudinal fasciculus to motor nuclei of extraocular muscles.

Dentatothalamic fibres cross the midline, bypass the red nucleus and end in the thalamic nucleus ventralis anterior (p. 1002), from which relay fibres radiate to cortical 'motor' regions. Thus large areas of the cerebellar cortex may influence the motor cortex via the dentate nuclei.

Crossed ascending fibres in the superior peduncle have been described as terminating in other thalamic nuclei, including the nucleus centromedianus, reticular nucleus, nuclei ventralis posterior and lateralis posterior, and in subthalamic and hypothalamic nuclei (Hassler 1950, Cohen 1958, Nimi et al 1962, Snider 1967).

Afferent fibres in the superior peduncle include the ventral spino-, tecto-, coeruleo- and descending hypothalamocerebellar tracts. **Ventral spinocerebellar tracts** are described on p. 935. In the spinal cord this laminated tract contains some ipsilateral but mostly crossed fibres; it ascends superficially and curves dorsally along the superior peduncle's lateral side to the cerebellum, where many crossed fibres cross back in the inferior cerebellar commissure, ending in 'hind-limb' cortical areas of ventral and dorsal vermian and paravermian regions (7.IIIA,B). **A superior spinocerebellar tract**, fore-limb counterpart of the ventral spinocerebellar, has been recognized by recording techniques; anatomical verification in primate brains is awaited.

Tectocerebellar tracts, descending from the tectum to the cerebellum, are paramedian in the superior medullary velum and probably arise in all four colliculi, ending in the intermediate vermian and paravermian cortex, including the dorsal region of the ventral lobe, declive and lobulus simplex, folium, tuber and pyramid (7.IIID). The exact origins and constitution are unknown. Though they are widely assumed to convey auditory and visual information direct to the cerebellum; alternative routes are the *tectopontocerebellar* and *occipitopontocerebellar* pathways.

The coeruleocerebellar tract contains noradrenergic fibres from aminergic neurons of the brain-stem reticular group A6 (central core of nucleus coeruleus, pp. 980, 993). Traversing the superior peduncle they are spread to the intracerebellar nuclei and cerebellar cortex, details being unknown.

Hypothalamocerebellar tracts, composed in part of cholinergic fibres, were described by Shute & Lewis (1965) as descending from posterior hypothalamic nuclei with the dorsal longitudinal fasciculus to the cerebellum, via its superior peduncle, to uncertain destinations. De Feudi (1974) has reviewed cerebellar cholinergic connections.

Summary of Cerebellar Connections

The description of the contents of cerebellar peduncles is tedious, the plethora of detail confusing. In the following summaries some details are ignored, others emphasized, in an attempt to clarify cerebellar connections.

THE CEREBELLAR INPUT

Input is *direct* or *indirect*. *Fibres entering without intervening synapses*, mostly to the cerebellar cortex, come from neurons in the spinal cord, medulla, pons and midbrain. *All* other connections influence cerebellar activity *indirectly* through one or more of these direct paths.

Direct cerebellar inputs are: (1) from the spinal cord via spinocerebellar tracts (including cuneocerebellar); (2) from olivary, reticular, vestibular and arcuate nuclear complexes of the medulla; (3) from ventral, rapheal and other pontine reticular nuclei; (4) from the nucleus coeruleus; (5) from the mesencephalic tectum.

A useful approximate division into archi-, paleo- and neocerebellum has been noted (7.IIIA). Apart from minor inconsistencies and overlap, the *archicerebellum* ('vestibulocerebellum') has largely vestibular connections; the *paleocerebellum* ('spinocerebellum') has direct terminals from the spinal cord, medullary reticular formation and accessory olivary nuclei; the *neocerebellum*, in the middle lobe's large hemispheres, receives massive *pontocerebellar* and inferior olivary connections and, in vermian and paravermian regions, a *tectocerebellar* input. (In accord with the imprecise but useful 'vestibulocerebellum' and 'spinocerebellum', addition of '*pontocerebellum*' and '*tectocerebellum*' may seem appropriate.) This crude parcelling of the cerebellar cortex into receiving areas for main *direct* afferent inputs may clarify complexities introduced by indirect inputs; it has already facilitated clinicopathological description (vide infra).

Indirect routes modifying cerebellar activity converge to the sources of the direct paths summarized above. They include other spinal routes, subcortical nuclei and extensive projections from the cerebral cortex. In addition to direct spinocerebellar tracts, accessory olivary nuclei and medullary reticular formation both project to the spinocerebellum and both receive spinal projections via spino-olivary and spinoreticular tracts. Limited regions of vestibular nuclei and the tectum receive fibres from spinovestibular and spinotectal tracts; but how much activity in vestibulocerebellar and tectocerebellar tracts is modified by spinal influences is uncertain. Nevertheless, spinal activity may reach the cerebellum in different orders of complexity. Direct spinocerebellar routes convey simple information; single fibres may carry patterns from stimulation of a single cutaneous or proprioceptive end organ; others carry patterns formed by the convergence and interaction of connections from two or more receptors, but even here transmission at the first synapse may be modified by descending paths such as the corticospinal. Indirect spinal paths presumably mediate further integration of spinal impulses with those converging by other routes to the medullary reticular formation, accessory olivary nuclei, etc., before entering the cerebellum (i.e. sites of '*cerebellar pre-integration*').

Similar generalizations apply to numerous routes by which the cerebral neocortex may modify cerebellar activity, the most massive being the corticopontocerebellar; with this may be linked to a cortico-arcuatocerebellar path. Other cell stations from which axons reach the cerebellar cortex also receive from the cerebral cortex, via corticotectal, corticoreticular and cortico-olivary tracts; neurons of spinocerebellar tracts are influenced by corticospinal fibres. Hence cerebral cortical activity may influence cerebellar input along most of its afferent paths.

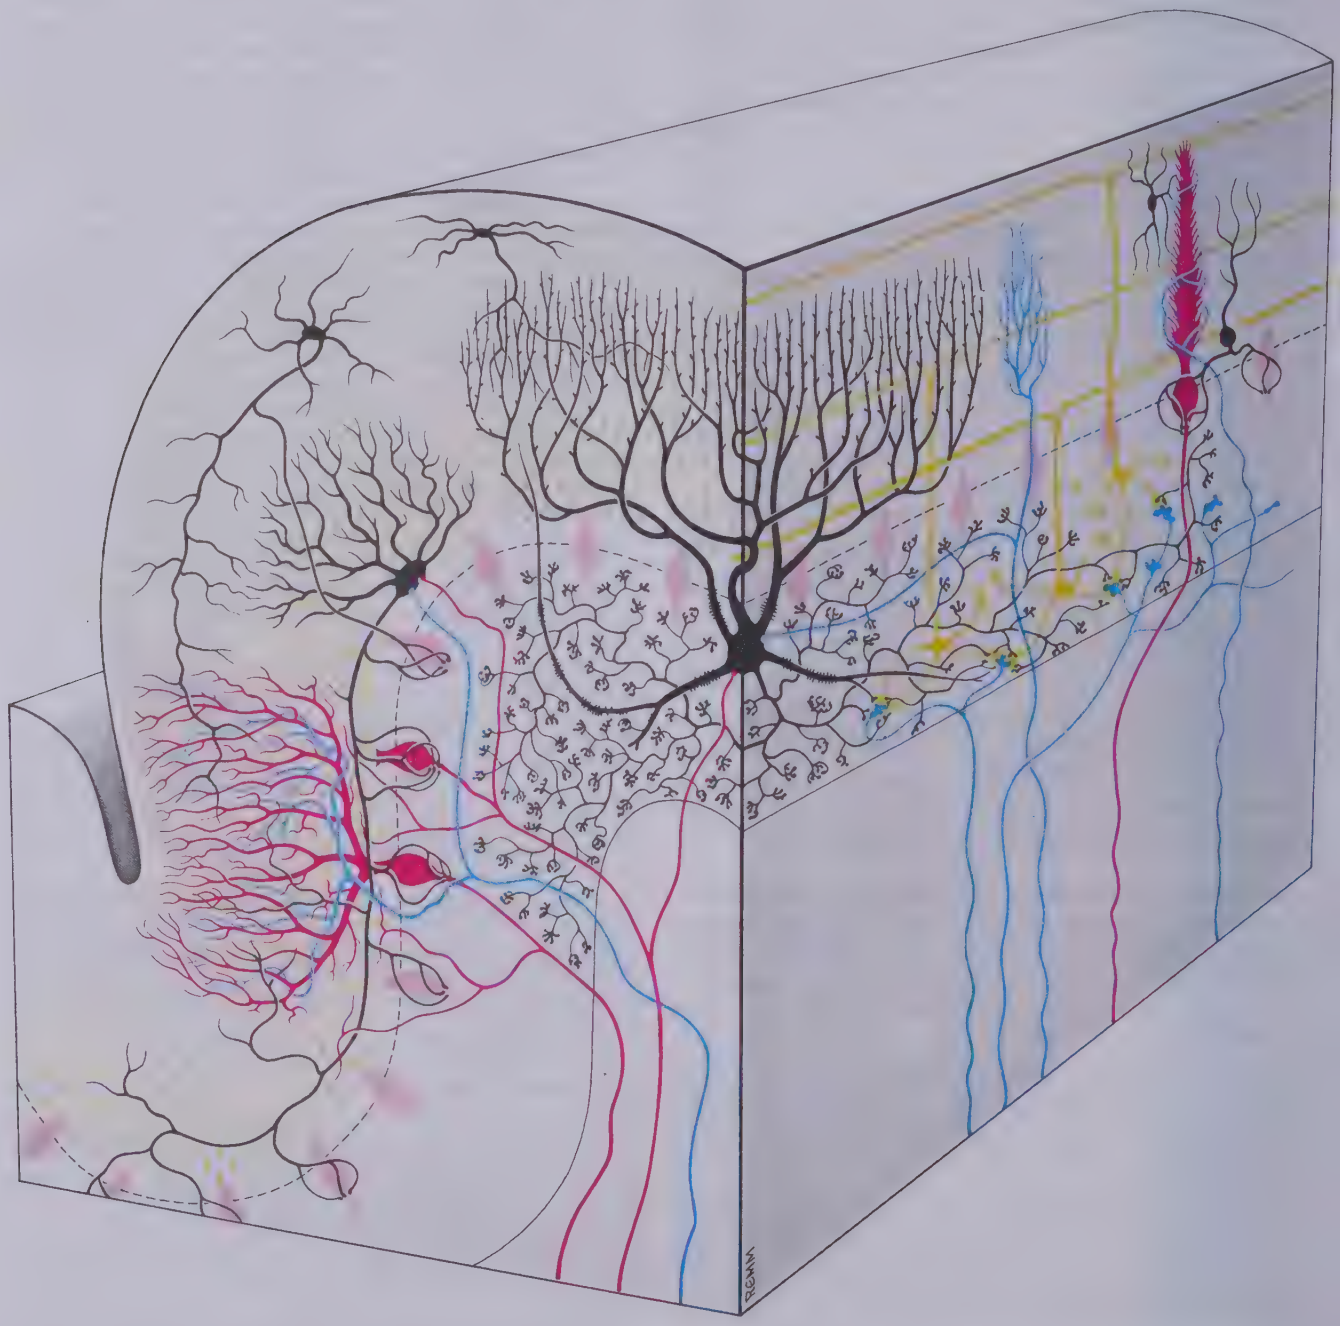
Various brain-stem nuclei projecting to the cerebellum are *not homogeneous* in their connections; e.g. there is much evidence that the olivary complex is not only somatotopically organized in relation to the cerebellar cortex, but varies regionally in terms of afferent connections. Thus, some parts may be largely concerned with *through routes*, e.g. the spino-olivocerebellar path; others may be sites for *pre-integration* of input converging along several afferent channels to the olivary nuclei, including some from the spinal cord and cerebral cortex, others from the corpus striatum, red nucleus and brain-stem reticular formation.

Clearly fuller comprehension of cerebellar activity requires greater knowledge of input and its presentation in the cerebellar cortex. Spinocerebellar and vestibulocerebellar tracts have been much analysed; but regarding the significance of cerebral cortical control and the degree of pre-integration in the brain stem both remain obscure.

THE CEREBELLAR OUTPUT

This starts with axons of Purkinje neurons in the cerebellar cortex and involves intracerebellar nuclei (fastigial, globose, emboliform and dentate) on both sides, which are described later. Most Purkinje axons synapse with neurons in these nuclei, whose axons are the main cerebellar outflow; but some in the flocculonodular cortex and others in the ventral and dorsal vermis have axons which *bypass* intracerebellar nuclei, passing direct to extracerebellar destinations.

The most obvious effects of cerebellar dysfunction are disturbances in muscular integration. It is hence instructive to relate cerebellar outflow to the regions concerned with locomotor control. A few cerebellospinal and cerebellonuclear fascicles have been reported but direct cerebellar connections to motor neuron pools in the spinal cord or brain stem are either *non-existent* or



functionally *negligible*. But *all major motor control regions of the brain stem and cerebrum* receive, directly or indirectly, profuse cerebellar connections; these include the vestibular nuclear complex, brain-stem reticular formation, red nucleus, tectum and, via the thalamus, the corpus striatum and cerebral motor cortex. From these arise all the main descending tracts: cortico-, tecto-, vestibulo-, rubro-, reticulospinal, etc. by which (usually through local interneurons) patterns in α and γ motor neurons are varied. It is evident, without further detail, that cerebellar control involves simultaneous activity at all levels. Despite the prominence of *locomotor* defects in cerebellar dysfunction, cerebral and cerebellar cortices may co-operate in other, as yet unrevealed activities. Certainly *autonomic* functions may be affected by cerebellar disease or experimental damage. Increasing evidence points to the cerebellar influence on electrical activity in *sensory* cortical areas; by connections with reticular formation and the thalamus it may also influence *ascending* sensory paths (Snider 1967).

Grey Matter of the Cerebellum

The cerebellar grey matter is distributed as the cortex and intracerebellar nuclei in the white core.

THE CEREBELLAR CORTEX

The cerebellar cortex (p. 971) is folded by many predominantly transverse curved fissures, closely arranged, approximately parallel and varying in depth; these separate lobes, lobules and folia,

7.105 The general organization of the cerebellar cortex; a single cerebellar folium has been sectioned vertically, both in its longitudinal axis (right part of the diagram) and transversely (on the left). Note: (1) Purkinje cells (red); (2) inhibitory interneurons (black) including outer stellate, basket and Golgi cells; (3) granule cells and their ascending axons which bifurcate into longitudinally disposed horizontal fibres (yellow); (4) climbing fibres and mossy afferents (blue). Note also the synaptic glomeruli formed between the terminals of the mossy afferent fibres, the complex dendrite tips of the granule cells and the ramifications of the Golgi cell axon. Redrawn from Eccles et al 1967 with the permission of the authors and publishers.

correspond to the primary, secondary, tertiary and sometimes quaternary laminae of the central white matter. The smallest laminae and their curved covers of cortex are the *cerebellar folia* (7.99, 110). So complexly pleated is the cortex that its 'unfolded' dorsoventral (caudorostral) extent would exceed a metre, and transversely measure about a seventh of this. The whole cortex is almost uniform in microscopic structure. Local differences, typical in the cerebral cortex, do not occur and sections from different areas are indistinguishable. The same homogeneity obtains throughout the mammalia and, with only minor differences, throughout the vertebrates.

The cerebellar cortex shows much geometric order in its elements, precisely arrayed relative to the tangential, longitudinal and transverse planes in individual folia (7.105). It contains: (1) the terminations of afferent 'climbing' and 'mossy' fibres; (2) five varieties of neuron—granular, outer stellate, basket, Golgi and Purkinje (only the latter's axons leave the cortex); and (3) neuroglia and blood vessels.

The cerebellar cortex has two main strata, the external *molecular* and internal *granular*. Some distinguish an intermediate *Purkinje layer* but here it is considered the most internal part of the molecular layer. Anatomical and physiological research on the cerebellar cortex has accumulated a wealth of data which can only be abbreviated here. For details and extensive bibliographies consult Dow (1942), Jansen & Brodal (1954), Dow & Moruzzi (1958), Eccles et al (1967), Fox & Snider (1967).

Brief introductory summary. Multitudes of granular neurons in the internal stratum are involved in one of the two main cerebellar cortical *inputs*, receiving terminals of mossy afferents (i.e. *all* except the olivocerebellar). The large Purkinje neurons are the cerebellar cortical *output*, their axons mostly converging on intracerebellar nuclei, from which tracts leave for the numerous destinations already described. Dendritic trees of Purkinje cells receive terminals from a dense array of *parallel fibres* from axons of granular neurons and from *climbing fibres* of the olivocerebellar tract. The remaining neurons, external stellate, basket and Golgi, are *inhibitory interneurons*, connecting the cortical elements in complex geometrical patterns (vide infra).

The cerebellar cortex thus has *two inputs*: climbing olivocerebellar fibres synapsing with Purkinje neurons and mossy fibres which connect with them via granular neurons and their parallel axons. Both excite the Purkinje cells, but contrast in structure and presumed modes of operation. The *sole output* comprises Purkinje axons, inhibitory to the neurons of intracerebellar nuclei, which in turn modify *all* the major motor controls in the brain stem and cerebrum. Purkinje activity is complicated by the complex surrounding 'shells' of inhibitory interneurons.

THE LAYERS OF THE CEREBELLAR CORTEX

The molecular layer, about 300–400 μm thick, has a sparse population of neurons, dendritic arborizations, non-myelinated axons and neuroglia. By ordinary histological technique it is almost featureless, contrasting with the granular layer's immense cellular population. It contains the following features (7.105):

(1) Most internal is a single layer of piriform somata of Purkinje neurons, widest in a transverse folial plane, narrow in sections along a folium.

(2) Complex Purkinje dendritic trees extend towards the surface and spread out in a transverse folial plane.

(3) Recurrent collaterals come from Purkinje axons.

(4) Dendritic trees of Golgi neurons, their somata in the granular layer, also reach towards the surface but span the territories of several Purkinje neurons transversely *and* longitudinally.

(5) Somata, dendrites and axons of external stellate neurons are superficially sited.

(6) Somata, dendrites and axons arise from the deeper basket cells.

(7) Axonal terminals of the deeper granule cells radiate into the molecular layer to bifurcate into branches extending in opposite directions along a folium, forming some of the parallel bundles traversing the dendritic trees (vide supra).

(8) Terminals of olivocerebellar climbing fibres ascend through the granular layer to contact Purkinje dendrites in the molecular layer.

(9) Radiating branches from large neurogliocytes in the granular layer surround all neuronal elements except at the synapses; at the surface their conical expansions join into an external limiting membrane.

The general disposition of the above elements is summarized in Figure 7.105.

The granular layer (7.105), about 100 μm thick in fissures and 400–500 μm on folial summits, contains an enormous number of 'microneurons', *granular neurons*: about 2·4 million per cubic millimetre in the simian cerebellar cortex, 2–7 million in the human cortex (Fox & Barnard 1957, Braitenberg & Atwood 1958). In summary it consists of:

(1) The somata of granular neurons and parts of their axons ascending to the molecular layer to become parallel fibres (7.18).

(2) The dendrites of granular neurons, with their terminal expansions.

(3) Branching terminals of mossy afferent fibres.

(4) Climbing fibres passing to the molecular layer.

(5) Somata, basal dendrites and complex axonal ramifications of Golgi neurons.

(6) Cerebellar *glomeruli*, synaptic complexes with four types of neurite: a mossy fibre terminal synapses with the granular and Golgi dendrites, while granular dendrites also receive synaptic contacts from Golgi terminals (p. 971).

(7) Somata of large neurogliocytes.

THE PURKINJE (PIRIFORM) NEURON (7.17B)

Purkinje (piriform) neurons have a specific geometry and occur only in the vertebrate cerebellar cortex. Their flattened somata are piriform in sections across a folium and narrow at right angles to this. Arranged in a single stratum, deepest in the molecular layer (7.105) and adjacent to the granular layer, individual Purkinje cells are separated by about 50 μm transversely and longitudinally 50–100 μm. Their somata measure vertically about 50–70 μm, transversely 30–35 μm.

One, or sometimes two large primary dendrites arise from the 'neck', the superficial pole, but branching varies with position. In deep interfoliar furrows the dendrite forks at once into two large stems diverging at nearly 180° in transverse foliar plane; from these a most abundant arborization, with several orders of subdivision, extends towards the surface. Near the foliar summits primary dendrites spread superficially before branching at more acute angles. In both sites branches of each neuron are confined to a narrow 'sheet' precisely in the transverse foliar plane. Purkinje neurons are more densely arranged at foliar summits than in fissures; these variations have been interpreted as Cartesian transformations, corresponding to the convexities and concavities due to 'folding' during development. Primary dendrites and first and second order branches have smooth surfaces; third order branches and beyond show a dense array of short *dendritic spines* for synapses with parallel rami of axons of granular neurons (vide infra). These *spiny terminals* (or *branchlets*) carry about 45 spines on each 10 μm of length; thus, on average (Fox & Barnard 1957), each Purkinje neuron has about 180 000 spines on its dendritic tree.

From a Purkinje neuron's base, near the granular layer, the axon traverses this layer into the subjacent white matter. Its initial 30 μm or so is narrow, amyelinate and like the soma in ultrastructure; its surface synapses with basket cell terminals. Hence some term this initial region a *preaxon*; beyond, it suddenly enlarges, acquires a myelin sheath and has collateral branches. The main axon proceeds in the white matter and finally forms a plexus, the terminals of which synapse in one of the intracerebellar nuclei; a few bypass these to reach the vestibular nuclei (p. 957). Collateral branches of Purkinje axons interweave as supra- and infraganglionic plexuses external and internal to their somata. Their terminations are uncertain but few, if any, such recurrent collaterals end on Purkinje neurons; they probably synapse with dendrites of the basket and Golgi neurons in the same, adjacent or even quite distant folia, as so-called association fibres, of unknown function.

Synapses with Purkinje cells (7.106) are made by: (1) parallel fascicles of axons from granular neurons, synapsing with Purkinje dendritic spines; (2) climbing olivocerebellar fibres, each largely

7.106 Detailed cytoarchitecture of part of the cerebellar cortex which includes the layer of Purkinje cell somata and the zones immediately superficial and deep to this. The vertical block face to the right is in the longitudinal axis of the cerebellar folium; the upper face is tangential with respect to the convex summit of the folium. The cell details are shown in the following colours: red = the soma of the Purkinje cell, its 'preaxon' passing from the lower pole and its apical stem dendrite with its first-order branches bearing dendritic spines. Blue = climbing fibres. Orange/yellow = horizontal fibres derived from the bifurcation of the ascending axons of granule cells. Mauve = Golgi cell soma, dendrites with spines and initial segment of its axon. Pale brown = the descending basket cell axons forming complex synapses on the preaxon of the Purkinje cell. Green = areas occupied by glial cell processes. Note the synapses between the horizontal axons and the dendritic spines of the Purkinje cell and Golgi cell. Compounded and redrawn from information and illustrations in Eccles et al 1967.

NEURONS OF THE CEREBELLAR CORTEX

restricted to one Purkinje neuron, its numerous branches following the ramifications of Purkinje dendrites to make hundreds, perhaps thousands of contacts with smooth interspinal areas; (3) synaptic terminals from external stellate neurons on smooth surfaces of large primary and secondary dendrites; (4) synapses of collaterals of basket neurons, ending among those of stellate neurons; (5) complex terminals of axons of basket neurons surrounding Purkinje preaxons. These contacts are summarized in 7.106.

The ultrastructure of Purkinje neurons has been described by Herndon (1963), Hámori & Szentágothai (1965, 1966a, b), Léránth & Hámori (1970); they contain all the elements common to neurons (p. 880); distinctive arrays of compressed lamellar membranes assist identification. Apart from the synapses, the whole cell surface is covered by processes of so-called Bergmann gliocytes.

THE GRANULAR NEURON

The varying thickness and immense cell population of the granular layer have been noted. Each neuron has a spherical nucleus, 5–8 μm in diameter, with a mere shell of cytoplasm 0·5–1·0 μm thick, containing a few small mitochondria, ribosomes and a diminutive Golgi complex. From its central aspect branch usually 3–5 (occasionally 1–7) dendrites, each about 10–30 μm in length, often single but sometimes branching before their claw-like terminal expansions; these synapse with the terminals of mossy fibres and other components to form *cerebellar glomeruli* in the intervals between granular neurons and visible by light microscopy. Their fine axons pass from their superficial aspect into the molecular layer and branch at a T-junction into two axons (*parallel fibres*) (7.105, 106), passing in opposite directions for a total of 2–3 mm along the folium. Near the initial dichotomy parallel fibres are smooth, but elsewhere have fusiform swellings and, near their termination, short hook-like projections; both are sites of synapses between the parallel fibre and many kinds of dendrite in the molecular layer. The quantitative aspects of these will be noted; most numerous are the synapses with Purkinje dendritic spines, less frequent those with the spines of Golgi dendrites and dendrites of external stellate and basket neurons. It had been estimated that 150 000–300 000 parallel fibres cross and probably synapse with a *single* Purkinje dendritic tree.

THE BASKET NEURON

Basket neurons of *large stellate type* occupy the internal half of the molecular layer. (They are sometimes termed *internal stellate neurons*.) Their dendrites have no specific form but, as in Purkinje neurons, they are flat arrays in a strictly transverse foliar plane. Dendritic surfaces have a few, irregular, long spines synapsing with parallel fibres which intersect their dendritic trees at right angles. The soma is covered by axosomatic synapses, possibly from recurrent collaterals of Purkinje and climbing axons.

Axons of basket neurons are deep in the molecular layer, superficial to the Purkinje neurons, their *stems* being in the *transverse* foliar plane. Continuing for about 1 mm, each covers the territories of 10–12 Purkinje neurons; but from the second neuron onwards descending collaterals pass towards the Purkinje somata, interweaving with collaterals from other basket neurons to form pericellular networks, or 'baskets', hence their vernacular name. Branches from each descending collateral and main axon also weave *longitudinally* in the folium to a further 3–6 rows of Purkinje neurons flanking the axon. Hence 100–200 Purkinje neurons may receive synapses from a single basket neuron. The somatic surfaces of Purkinje neurons are devoid of synapses; synapses of descending basket collaterals cluster around the Purkinje *preaxon* (7.106). Axons of basket neurons have fewer ascending collaterals, which may synapse with the smooth bases of Purkinje dendrites.

Basket neurons provide a unique synaptic system: activity in a fascicle of parallel fibres intersects and activates a longitudinal row of their dendrites. Because their axons are transverse in the folium they act on the origins of Purkinje axons in longitudinal strips on both sides of the fascicle.

THE EXTERNAL STELLATE NEURON

Smaller than the 'basket' cells, *external stellate neurons* are dispersed in the superficial half of the molecular layer. Their dendritic trees, smaller than in basket neurons, are in general similar, with synaptic spines and transverse foliar orientation. They also are traversed at right angles by parallel fibres, with which their spines *and* smooth areas synapse. The origin of apparent sparse axosomatic synapses is uncertain. The smallest stellate neurons have abundant local arborizations, ending on Purkinje dendritic spines; the longer axons of larger neurons pass transversely in a folium to similar sites on remoter Purkinje neurons. The largest *external* stellate neurons have descending collaterals which accompany those of the *internal* stellate neurons ('basket cells' proper).

THE GOLGI NEURON

The Golgi type, which are the largest stellate neurons, occupy the superficial zone of the granular layer, adjoining the Purkinje somata. Large dendrites radiate all over the soma, many curving into the molecular layer to arborize, their courses predominantly at right angles to the surface. Their dendritic trees are *not* compressed, appearing much the same in transverse and longitudinal foliar section; in both planes they overlap the territories of three Purkinje cells. The dendritic tree of a Golgi neuron thus approaches, but does not overlap, those of its fellows; each intermingles, in the molecular layer, with the dendritic fields of about 10 Purkinje neurons. Some Golgi dendrites, however, do not enter the molecular layer, dividing in the granular layer to join the cerebellar glomeruli (vide infra).

A Golgi neuron's axon arises from its soma's central aspect or from the base of a central dendrite, immediately dividing into a profuse arborization deployed through the full thickness of the granular layer and occupying a volume which, nearer the white matter, corresponds to its dendritic tree in the molecular layer, i.e. it does not overlap adjacent Golgi fields. The main synaptic input to Golgi neurons is from parallel fibres in the molecular layer, synapsing with the few spines on its dendrites. Golgi axonal terminals take part in cerebellar glomeruli. As regards Golgi neurons, the cerebellar cortex thus consists of a series of units, crudely hexagonal in surface view, which adjoin but do not overlap. Within each are about 10 Purkinje cell territories and internal to these a great number of granular neurons and synaptic glomeruli.

INPUTS TO THE CEREBELLAR CORTEX

As already mentioned, two inputs serve the cerebellar cortex, climbing fibres (*neurofibrae ascendentes*) and mossy afferents (*neurofibrae muscoideae*) (7.105).

Climbing fibres, illustrated by Cajal but long of uncertain origin, are now established as largely olivocerebellar, with a point-to-point correlation between olivary complex and cerebellar cortex (p. 976). Electronic coupling (through nexuses or gap-junctions) between their inferior olivary origins has been observed (Llinas et al 1974, Sotelo et al 1974). Each fibre traverses the white matter and granular layer without branching, to reach a *single* Purkinje neuron, where it divides repeatedly with its terminal branches applied to the Purkinje dendrites in much of their length, making numerous synapses with the smooth dendritic areas. A few collateral branches leave the climbing fibres, some descending to synapse with Golgi somata and dendrites, others with nearby basket or external stellate neurons. Both mossy and climbing fibres are excitatory; the former excite single Purkinje neurons, with a weaker effect on adjacent interneurons.

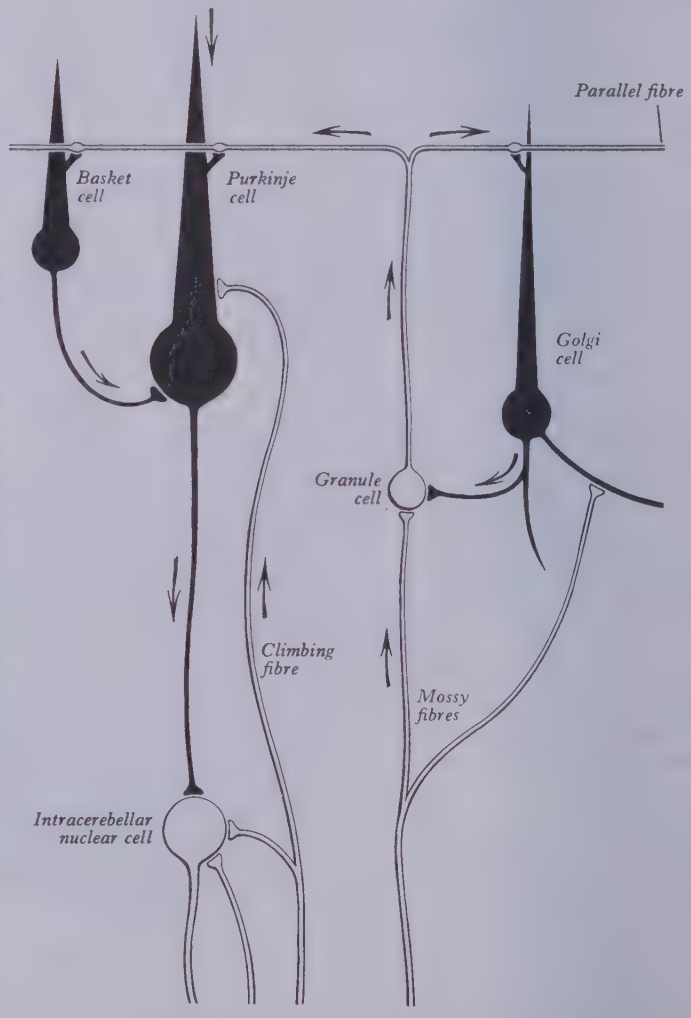
Mossy (muscoid) afferent fibres are widely agreed to include *all* afferents except the olivocerebellar. They also are excitatory but otherwise contrast with the localized climbing input. As each mossy fibre traverses the white matter its collateral branches diverge to several adjacent folia; within each the branch traverses its central lamina, giving numerous ramules to the granular layer on both foliar aspects; these divide again into two or three terminals, which expand into grape-like synaptic

7.107 A stereodiagram illustrating the structure of a cerebellar synaptic glomerulus. Blue = mossy afferent fibre rosette. Red = granule cell dendrites. Yellow = terminals of Golgi cell axon. Green = Golgi cell dendrite. Grey = neurological capsule. Note that the essential synaptic contacts are axodendritic between: mossy afferent fibres and granule cell dendrites; mossy afferents and Golgi cell dendrites; Golgi cell axons and granule cell dendrites. From Eccles et al 1967, by courtesy of the authors and publishers.

terminals (mossy fibre *rosettes*), each in the centre of a cerebellar *glomerulus*.

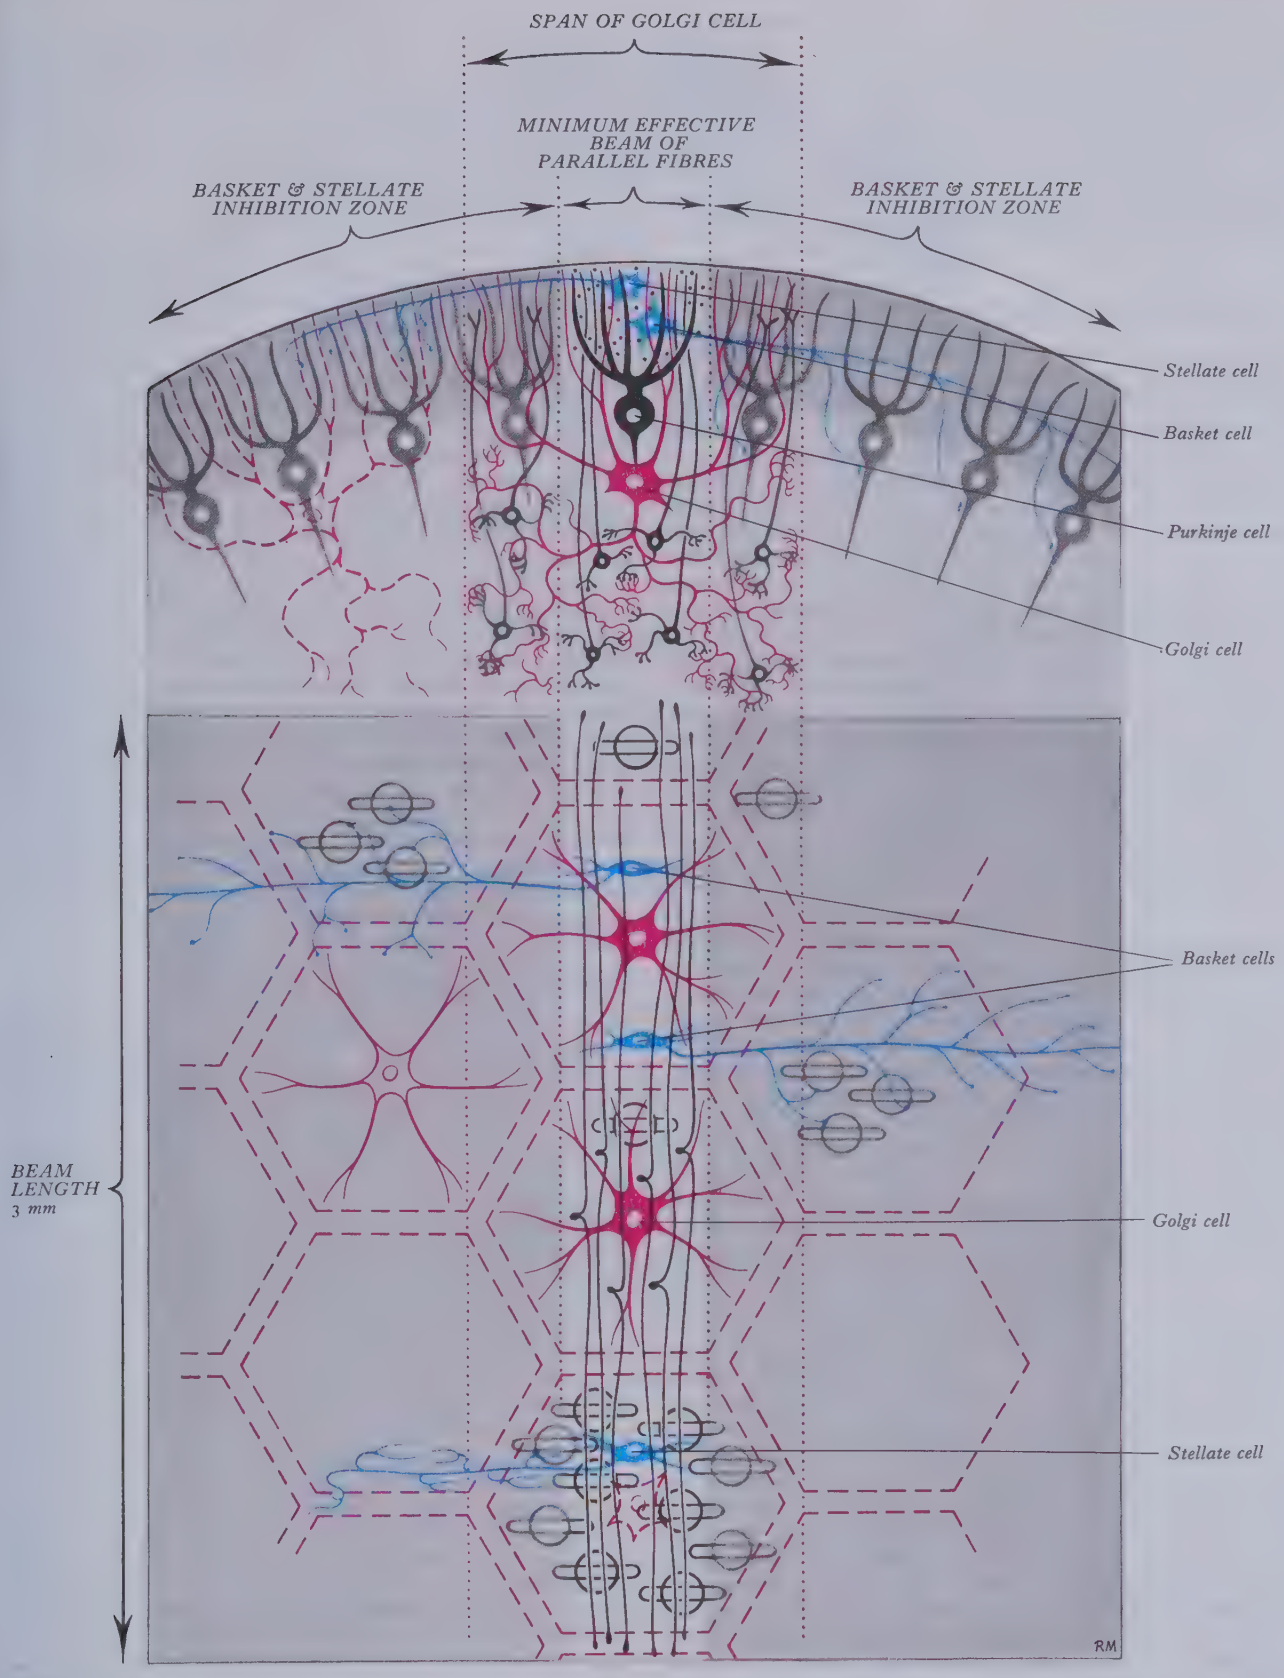
Cerebellar glomeruli are complex synaptic corpuscles containing a central mossy fibre 'rosette', dendrites of several granular neurons, terminals of Golgi axons and sometimes a Golgi dendrite. Each glomerulus, roughly spherical or ovoid, is only about 10 μm in its greatest diameter; they occur in a ratio to granular neurons of about 1 to 5. All synapses are axodendritic. The central 'rosette' establishes contact with a surrounding spray of up to 20 granular dendrites and, when present, the spine-studded surface of a Golgi dendrite. The Golgi terminals synapse with several dendrites of granular neurons, as shown in diagram 7.107. The mossy ('muscoid') terminals are excitatory to granular neurons and, if included, Golgi dendrites. Conversely, the Golgi neuron, an inhibitory interneuron, can inhibit the granular neuron through its axodendritic contacts.

QUANTITATIVE ASPECTS OF THE CEREBELLAR CORTEX



In its regular, repetitive cytoarchitecture, the cerebellar cortex lends itself to quantitative methods (Eccles et al 1967, Fox & Bernard 1957, Fox et al 1967, Braitenberg 1967, 1977). But throughout it shows extremes in neuronal population, in convergence and divergence or one-to-one transmission and in complex arrays of inhibitory interneuronal circuits.

A vertical column of human cerebellar cortex, 1 mm square in area at a foliar summit, contains about 500 Purkinje, 600 basket, 50 Golgi and perhaps 3 000 000 granular neurons, with about 600 000 glomeruli: It is difficult to estimate the total cerebellar cortical area; but since its sagittal dimension (p. 969) is said to be a metre, the area must be many thousands of square millimetres. Hence the figures cited must be multiplied by a factor of perhaps 10^5 or more, indicating the vast population of cerebellar components capable of incalculably numerous integrations.



On the *input side* each climbing fibre synapses with *only one* Purkinje neuron (and by collaterals with an undetermined number of interneurons). In contrast a single mossy fibre shows *enormous divergence*, synapsing with 400 or more granular neurons in one folium; if branches to adjacent folia are included, the number is probably several thousand. Conversely, each granular neuron probably synapses with four or five different mossy fibre terminals.

Ascending axons of granular neurons bifurcate into parallel fibres, synapsing with Purkinje, Golgi, basket (internal) and external stellate neurons. A parallel fibre travels about 2–3 mm and synapses with 300–450 Purkinje neurons. Thus divergence from a mossy fibre through the granular neurons is to perhaps hundreds of thousands of Purkinje neurons; there is uncertainty about the amount of overlap between parallel fibre territories, but enormous convergence of paths to individual Purkinje neurons exists, a dendritic tree of one receiving 400 000 synapses from different parallel fibres (Napper & Harvey 1988).

In discussing a 'module concept' of *cerebral* cortical architecture Szentágothai (1975, 1978) has also surveyed the *development* of quantitative knowledge of the cerebellar cortex. Its first definition as a three-dimensional rectangular lattice (Braitenberg

7.108 An analysis of the essential circuitry and synaptic contacts between the climbing and mossy afferent fibres, the main neuronal elements of the cerebellar cortex and the neurons of the intracerebellar nuclei, based upon cytological and microelectrode studies. Excitatory cells, neurites and terminals are white surrounded by a black line; inhibitory elements are solid black. By courtesy of J. C. Eccles.

7.109 The concept of the complex neuronal integrative units of the cerebellar cortex. The neurons and their processes are shown in a transverse section of a cerebellar folium (above) and in surface view (below). Neurons in full colour (black, red or blue), or in full coloured outline, are in a state of excitation. Neurons in grey or interrupted outlines are inactive. Full black or grey, black or grey outlines = Purkinje cells, granule cells and their parallel fibre bundles; blue = basket and stellate cells; red = Golgi cells. The white longitudinal strip indicates activation of a locus of granule cells, their bundle of parallel fibres and the associated longitudinal row of Purkinje cells. Simultaneous activation of the basket and stellate inhibitory interneurons by the parallel fibre bundle causes zones of lateral inhibition (grey shading) to flank the activated strip. These zones of inhibited Purkinje cells are in reality about ten rows wide; only four rows are illustrated here (grey profiles). If the active bundle of parallel fibres reaches a critical width, inhibitory Golgi interneurons become active and reduce or stop mossy fibre input in the cerebellar glomeruli. The inhibitory territories of the Golgi cells are indicated by the array of red hexagons. See text for further description. Redrawn from Szentágothai 1967 by courtesy of the author and publishers.

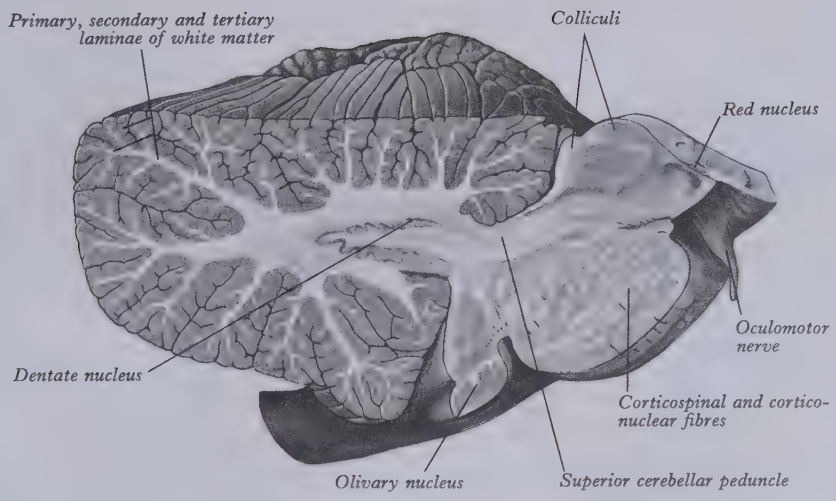
& Atwood 1958) was followed by a hypothetical division into assumed functional spaces (Szentágothai 1963, 1965), later defined physiologically (Eccles et al 1967) and structurally corroborated (Uchizono 1967) in terms of excitatory and inhibitory zones of interaction. Detailed analyses of feline cerebellum (Palkovits et al 1971a,b,c, 1972) helped 'to describe the cerebellar cortical network statistically in numerical and geometric terms, considerably refining the earlier crude qualitative guesses as to spatial and numerical distribution of excitatory and inhibitory interactions'. For reviews, see Ito (1983), Gilman (1985).

MECHANISMS OF THE CEREBELLAR CORTEX

Structural research on the cerebellum, ranging from comparative morphology, developmental analysis and studies of gross connectivity, to quantitative cytology, cell geometry and synaptic relations by ultrastructural techniques, has been paralleled in volume by impressive neurophysiological research (Dow 1942, Dow & Moruzzi 1958, Eccles et al 1967, Ito et al 1964, Ito & Yoshida 1966, Snider 1967, Szentágothai 1967, Eccles 1970, and p. 968). Increasing synthesis in the field has led to several proposed mechanisms, probably interlocking in normal cerebellar function.

The cerebellar cortex has two distinct inputs, climbing and mossy fibres, and only one output, axons of Purkinje neurons (7.108). Both inputs convey information, at least in part, from similar sources: exteroceptors and proprioceptors, brain-stem reticular formation and the cerebral cortex (vide supra). Both inputs are excitatory, but climbing fibres exert a one-to-one, all-or-none excitation on *individual* Purkinje neurons, each mossy afferent having a *diffuse* excitatory effect via hundreds of excitatory granular neurons to *thousands* of Purkinje neurons, which are exclusively inhibitory, their axons exerting varying inhibitory patterns on intracerebellar and vestibular nuclei.

The remaining components, internal (basket) and external stellate and Golgi neurons, each with their particular geometry, input and output, are all inhibitory interneurons. Whatever type of recording or preparation is used, most neurons show a low level of 'background' discharge, even under quiescent conditions. Some use the term 'spontaneous' for this; whether it is intrinsic remains uncertain but upon such a background orderly responses to specific patterns of input must occur. Szentágothai (1967) suggested that climbing fibres and their synapses, largely concentrated on individual Purkinje neurons, do not provide an integrative mechanism, presuming that their informational flow has been *pre-integrated* in the olivary nuclear complexes. He suggested that *integrative units* of cerebellar cortex involve the mossy afferent input, granular neurons, parallel fibres, Purkinje neurons and varieties of interneuron. Their supposed interactions are summarized in 7.108, 109. Mossy afferents may excite a locus of granular neurons causing activity in a narrow fascicle of parallel fibres, about 3 mm in length, which courses along a folium's molecular layer to excite dendritic fields in its path, i.e. Purkinje, Golgi, basket and external stellate dendrites. If the fascicle is very narrow or its activity low, no cells will respond; but as its size increases to the width of the Purkinje dendritic fields, it excites a row of Purkinje and related basket and stellate neurons. Golgi neurons do not respond, since only a small part of their larger dendritic fields receives an input from such parallel fibres. Hence a row of Purkinje neurons, about 3 mm long, in the folium's long axis responds with volleys of impulses. Because of the slow conduction in small parallel fibres (a few decimetres per second) and regular spacing of Purkinje neurons, these are excited *sequentially*. Impulses in parallel fibres arrive at *successive* Purkinje dendrites at intervals of about a tenth of a millisecond, suggesting that the cerebellar cortex is a *timing device*. The transverse disposition of internal and external stellate neurons' axons and terminals ensures *simultaneous* activation by a parallel fascicle, resulting in longitudinal cortical strips containing inhibited Purkinje neurons which flank the active rows on each side. With continual fluctuations of activity in input via mossy fibres, the essential cerebellar response is an ever-changing pattern of innumerable 'unit rows' of excited Purkinje neurons, flanked by inhibitory zones; thus it provides neural 'sharpening', by which the more active parallel bundles are selected from the general background of cortical activity. Should the active fascicle of parallel fibres become broader than the width of a single row of Purkinje neurons, another mechanism comes into play, mediated by Golgi neurons. The parallel fibres reach a critical width and now excite Golgi dendrites and these reduce the input by the mossy fibres via granular neurons by their inhibitory synaptic terminals on the latters' dendrites in the synaptic glomeruli (p. 972); the principal function of Golgi neurons thus appears to be a 'choke' to prevent the excessive broadening of active fascicles.



Upon this incessantly changing pattern of *sequentially* excited, inhibited or relatively quiescent rows of Purkinje neurons, it is imagined that the sharply localized excitatory effect of climbing fibres is exerted, the resultant at any Purkinje neuron depending on the strength of stimulation by the climbing fibre and the neuron's state. By such means changing inhibitory patterns are transmitted by Purkinje neurons to intracerebellar nuclei and thence to motor control in the cerebrum and brain stem. But how co-operation between localized climbing fibre activity and the time-base provided by active parallel fibres can co-ordinate the dynamics of striated muscles remains an enigma.

Other complexities in intracortical cerebellar circuits include the complication of the effects of Purkinje collaterals and climbing fibres on the various inhibitory interneurons, problems posed by Golgi dendrites in synaptic glomeruli and differential 'on' and 'off' responses in different interneurons. Interesting mathematical analyses of cerebellar structure suggest that it acts as an accurate *biological clock*, incorporating *delay paths*, perhaps important in controlling the correct sequence of events in e.g. rapid 'voluntary' movements (Braitenberg 1967). These *ideas* have been expanded and refined by Braitenberg (1977) and others. The matter, however fascinating, cannot be pursued here, but perhaps enough has been said to excite interest in the detailed investigations, still continuing, into the *higher integrative units* of the cerebellar cortex. We are still far, however, from a comprehensive understanding of the overall relation of the cerebellum to complex motor patterns of the individual.

CEREBELLAR CHEMOARCHITECTURE

The cerebellar cortex is comparatively well understood but gaps remain. Briefly, Purkinje neurons, exclusively inhibitory, contain in various combinations at least three inhibitory neuromediators: GABA (gamma aminobutyric acid), the peptide motilin and the amino acid taurine. Combinations are GABA plus motilin, GABA plus taurine, taurine plus motilin. Some 30% of Purkinje neurons contain none of these; presumably one or more inhibitory neuromediators are yet to be discovered.

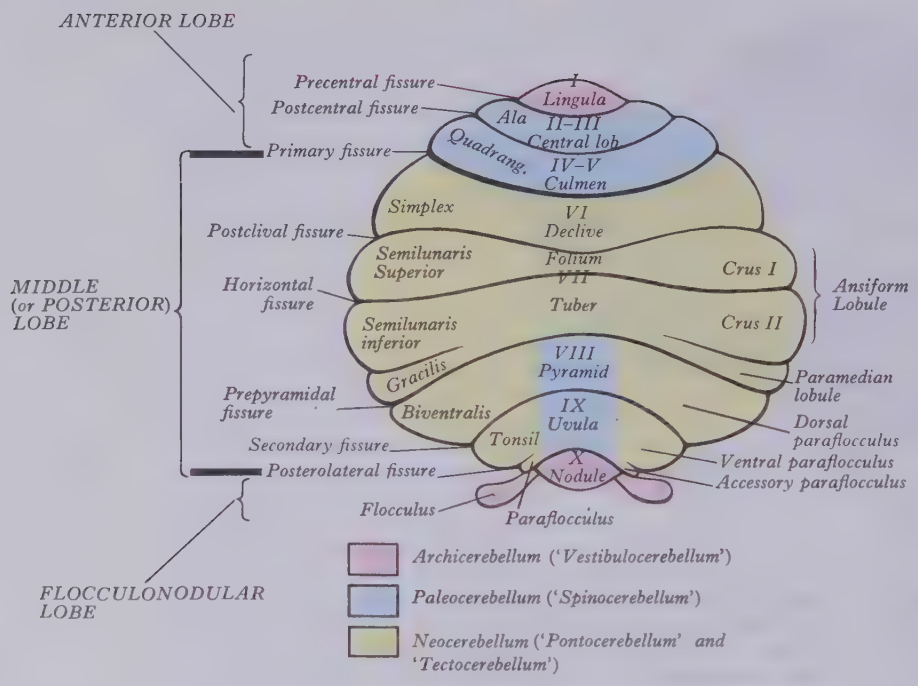
The outer stellate and basket inhibitory interneurons are both probably GABA-ergic, but a proportion of outer stellate cells may contain taurine. Golgi inhibitory interneurons are mainly GABA-ergic but a proportion contain enkephalin; whether these are two separate populations of neurons or the two neuromediators co-exist in the same neurons is not established. The cerebellar input through excitatory climbing fibres is considered to be mediated by glutamate and aspartate (but precise technical means for their localization is awaited). Of the mossy fibre input, a proportion may be cholinergic but the status of the vast majority is unknown. The innumerable parallel fibres derived from the bifurcation of granule cell axons are excitatory to the dendrite of Purkinje, outer stellate, basket and Golgi neurons; there is strong evidence that glutamate is the excitatory neuromediator. The noradrenergic and serotonergic fibres form a rich plexus in the granular layer of the cortex, then enter the molecular layer and provide both radial fibres and fibres that bifurcate and run in the long axis of a folium in company with parallel fibres. The aminergic fibres are fine, varicose and form extensive cortical plexuses; their release of noradrenalin and serotonin is assumed to be non-synaptic and their effects are paracrine involving volumes of tissue. The NA coeruleo-cerebellar projection, when active, inhibits Purkinje cell firing not by direct action but via the enriched generation of cyclic AMP which acts as a 'second messenger'. Thus in terms of neuromediator profiles the cerebellar cortex is relatively simple, compared e.g. with the more complex olfactory bulb, but these

7.110 Oblique vertical section through the right cerebellar hemisphere and right half of the brain stem. Note the arbor vitae.

are dominated by the neuromediator-rich and neuromediator-dense structures grouped by Nieuwenhuys (1986) as a 'paracrine' core and paracores. These include large limbic-associated parts of the basal telencephalic nuclei, septal areas, amygdala and other limbic structures, the medial forebrain bundle and related parts of the hypothalamus, parts and fasciculi of the brain-stem reticular formation, spinal intermediate grey matter (and dorsal grey column).

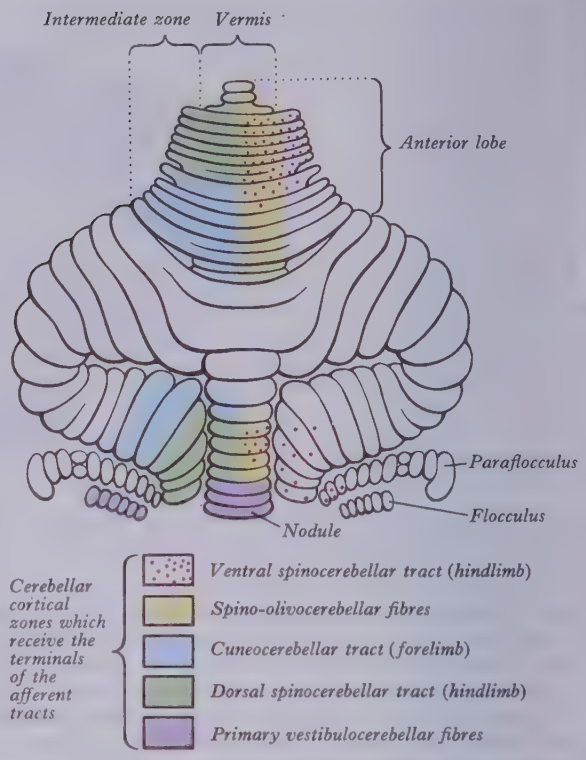
THE INTRACEREBELLAR NUCLEI

Four grey masses are embedded in the cerebellar white core on each side, the *intracerebellar nuclei*, sometimes termed 'roof' nuclei, though some only adjoin the ventricular roof. Most lateral and largest is the *nucleus dentatus*, medial to which are the smaller *nuclei emboliformis* and *globosus*, the most medial being the *nucleus fastigii*. In most mammals only three appear: a nucleus lateralis corresponding in part to the nucleus dentatus, a nucleus interpositus corresponding largely to globose and emboliform nuclei and a nucleus medialis corresponding to the nucleus fastigii. Precise homologies of nucleus interpositus are uncertain (Jansen & Brodal 1954). These differences must be noted, because so much information from other mammals is extrapolated to the human cerebellum. The nucleus fastigii is phylogenetically oldest and largely associated with the archicerebellum; the more recent globose and emboliform nuclei are associated with the paleocerebellum; the nucleus dentatus, most recent, is associated with the neocerebellum (vide infra).



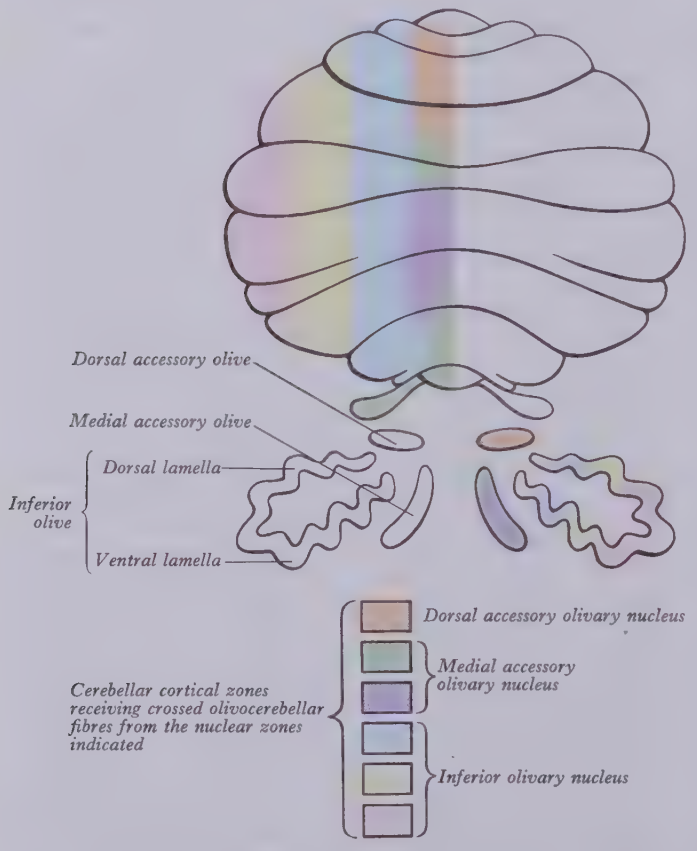
The nucleus dentatus (7.110), near the white core of its hemisphere, is an irregularly folded grey lamina containing a mass of white fibres largely derived from neurons in the grey lamina, which is deficient ventromedially; through this so-called 'hilum' fibres stream out to form much of the superior cerebellar peduncle (p. 966). **The nucleus emboliformis** partially covers the dentate hilum, **the nucleus globosus** being still more medial and dorsoventrally elongated; **the nucleus fastigii** is near the midline and in the ventral (anterior) part of the superior vermis.

Prominent in these nuclei are large multipolar neurons with simple, stellate but irregular arborizations, the numbers of dendrites increasing from the fastigial to the dentate nucleus; dendritic trees of adjacent neurons overlap in the fastigial nucleus but are more distinct, with their own territories, in the dentate. Their axons make one or two loops before leaving their nuclei to form **cerebellar outflow tracts** in superior and inferior cerebellar peduncles. In these loops they give off recurrent collaterals ending locally in their nucleus. The nuclei also contain numerous small neurons, some probably local Golgi type II interneurons, others contributing to the peduncles (Jansen & Jansen 1955, Flood & Jansen 1966).

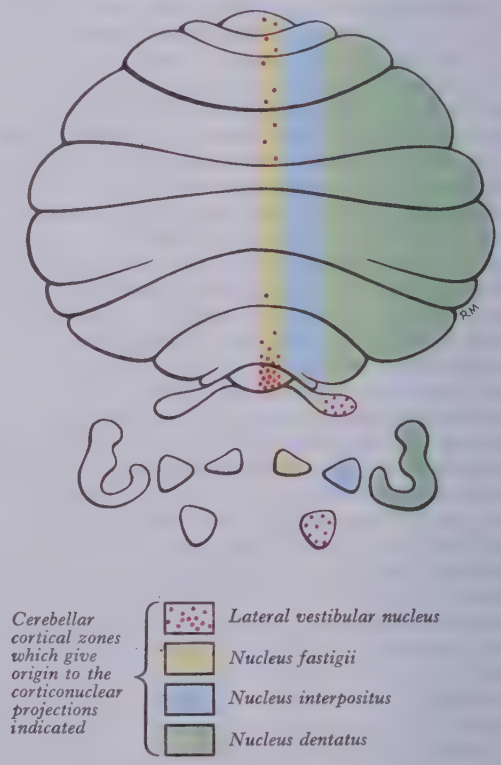


Afferent connections to the intracerebellar nuclei are from intrinsic and extrinsic sources. They make axodendritic and axosomatic synapses with terminals of Purkinje axons, which enter the nuclei and form pericellular nets round several neurons; each net is derived from more than one Purkinje neuron, i.e. there is divergence *and* convergence in the nucleus. Since Purkinje neurons are all inhibitory, attention is focussed on other afferents, many presumably excitatory. Rubrocerebellar fibres are said to reach these nuclei (Courville & Brodal 1966) and also collateral branches from spino-, ponto-, olivo- and reticulocerebellar tracts (Eccles et al 1967). Noradrenergic and serotonergic fibres from brain-stem reticular nuclei also reach them. Cerebellar outflow is hence perhaps integrated in these nuclei into patterns of excitation from such extracerebellar sources, combined with inhibitory patterns from Purkinje neurons, modified by local interneurons.

STRUCTURAL AND FUNCTIONAL CEREBELLAR LOCALIZATION

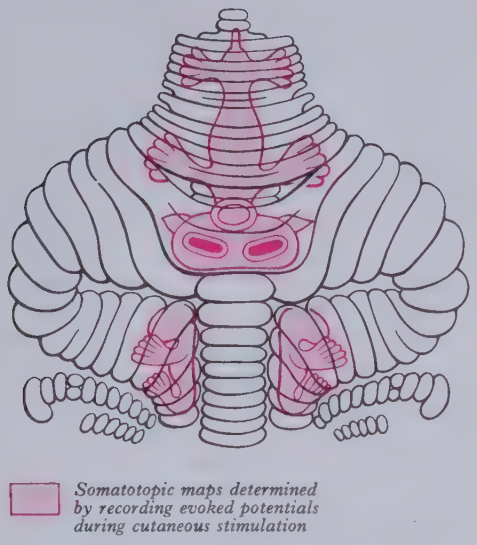


Since the cerebellar cortex is largely uniform in microstructure and microcircuitry, it may be assumed, as investigations indeed indicate, that its intrinsic mode of operation is also uniform. Functional localization, like that long held to exist in cerebral neocortical areas (but vide infra) does not exist in the cerebellar cortex. Cerebellar localization reflects the manner in which functionally dissimilar afferent tracts end in different regions of this *homogeneous* cortex; equally it reflects the differential projection of different cortical cerebellar areas to intracerebellar nuclei and thence to influence diverse brain-stem centres, the diencephalon and cerebral neocortex. (It is becoming increasingly clear, however, that there is also a *fundamental intrinsic uniformity* in the *cerebral neocortex* and that functional localization is conferred on it by extrinsic connections; see pp. 1041, 1052.) Cerebellar localization has been much studied; foundations were laid by comparative, developmental and connectivity studies (Jansen & Brodal 1954, Smith 1903, Riley 1930, Larsell 1937, 1953, Nieuwenhuys 1967) and detailed analysis of patterns of connection (Brodal 1969). Studies of changes in electrical potential evoked by 'natural' or 'artificial' stimulation have included special sense organs, peripheral nerves, the cerebrum, brain stem and spinal cord (Snider 1936, 1940, 1945, Snider & Eldred 1951, 1952, Dow & Moruzzi 1958). These have varied from a crude recording of exposed cerebellum to recording of focal potentials by inserted electrodes and of 'units' by microelectrodes. Cortical stimulation has been used to modify alternatively elicited movements. The behavioural effects of selective cerebellar ablation and of human cerebellar disease have provided some information. Examples will be mentioned here; but since experiments have used a range of mammals, with considerable variation in cerebellar morphology, illustrations are simplified and the areas designated vary between species, including mankind. Primary division into *archicerebellum*, *paleocerebellum* and *neocerebellum* has been noted, and their approximation, with some overlap, to major patterns of afferent cerebellar connections, summarized in the terms *'vestibulocerebellum'*, *'spinocerebellum'* and *'pontocerebellum'* (including *'tectocerebellum'*) (7.111A).

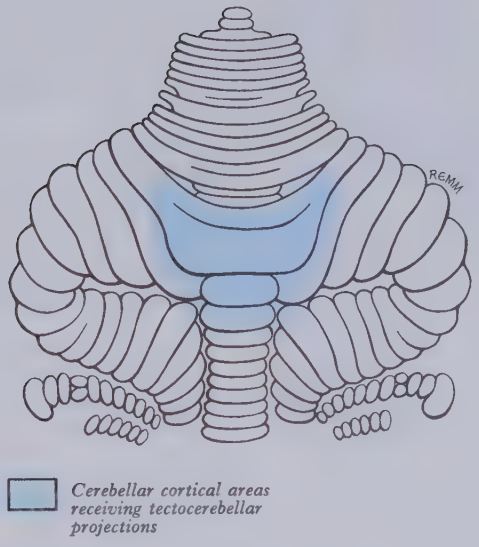


A. Cerebellar terminology. The cerebellar lobes, lobules and fissures and the approximate extent of the archi-, paleo- and neocerebellum are indicated. The subdivisions of the vermis are both named and numbered (after Larsell). On the left are terms widely used in human neuroanatomy; on the right are additional terms often used in general mammalian neuroanatomy.

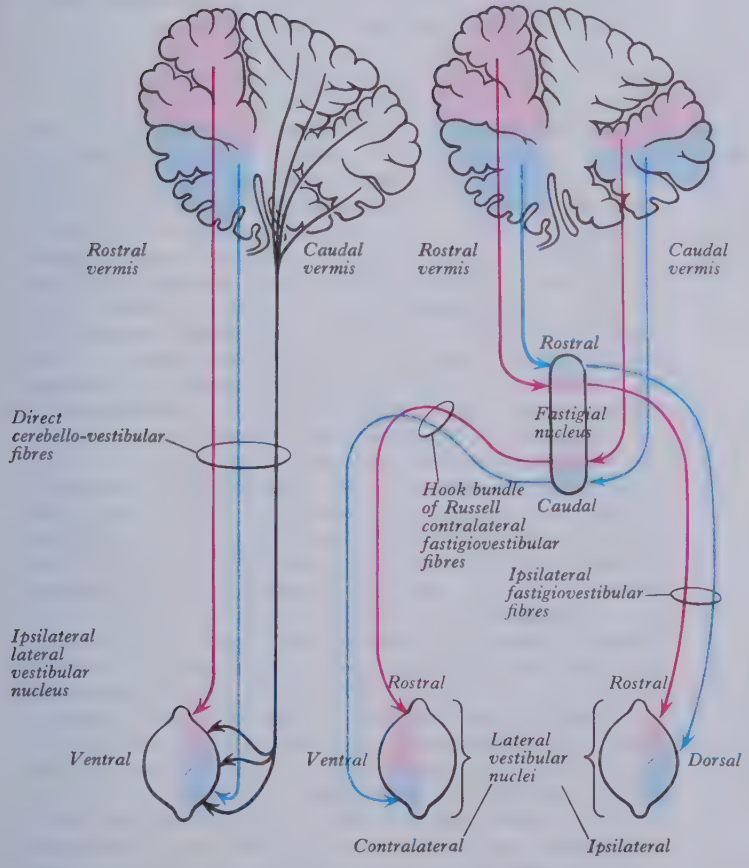
B. The cerebellar cortical areas of termination of the afferent tracts indicated, derived from experimental studies.



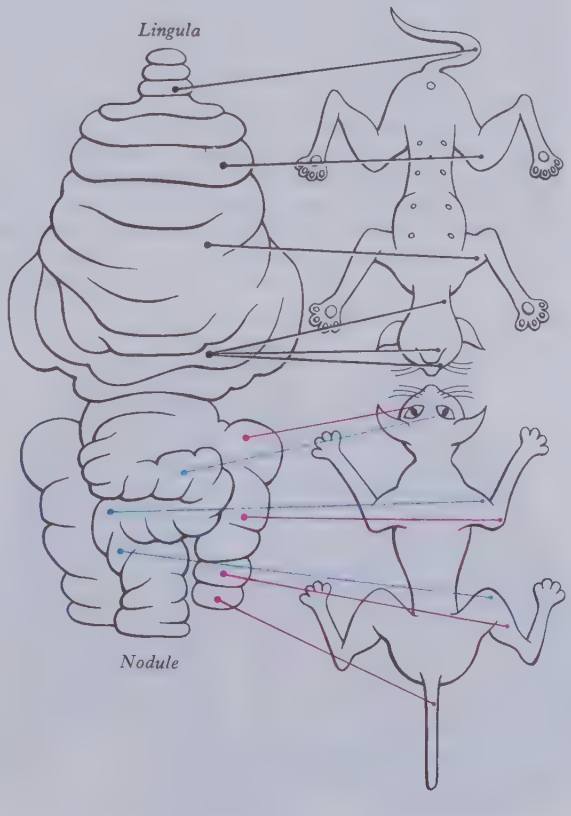
E. An analysis of the topical organization of the cortical zones of the cerebellum which receive crossed olivocerebellar (climbing) fibres from the different parts of the inferior olivary complex of nuclei.



F. An analysis of the topically organized projections of cerebellar cortical Purkinje cell axons on to the lateral vestibular nucleus and the intracerebellar nuclei.



7.IIIA–H This series of diagrams illustrates certain features of the localization of structure and function in the cerebellum: G is a median sagittal section of the feline cerebellum; in all the remaining diagrams it is assumed that the cerebellum has been flattened and viewed from the dorsal aspect so that its whole rostro-caudal extent can be seen. A, E and F are approximate outlines of the human cerebellum; B, C, D and H are of the



C. The somatotopic arrangements of the evoked potentials recorded from the cerebellar cortex during cutaneous stimulation.

D. The cerebellar cortical areas receiving tectocerebellar projections.

G. The arrangement of direct cerebello-vestibular and indirect cerebello-fastigio-vestibular projections from the cerebellar vermis of the cat.

H. The somatotopic pattern of movements elicited in different parts of the body during stimulation of the cerebellar cortex in the decerebrate cat.

feline cerebellum. Detailed descriptions of the information in these diagrams are in the text and in the references quoted.

Illustrations B, F and G were redrawn and modified from Brodal (1969), C and D were redrawn and modified from Snider (1952) and H from Hampson et al (1952) with permission from the authors and publishers.

The localization, in feline experimentees, of areas of termination of primary vestibulocerebellar fibres and of spino-, cuneo- and spino-olivocerebellar tracts appear in 7.111B. Double distributions of these to separate rostral and caudal, vermian and paravermian zones should be noted; these areas make up the spinocerebellum and within them a general somatotopy of hind- and fore-limbs is shown. Primary vestibular fibres end mainly in the flocculus, nodule and part of the uvula.

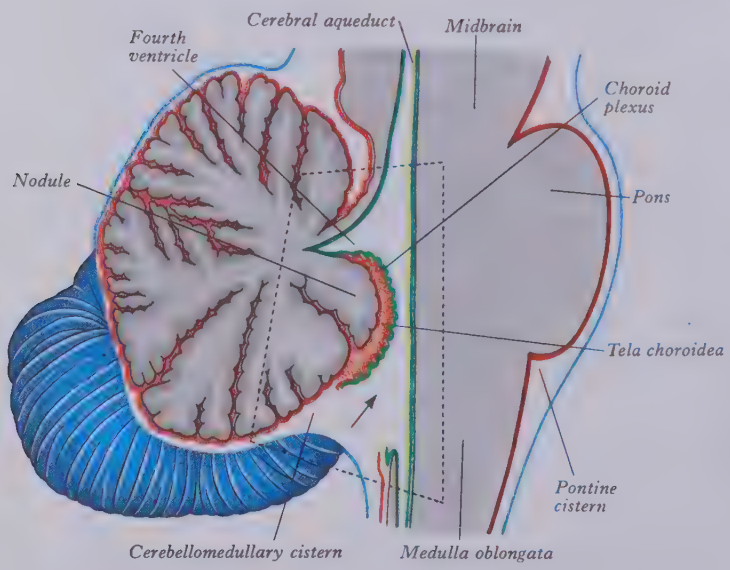


Illustration 7.111C is a somatotopic record of potentials evoked during stimulation of cutaneous receptors (Snider 1952, Hampson et al 1952); it corresponds well with diagram 7.111B, based on neuroanatomical degeneration techniques. Rostral and caudal parts of the spinocerebellum are again evident but responses to facial stimulation are included. Different regions are represented in reverse order in rostral and caudal cortical areas; in the former representation is ipsilateral and bilateral in the latter.

Illustration 7.111D shows the area responding to visual and auditory stimulation, and stimulation of occipital areas of the cerebral cortex. Visual and auditory areas are almost coincident and include central regions of the vermis and adjacent paravermian zones, overlapping an area for the face in the ventral spinocerebellum, as determined by tactile stimulation. How far visual and auditory responses are due to tectocerebellar paths or some less direct one is uncertain (p. 987). Punctate correlation between nuclei of the olivary complex and contralateral cerebellar cortex is shown simplified in 7.111E.

These examples are based on the different distributions of afferent tracts to the cerebellar cortex. The main receiving areas are generally arranged in a dorsoventral sequence of *transverse* strips. Evidence is equally clear for the localization of endings of Purkinje axons; but this is *longitudinal* (Jansen & Brodal 1954, Eager 1966, Goodman et al 1963, Voogd 1964, Korneliussen 1968). Most Purkinje axons end in the intracerebellar nuclei but some in the lateral vestibular nucleus. Cerebellar corticonuclear projections are summarized in Figure 7.111F. Direct cerebellovestibular fibres start from the flocculus, nodule and much of the rest of the vermis but particularly its rostral and caudal regions. Projections to the intracerebellar nuclei show an orderly longitudinal arrangement; on each side the cerebellar cortex may be divided into *medial*, *intermediate* and *lateral zones*. Fibres leaving the medial zone (vermis) converge on the nucleus fastigii, their craniocaudal sequence preserved during their convergence and termination. The intermediate zone (a longitudinal paravermian strip) projects to the nuclei globosus and emboliformis, the lateral zone (cerebellar hemisphere) to the nucleus dentatus. In each zone an orderly craniocaudal sequence of cortical origin of axons is maintained to the nuclear terminations. Almost all these corticonuclear projections are ipsilateral but fastigial nuclei receive bilaterally from the vermian cortex. Recalling the main cerebellar outflow and its nuclei of origin (pp. 967, 968), it is clear that the vermis mainly influences the vestibular nuclei and brain-stem reticular formation. The intermediate paravermian cortex influences the red nucleus and midbrain tegmentum; the cerebellar hemisphere, through the nucleus dentatus and thalamus, mainly affects activity in the corpus striatum and cerebral cortex. In part these outflows are somatotopically organized, including direct and indirect vermian projections to the lateral vestibular nucleus (7.111G) and intermediate projections to the red nucleus, correlating well with the organization in the nuclei themselves and also in the lateral vestibulospinal and rubrospinal tracts (Brodal et al 1962, Courville 1966). Similar localization appears in the thalamic nucleus ventralis lateralis, which receives dentatothalamic projections and projects to the cerebral motor cortex (Walker 1934).

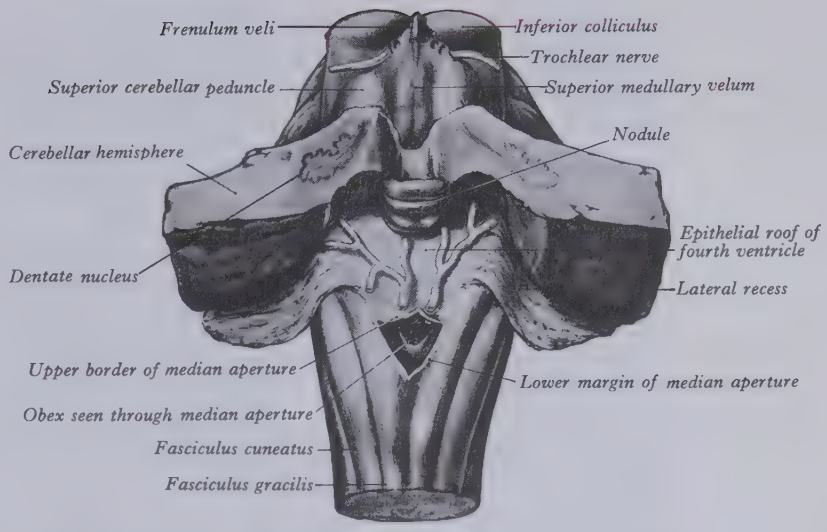
These descriptions, of course, apply to experimental animals but in general will probably be found applicable to the human cerebellum; interesting physiological parallels have already been shown. Cerebellar stimulation often modifies movements generated by simultaneous reflex or cerebral cortical stimulation; cerebellar stimulation in *decerebrate* animals elicits discrete movements (7.111H). Again, rostral and caudal areas corresponding to the spinocerebellum display a somatotopic order (Hampson et al 1952). The rostral area mediates ipsilateral responses, the caudal bilateral responses.

Such investigations, combined with effects of ablation (Chambers & Sprague 1955a,b), suggest that the vermis controls posture, tone, locomotion and equilibrium in the *whole body*, the intermediate zone controlling posture and movements in *ipsilateral limbs*. The lateral zone's role is obscure.

7.112 Sagittal section through the brain stem and the cerebellum close to the median plane. The black arrow is placed in the median aperture of the fourth ventricle. The area enclosed by the interrupted lines is shown enlarged in 7.114. Blue = arachnoid mater. Red = pia mater. Green = ependyma.

CEREBELLAR DYSFUNCTION

Innumerable reports on the behavioural effects of human cerebellar disease and of selective experimental ablations are available and have been reviewed by Holmes (1939), Wyke (1947), Brown (1949), Dow & Moruzzi (1958), Dow (1969) etc. In essence the cerebellum has an input from cutaneous receptors, proprioceptors, eyes, ears, brain-stem reticular formation and the cerebral cortex; this is integrated and discharged to motor controls in the cerebrum and brain stem. Its normal action is necessary for smooth, co-ordinated, effective movement. The more obvious effects of cerebellar dysfunction include: (1) disturbance in equilibrium; (2) disturbance of muscle 'tone', or resistance to stretch, tendon reflexes and ability to stabilize joints; (3) motor inco-ordination (*ataxia*) due to irregularities in timing, rate and force of the contraction in synergistic muscles.



Disequilibrium shows as a tendency to fall when standing and perhaps unsteady gait, with sensations of spinning, nausea, etc. The affected muscles are soft, tendon reflexes diminished and muscles tire easily (*asthenia*). Lowering of joint control may progress to pendular swinging of a limb segment after displacement or to 'flail' joints. *Muscular inco-ordination* is basic in most cerebellar dysfunction, affecting the regions variably. Hence symptoms vary. *Asynergia* is a diminished capacity for smooth, orderly action between muscle groups. A complex act may become an irregular sequence, *decomposition of movements*. A defect in rapid alternating movements, e.g. supination and pronation, may develop, *dysdiadochokinesis*. Control of range of movement may be lost, *dysmetria*. Locomotor disturbances, a tendency to fall, and (with closed eyes) deviations from the intended course are common. So is an inability to point accurately, *past-pointing*. *Tremor* is usually absent at rest but *intention tremor* may appear, intensified by movement; tremor may also affect the head or trunk. Muscular inco-ordination produces *defects of speech*. *Cerebellar nystagmus* may occur, conjugate drift of the gaze followed by a rapid return. But attempts to correlate clinical phenomena with different cerebellar regions, or with experimental results, have had limited success.

In the *flocculonodular syndrome*, with damage to the nodule, uvula and flocculus in man and other animals, the main feature is imbalance: swaying, staggering and a tendency to fall backwards. Positional nystagmus is often present. These effects are attributable to upset of the integration between vestibular nuclei and the '*vestibulocerebellum*'.

In experimental animals, *ablation* of the vermis in the anterior lobe exaggerates tendon reflexes and rigidity, already present in decerebrate preparations; vermian *stimulation* reduces rigidity. The converse results from ablation or stimulation of paravermian parts of the anterior lobe. These effects show somatotopy but have not been clearly demonstrated in man.

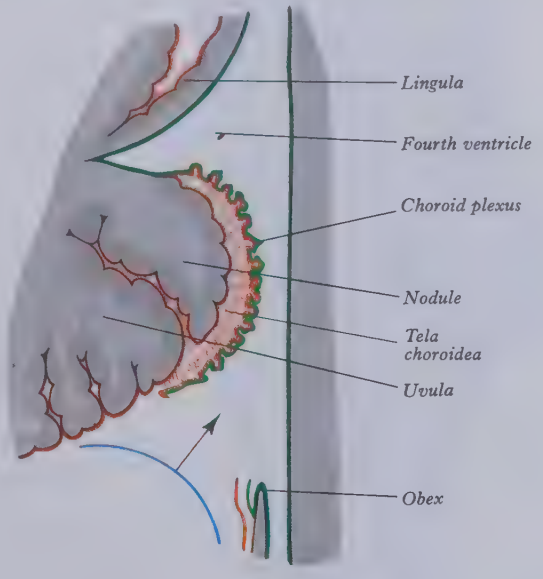
Most human cerebellar disorder is *neocerebellar*, involving one or both hemispheres or their outflows. In unilateral disease, if severe, the hypotonia and inco-ordination noted above appear *on the side* of the lesion, but gross intention tremor and staggering only appear if the dentate nucleus or superior cerebellar peduncle are involved. Small cortical lesions have little effect; even quite extensive disease, though causing transient dysfunction, is followed by rapid improvement in locomotor control. Such *cerebellar compensation* is not yet explained.

Despite the prominence of locomotor effects in cerebellar dysfunction it seems probable that the cerebellum is extensively, but less overtly, involved in other activities such as motor memory, *autonomic homeostasis* and *modulation of sensory transmission*.

7.113 Dorsal aspect of the roof and the lateral recesses of the fourth ventricle, exposed by removal of parts of the cerebellum.

The Fourth Ventricle

The fourth ventricle (7.112, 115, 116), a cavity of complex shape, lies ventral to the cerebellum and dorsal to the pons and upper half of the medulla. Developmentally it has three parts: *superior*, part of the isthmus rhombencephali (p. 185); *intermediate*, the metencephalic (pontine); and *inferior*, myelencephalic (medullary). It is lined by ependyma, continuous below with the medulla's central canal and above with the cerebral aqueduct, connecting it to the third ventricle. At its mid-level a narrow, curved *lateral recess* extends on each side between the inferior cerebellar and floccular peduncles then, reaching the flocculus, it is crossed ventrally by the glossopharyngeal and vagal fila. Its lateral end is open, allowing a variable part of the ventricle's choroid plexus to protrude into the subarachnoid space (7.81). In its midline the cavity extends dorsally into the white cerebellar core as a *median dorsal recess* (7.112, 180, 181) above the nodule; on each side a *lateral dorsal recess* extends still further dorsally (7.181), cranial to the inferior medullary velum and caudal to the cerebellar nuclei but separated from them by a thin white lamina. The ventricle has lateral boundaries, a roof and a rhomboidal ventral floor, the *rhomboid fossa*.



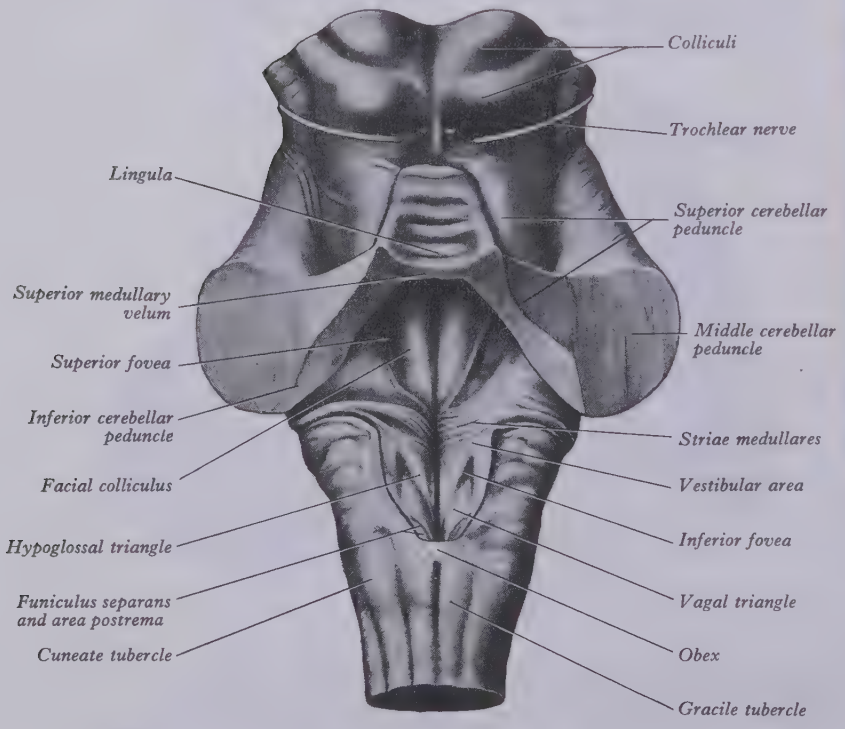
Lateral boundaries. Each is formed inferiorly by the gracile and cuneate tubercles, fasciculus cuneatus and inferior cerebellar peduncle, superiorly by the superior cerebellar peduncle.

The roof (7.113) extends dorsally into the median and lateral dorsal recesses. Its upper part is simple, formed by the superior peduncles and superior medullary velum. The peduncles (p. 917), emerging from the cerebellum superoventrally, are at first lateral boundaries but near the inferior colliculi they converge to overlap the ventricle as part of its roof. The *superior medullary velum* (p. 963) fills the angle between them and is continuous dorsally with the cerebellar white core; it is covered dorsally by the lingula of the superior vermis (7.115).

Inferiorly the roof is more complex but mostly a thin sheet, devoid of nervous tissue, formed by ventricular ependyma and the pia mater of the tela choroidea, which covers it dorsally (7.113, 114). The sheet is interrupted by an inferior *median aperture* (7.113, 114), through which the ventricle connects with the subarachnoid space. *The tela choroidea of the fourth ventricle*, a double layer of pia mater, is between the cerebellum and inferior part of the ventricle's roof. Its dorsal layer covers the inferior vermis and, reaching the nodule, is reflected ventro-inferiorly in direct contact with the ependyma. In the tela, vascular fringes form the fourth ventricle's choroid plexus. On each side, the tela choroidea is in contact with the ependyma until it reaches the inferolateral border of the ventricular floor, marked by a narrow, white ridge, the *taenia*; the paired taeniae are continuous below with a curved margin, the *obex*, which overlaps the ventricle's inferior angle and is covered by ependyma on both its aspects (7.114). Superiorly the taeniae extend laterally along the inferior borders of the lateral recesses.

Apertures in the roof. In the caudal part of the roof are three openings. The *median aperture* is large, inferior to the nodule (7.113, 114) and varies in size, with an irregular upper border drawn dorsally towards the inferior vermian surface to face the cerebellomedullary cistern (7.112). *Lateral apertures*, terminal in the lateral recesses, are partly occupied by the choroid plexus which protrudes into the subarachnoid space (7.81); the ependyma and pia mater are continuous at their margins. These are the only connections between the ventricular system and the subarachnoid space. Occasionally a lateral recess may fail to open but a median aperture is constant.

The choroid plexuses. Bilateral fringes of the vascular tela choroidea contain choroid plexuses; these invaginate the caudal part of the roof and are covered by ependyma which is modified as a secretory epithelium. Each has vertical and horizontal limbs. The two longitudinal vertical fringes flank the midline, fusing at



7.114 An enlargement of the part of 7.112 which is enclosed by an interrupted line. Blue = arachnoid mater. Red = pia mater. Green = ependyma. The black arrow traverses the median aperture of the roof of the fourth ventricle.

the cranial margin of the median aperture and often prolonged on the ventral vermian aspect, to which they adhere (Hewitt 1960). The horizontal parts are continuous, project into the ventricle, passing into its lateral recesses, and emerge through the lateral apertures, still covered by ependyma. The entire structure is like a T, with a double vertical limb. This form varies widely (Lang & Schafer 1977). Arterial supply is from the inferior cerebellar arteries (pp. 752, 753). For details of supply and drainage consult Maillot et al (1976).

The rhomboid fossa (7.86, 115, 116), the fourth ventricle's rhombic floor, is formed by dorsal sufaces of the pons and the 'open' cranial half of the medulla, covered by grey matter continuous with that of the walls of the medullary and spinal central canals; superficial to this is a thin lamina of neuroglia covered by ependyma. The floor is divided into superior, intermediate and inferior areas. The *superior* (rostral) area is triangular, limited laterally by superior cerebellar peduncles; its apex is continuous with the cerebral aqueduct's wall, its base an arbitrary line through the upper ends of two small *superior foveae*. The *intermediate* area descends from this to taenial level, where they extend horizontally into the lateral recesses. The *inferior* (caudal) area, also triangular, is continuous below with the wall of the medullary central canal. The fossa is divided vertically by a *median sulcus*, flanking which are paired *medial eminences*, each bounded laterally by a *sulcus limitans*. In the superior area each eminence occupies its half of the floor; but medial to the superior fovea it is expanded into a long *facial colliculus*, superficial to the abducent nucleus but partly produced by radicular facial nerve fibres. In the floor's inferior area each medial eminence is a *hypoglossal triangle* (*trigonum hypoglossi*), with medial and lateral parts separated by faint oblique furrows; the medial area corresponds to the upper pole of the hypoglossal nucleus, the lateral to the *nucleus intercalatus* (p. 956).

Each *sulcus limitans* lies lateral to the medial eminence and in its upper part is itself the lateral limit of the floor and presents a bluish-grey *locus coeruleus*, overlying a group of pigmented nerve cells. The *nucleus coeruleus* corresponds partly to the locus but ascends to the lower end of the mesencephalic trigeminal nucleus and may overlap it. Some of its neurons contain neuromelanin, especially in human midbrains (Foley & Baxter 1958); at pontine levels it spreads into the adjacent reticular formation, of which it is usually considered a part (Russell 1955, Webster 1978). All its central neurons are noradrenergic (Dahlstrom & Fuxe 1964, Fuxe et al 1970), by far the largest group of noradrenergic neurons so far observed in mammalian brains (p. 993). Stereotactic lesions of both nuclei (in rats) show them to be the main and probably sole source of fibres in the *dorsal noradrenergic bundle*, part of the central tegmental fasciculus (Ungerstedt 1971). Ramón-Moliner & Dansereau (1974) demonstrated in the feline nucleus coeruleus high concentrations of acetylcholinesterase, a finding not inconsistent with the above view. Afferent nuclear connections are less certain, but probably include ascending spinal fibres, brain-stem reticular nuclei, trigeminal nuclei, and possibly forebrain centres. Efferent nuclear projections have, in contrast, been much investigated (Maeda et al 1973, Lindvall & Bjorkland 1974, Freedman et al 1975, Kievit & Kuypers 1975, Gatter & Powell 1977, Pickel et al 1977, Bowden et al 1978, Nieuwenhuys 1986) by both immunofluorescence and autoradiography. Briefly, the nucleus has a descending, local brain-stem and profuse ascending projections; descending fibres enter the ventrolateral spinal funiculus and apparently end *bilaterally* in ventral, intermediate and dorsal grey columns *throughout* the cord; laminar destinations are mainly IV–VIII. Local fibres project to many 'specific' and reticular bulbopontine nuclei; others traverse the superior cerebellar peduncle, some ending in intracerebellar nuclei, most in the cerebellar cortex, arborizing around Purkinje somata or continuing into the molecular layer. As indicated, ascending fibres form the *dorsal noradrenergic bundle*; in the upper midbrain the paired

7.115 The rhomboid fossa or 'floor' of the fourth ventricle.

7.116 A dorsal view of the brain stem including the floor of the rhomboid fossa. For identification of structures compare with 7.115. In addition to the structures shown in the latter, note: (1) the crenated outlines of the right and left dentate nuclei in the sectioned surface of the cerebellar white matter opposite the widest part of the rhomboid fossa; (2) the midline pineal gland cranial to the superior colliculi; (3) the rounded pulvinar of the dorsal thalami which encroach on the uppermost part of the photograph; (4) the right and left habenular trigones immediately lateral to the base of the pineal; (5) the medial geniculate bodies, lateral to the superior colliculi. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

bundles exchange some fibres, continuing through the diencephalon in the lateral hypothalamic medial forebrain bundle (p. 1009), its continuation being via the septal region into supracallosal longitudinal stria and cingulum. Numerous complex side branches (p. 1035) pass to a remarkable diversity of destinations, which in the midbrain include the periaqueductal grey matter, reticular nuclei and the colliculi; diencephalic arborizations end in all principal thalamic, geniculate and habenular nuclei and, probably indirectly, hypothalamic nuclei. Telencephalic destinations are major 'limbic' structures, e.g. the septal nuclei, amygdala, hippocampus, subiculum and cingulate, retrosplenial and parahippocampal gyri; all the neocortex is held to receive a uniform, diffuse, bilateral input. The compact, relatively small nucleus coeruleus appears to be concerned with somatic motor and visceral control, the complex hierarchy of sleep 'centres', cognitive mapping, general affective behaviour and in modulating general neocortical and thalamic activity. (For the ventral noradrenergic bundle see p. 993.)

At the level of the facial colliculus the sulcus limitans widens into the *superior fovea* and inferiorly presents an *inferior fovea*. Lateral to the foveae is a rounded *vestibular area*, extending into the lateral recess, where it becomes the *auditory tubercle*, produced by the subjacent dorsal cochlear nucleus and cochlear part of the eighth cranial nerve (p. 958). Winding round the inferior cerebellar peduncle and across the vestibular area and medial eminence to enter the median sulcus are the *striae medullares* (p. 960). Caudal to the inferior fovea, between the hypoglossal triangle and vestibular area, is the *vagal triangle* (*trigonum vagi*), overlying the dorsal vagal nucleus (p. 1114). The triangle is crossed below by a narrow translucent ridge, the *funiculus separans*; between this and the gracile tubercle is a small *area postrema*. The funiculus is covered by thickened ependyma containing tanycytes; the area postrema has a similar covering over loose, vascular neuroglial tissue containing neurons of moderate size. In these regions the blood–brain barrier may be modified. The specialized ependyma is like areas in the third ventricle and cerebral aqueduct (vide infra, also p. 894). The ependymocytes and tanycytes may be involved in: (1) secretion into cerebrospinal fluid, (2) transport of neurochemicals from subjacent neurons, glia or vessels to cerebrospinal fluid, (3) transport of neurochemicals from cerebrospinal fluid to the same subjacent structures, and (4) chemoreception (area postrema) (Brizzee & Neal 1954, Borison & Borison 1973, Collins & Woollam 1981).

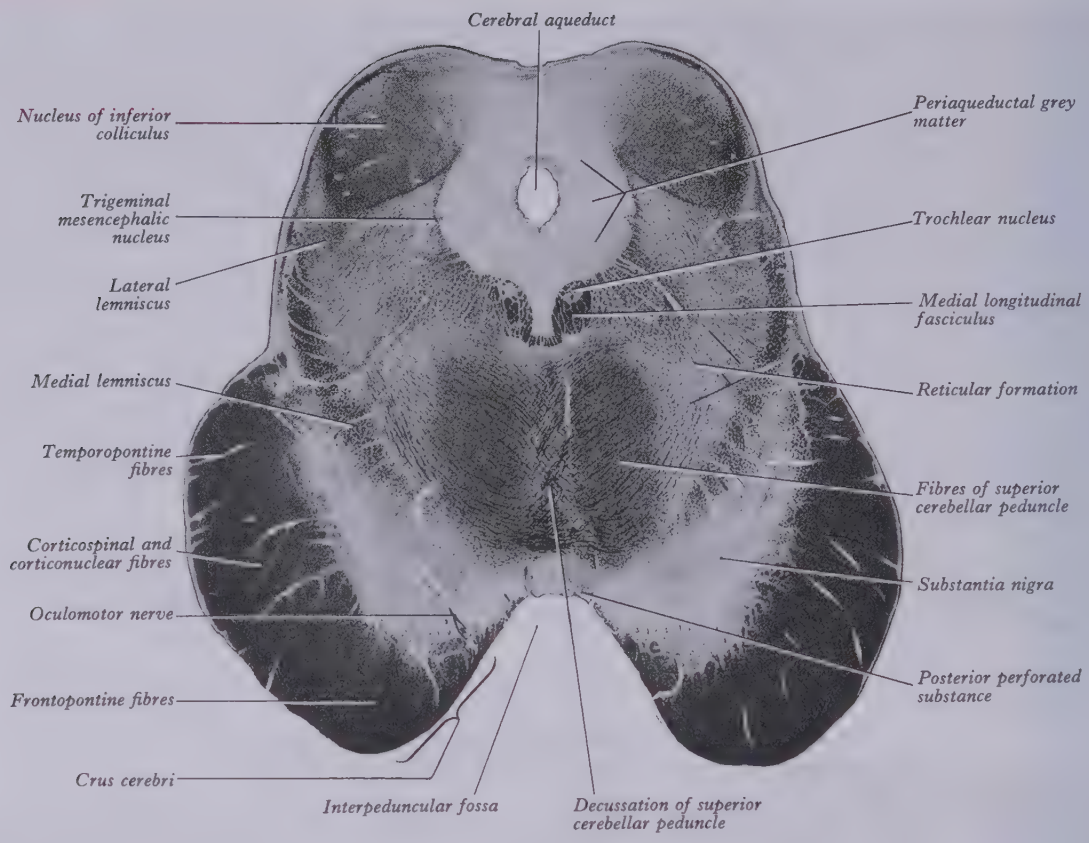
The caudal ventricular floor, towards its inferior apex, resembles a pen nib, hence the term *calamus scriptorius*. (For the phylogenetic and ontogenetic development of the fourth ventricle consult Kier 1977.)

THE MESENCEPHALON OR MIDBRAIN

The midbrain (7.115–118) develops from the intermediate primary cerebral vesicle (p. 189). In human development and phylogenetically it remains simpler than either forebrain or hindbrain. In earlier vertebrates its major feature is the development in its roof plate of higher visual (p. 987) and, later, higher auditory centres. In mammals it is often stated that these become reflex centres, their original function as 'higher' sensory centres being transferred to the cerebral cortex. As this *telencephalization* proceeds, the midbrain is traversed by increasing numbers of neural paths originating or terminating in the cerebral cortex. Midbrain mechanisms also contribute extensively to the reticular system (pp. 932, 988). These statements are merely introductory: some midbrain activities remain reflex, e.g. 'light', 'accommodation', 'visuospinal' and 'auditory' reflexes and many others, but it is misleading to overlook the roles of its intrinsic nuclei, e.g. the colliculi, and reticular elements which mediate, as at other levels, complex interactions between afferent and efferent pathways. It should also be remembered that it is the *only* connection between the forebrain and hindbrain.

EXTERNAL FEATURES

The midbrain traverses the hiatus in the tentorium cerebelli (7.85), connecting the pons and cerebellum with the forebrain. It is the shortest brain-stem segment, not more than 2 cm in length. Lateral to it are the parahippocampal gyri, hiding its sides when the inferior surface of the brain is examined. Its long axis inclines ventrally as it ascends. For description it is divided into right and left halves, *cerebral peduncles*, each demarcated into a ventral *crus cerebri* and a dorsal *tegmental part* by a bilateral pigmented lamina, the *substantia nigra*. The two crura are separate, the tegmental parts united as a single tegmentum and traversed by the *cerebral aqueduct* connecting the third and fourth ventricles. The region dorsal to an oblique coronal plane, including the aqueduct, is the *tectum*, with dorsally four *rounded colliculi* in superior and inferior pairs.



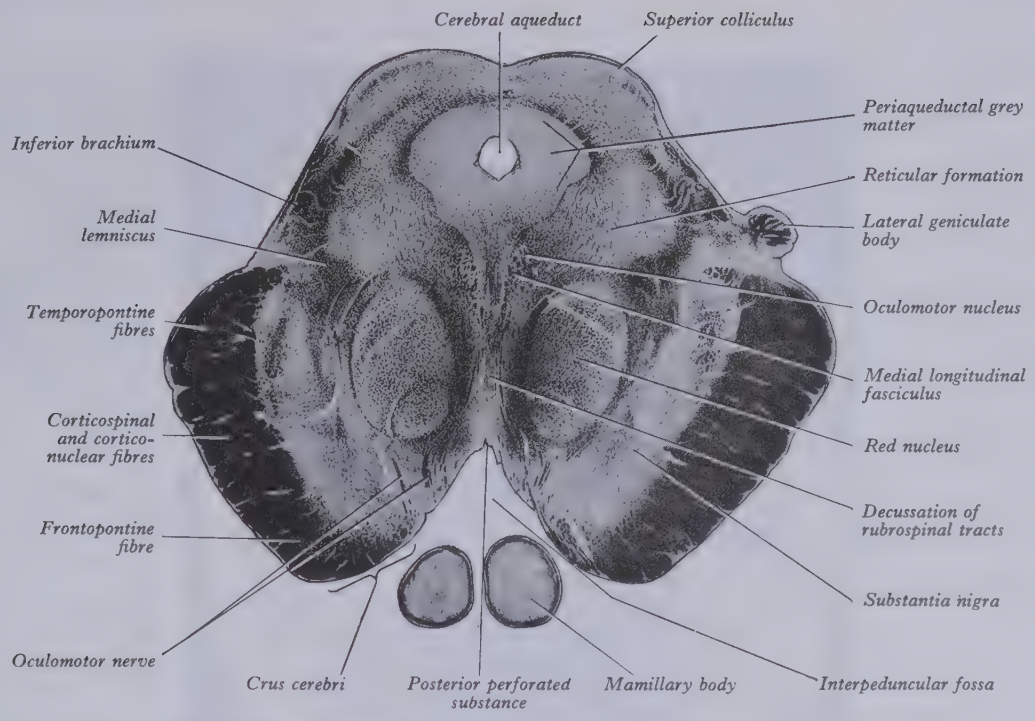
Crura cerebri are superficially corrugated and emerge from the cerebral hemispheres, converging as they descend to meet where they enter the pons, forming here the caudolateral boundaries of the *interpeduncular fossa* (p. 1007). The median caudal part of the fossa is a greyish area, the *posterior perforated substance* (p. 1007), through which pass central branches of the posterior cerebral arteries. The ventral (basilar) crural surfaces are crossed, curving mediolaterally near the pons, by the superior cerebellar and posterior cerebral arteries; near the crural entry into the hemispheres, the optic tracts wind dorsolaterally around them. Over each crus, near the pons, a thin white *taenia pontis* often appears, extending into the cerebellum between its middle and superior peduncles. Each crus bears a *medial sulcus*, from which roots of the oculomotor nerve emerge (7.81, 82, 118). Its lateral surface adjoins the parahippocampal gyrus and is crossed by the trochlear nerve (7.125); it bears a longitudinal *lateral sulcus*, in which fibres of the lateral lemniscus reach and form a surface elevation which inclines rostrodorsally and in part joins the inferior colliculus; the rest continues into the inferior brachium.

The *colliculi* (*corpora quadrigemina*) (7.115, 116, 125) are four eminences, above the superior medullary velum and inferior to the pineal gland and posterior commissure, the whole sloping ventrally as it ascends. Below the splenium, they are partly overlapped on each side by the pulvinar of the dorsal thalamus. In superior and inferior pairs, they are separated by a cruciform sulcus, whose upper limit expands into a depression for the *pineal gland* (7.125); from its caudal end a median *frenulum veli* is prolonged down over the superior medullary velum; lateral to the frenulum the trochlear nerves emerge; they pass ventrally over the lateral aspects of the cerebral peduncles and traverse the interpeduncular cistern to the petrosal end of the cavernous sinus. The *superior colliculi*, larger and darker, are stations for visual responses (p. 986). The *inferior colliculi*, smaller but more prominent, are associated with auditory paths (p. 986). Difference in colour is due to superficial layers of neurons in the superior colliculi (p. 987).

From the lateral aspect of each colliculus a *brachium ascends ventrolaterally*. *The brachium of the superior colliculus* passes below the pulvinar, partly overlapping the medial geniculate body, continuing partly into the lateral geniculate body (p. 1016) and partly into the optic tract. It conducts fibres from the retina and optic radiation to the superior colliculus. *The brachium of the inferior colliculus* ascends ventrally, conveying fibres from the lateral lemniscus and inferior colliculus to the medial geniculate body.

INTERNAL STRUCTURE OF THE MIDBRAIN

In transverse section each cerebral peduncle has, as noted above, dorsal and ventral regions separated by the *substantia nigra* (7.117, 118), the dorsal being the *tegmentum* and the ventral the *crura cerebri*. The crura are separated while the tegmental parts are continuous.



7.117 Transverse section of the midbrain through the inferior colliculi. Weigert Pal preparation. Magnification × 4.

Each **crus cerebri**, semilunar in section, contains corticospinal, corticonuclear and corticopontine fibres (7.117, 118). The first two occupy the middle crural two-thirds, descending via the pons and medulla, where corticonuclear fibres end in nuclei of the cranial nerves and other brain-stem nuclei; corticospinal fibres continue into the medullary pyramid. Corticopontine fibres arise in the cerebral cortex and end in the nuclei pontis. They form two groups: the *frontopontine* from the frontal lobe, principally areas 6 and 4, traversing the internal capsule and then occupying the medial sixth of the crus cerebri; and *temporopontine* fibres from the temporal lobe, also traversing the internal capsule but coming to occupy the lateral sixth of the crus; both end in the pontine nuclei. *Parieto-* and *occipitopontine* fibres are also described in the crus, medial to the temporopontine, which is largely from the posterior region of the temporal lobe; occipitopontine fibres do *not* include a projection from the striate cortex (Verhaart & Mechelse 1954).

A band of fibres, *the tractus peduncularis transversus*, may be visible emerging from the optic tract on the lateral peduncular aspect to pass round its ventral surface midway between the pons and the optic tract and disappearing into the interpeduncular fossa dorsolateral to the corpus mamillare, where it terminates in a small *nucleus of the transverse peduncular tract*, medial to the substantia nigra. The tract, constant in many lower mammals, is identifiable in only 30% of human brains. Since it degenerates after ocular enucleation, it may be part of the visual pathway; it projects to oculomotor nuclei in some mammals (Gillilan 1941, p. 1015).

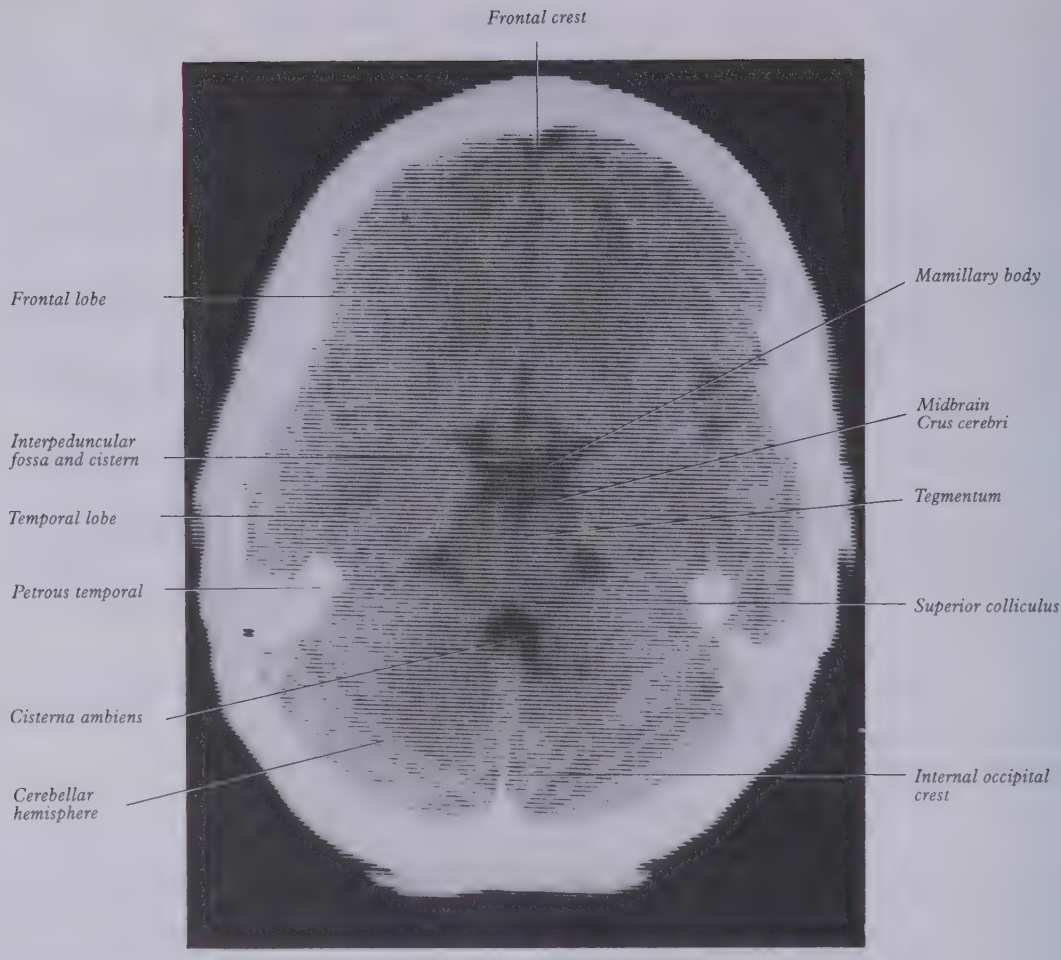
The substantia nigra, a bilateral lamina of numerous pigmented (neuromelanin-containing) multipolar neurons, extends through the whole midbrain. Its pigmentation is easily visible in transverse or coronal sections (7.117, 118). The pigment is related to the aminergic status of many mesencephalic reticular neurons, increases with age, is more abundant in primates, maximal in man (Marsden 1961) and present even in albinos. The nucleus is semilunar in transverse section, concave dorsally; from its convex ventral surface extensions pass between fibres of the crus cerebri. Thicker medially, it reaches from the medial to the lateral crural sulcus and from the pons to the subthalamic region; its medial part is traversed by radicular oculomotor fibres streaming ventrally to their oculomotor sulcus. It is divisible into a dorsal *pars compacta* of medium-sized neurons, many pigmented, and a ventral *pars reticularis*, intermingled with fibres of the crus cerebri, containing fewer neurons, some with small amounts of pigment; the ventral part reaches the subthalamic region and is considered continuous with the globus pallidus, which it structurally resembles; both contain iron in unusual amounts. In submammalian vertebrates a well-developed *pars lateralis* is recognizable but is insignificant in man (Huber & Crosby 1933), though it has been shown to project to the tectum in primates (Woodburne et al 1946).

The substantia nigra is connected with the cerebral cortex, spinal cord, hypothalamus and basal nuclei. Corticonigral fibres arise from precentral and probably postcentral gyri, a few terminating on neurons in the *pars reticularis* and many being fibres of passage to the red nucleus and reticular formation. Collaterals from fibres in sensory tracts from the spinal cord are also said to end in the substantia nigra; fibres from the mammillary peduncle and subthalamic nucleus have also been traced to its neurons. Connections with basal nuclei are efferent nigrostriatal, passing to the caudate nucleus, putamen and possibly globus pallidus (the latter often strongly denied); afferent strionigral fibres also exist. Efferent fibres also enter the tegmentum, probably ending in its reticular formation, whence impulses are relayed to spinal ventral column neurons. A major efferent connection in cats is nigrotegmental (Afifi & Kaelber 1965). Lesions medial in the substantia, also in cats (Marcos 1969), indicate that some fibres pass to the ventral thalamus; nigrocortical connections have also been described in cats (Negro 1969). A nigrothalamic projection has been confirmed in monkeys by autoradiographic tracing (Carpenter et al 1976); terminals were identified in the medial part of nucleus ventralis intermedius, the magnocellular part of nucleus ventralis anterior and the juxtalaminar part of nucleus medialis dorsalis (p. 1002). Jayaraman et al (1977), by the same techniques

7.118 Transverse section of the midbrain through the superior colliculi. Weigert Pal preparation. Magnification × 3.

and also in monkeys, have described a tectal projection, fibres derived largely from the superolateral region of the substantia nigra ending in intermediate strata of lower levels in the ipsilateral inferior colliculus. The pars lateralis of the substantia nigra includes the dopaminergic cell group A9; the pars compacta constitutes group A10 (p. 993).

The mesencephalic tegmentum differs according to the level of section. It is directly continuous below with the pontine tegmentum and contains the same tracts. At inferior collicular level grey matter is restricted to environs of the cerebral aqueduct, scattered collections in the reticular formation (7.117, 118, 122) and the tectum (p. 986). The *trochlear nucleus* is in the ventral grey matter near the midline, in a position corresponding to abducent and hypoglossal nuclei. With the medial longitudinal fasciculus running immediately ventral, it extends through the lower half of the midbrain, just caudal to the oculomotor nucleus. In some primates these nuclei are merged and distinguished only by the arrangement of their neurons, the trochlear cells being also smaller. Trochlear *efferent fibres* pass *laterodorsally* round the central grey matter, then descend medial to the trigeminal mesencephalic nucleus to reach the upper end of the superior medullary velum, where they decussate and emerge lateral to the frenulum (7.115, 116). A few fibres may not decussate in all vertebrates. The trochlear nerve may originally have supplied muscles of a pineal eye, accounting for its dorsal course. Embryological evidence (Pearson 1943) and phylogenetic data support a more dorsal origin of its nucleus.



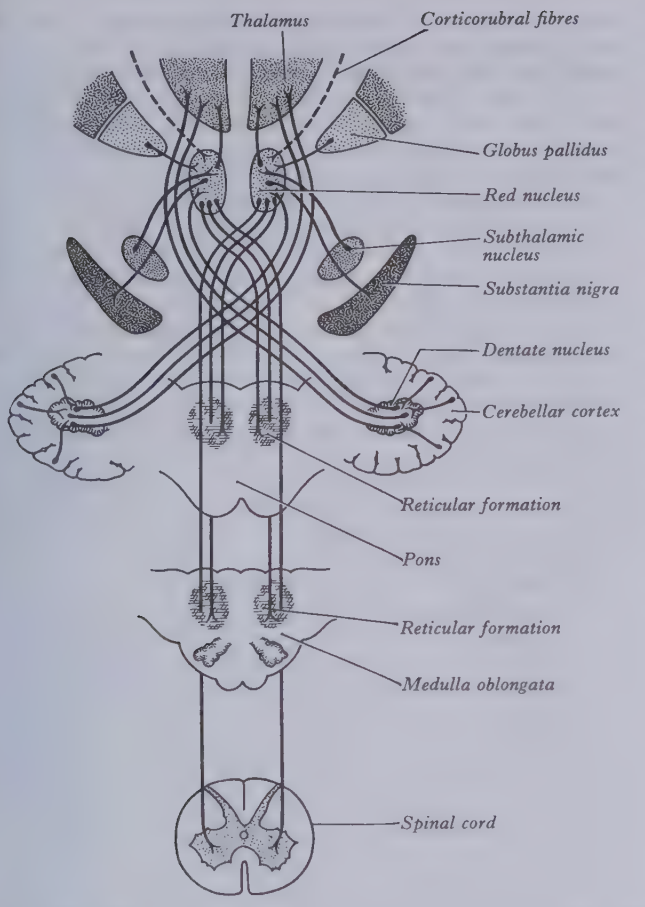
The *trigeminal mesencephalic nucleus* is lateral in the central grey matter, ascending from the upper pole of the main trigeminal sensory nucleus in the pons to superior collicular level in the midbrain. It is accompanied by a tract of both peripheral and central branches from its axons. Its large ovoid neurons are unipolar, as in sensory ganglia, in many small groups which extend as curved laminae on each lateral margin of the periaqueductual grey matter. Neurons are most numerous in its lower level. Attempts to categorize them have failed; they have few dendrites and are usually so close that somato-somatic contacts have been suggested (Hinrichsen & Larramendi 1969). For connections see pp. 1099, 1122. Apart from these nuclei the mesencephalic tegmentum contains many scattered neurons; most are included in the reticular formation (p. 988).

The *white matter* contains all the tracts mentioned in the pontine tegmentum; prominent is the large decussation of the superior cerebellar peduncles (p. 966), which enter the tegmentum and pass ventromedially round central grey matter to the median raphe, where most fibres cross in the *decussation of the superior cerebellar peduncles* and then separate into ascending and descending fascicles. Some *ascending* fibres end in or give collaterals to the red nucleus, which they encapsulate and penetrate; many others ascend to the nucleus ventralis lateralis of the thalamus. Some, uncrossed, have branches believed to end in the circumaqueductal grey matter and reticular formation, interstitial nucleus and posterior commissural nucleus (sometimes, perhaps mistakenly, see Ingram & Ranson 1953, called the nucleus of Darkschewitsch); the latter nucleus may send efferent fibres to the medial longitudinal fasciculus and posterior commissure. *Descending* fascicles end in the pontine and medullary reticular formation, the olivary complex and possibly cranial motor nuclei (pp. 966, 967).

The *medial longitudinal fasciculus* adjoins the somatic efferent column, dorsal to the decussating superior cerebellar peduncles. The *medial*, *trigeminal* and *lateral lemnisci* and *lateral spinothalamic tract* (spinal lemniscus) form a curved band dorsolateral to the substantia nigra. Some fibres of the lateral lemniscus end in the inferior collicular nucleus, encapsulating it and synapsing with its neurons. The remaining direct lemniscal and inferior collicular-derived fibres enter the inferior collicular brachium, which commences at this level and conducts them to the medial geniculate body. Some fibres to the inferior colliculus are collaterals of direct lemniscal fibres.

Superiorly, level with the superior colliculus, the tegmentum contains the *red nucleus*, extending into the subthalamic region. *Central grey matter* round the aqueduct contains ventromedially the *oculomotor nucleus*, elongated and related ventrolaterally to the medial longitudinal fasciculus; below, it reaches the trochlear nucleus (7.117). The oculomotor is divisible into neuronal groups partially correlated with the nerve's motor distribution; they include a visceral efferent *accessory oculomotor nucleus* (Edinger-Westphal), dorsal to the main nucleus (p. 1056).

The red nucleus is an ovoid mass with a pink tinge, about 5 mm in diameter, dorsomedial to the substantia nigra (7.118). The tint appears only in fresh material and is due to a ferric



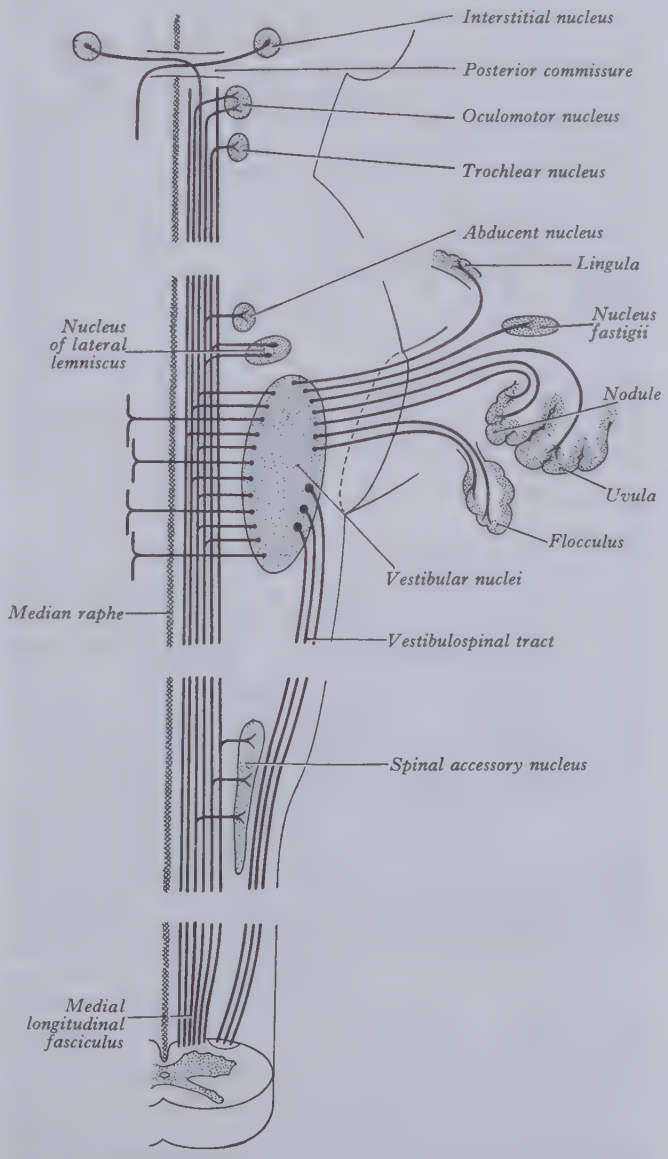
7.119 Horizontal computed tomogram through the head at the level of the midbrain. Supplied by Shaun Gallagher, Guy's Hospital, London; photography by Sarah Smith.

pigment in many neurons; these are mostly multipolar, of varying size, mostly large or small. Their proportions and arrangements vary in mammalian groups; in primates the *magnocellular* element is decreased, with a reciprocal increase of *parvocellular* complement. Small multipolar neurons occur in all parts, but in human nuclei the larger neurons are restricted to the lower level. Condé & Condé (1973) classified feline rubral cells as multipolar, pyramidal, fusiform and spherical, emphasizing also a heterogeneous nuclear cytoarchitecture; multipolar neurons predominated below, pyramidal and spherical at higher levels, but all occurred at all levels. Superiorly the red nucleus is poorly demarcated, blending into the reticular formation and caudal pole of the interstitial nucleus' lower end (Davenport & Ranson 1930). Inferior *compact* and superior *diffuse* architectonic regions have been described; the whole mass is traversed and surrounded by fascicles of nerve fibres, including many from the oculomotor nucleus (7.118). This makes the red nucleus appear reticular. Its magnocellular element is considered phylogenetically old, which accords with the parvocellular predominance in primates. *Afferent connections* are complex and many; only those well attested are noted here. Some occur in other mammals but are uncertain in man. Uncrossed corticorubral fibres from the sensorimotor cortex appear in cats (and other mammals); an area frontal to the precentral gyrus (p. 1055), termed 'supplementary motor area' in the feline cerebrum, projects bilaterally to the red nuclei; somatotopy has been shown in these fibres and nuclear terminations, conforming with localization in the rubrospinal tract (vide infra). The cortical projection is from primary somatomotor and somatosensory areas. Brown (1974) has described their terminations as axodendritic and largely in peripheral parts of the red nucleus. There are also bilateral, probably reciprocal connections with the superior colliculi. Feline red nuclei also receive nerve fibres from the contralateral nucleus interpositus, corresponding to human globose and emboliform nuclei and from the contralateral dentate nucleus. All these cerebellar connections and perhaps others (p. 966) traverse the superior cerebellar peduncle and display some somatotopy. Other reputed sources of afferents are the globus pallidus, subthalamic and hypothalamic nuclei, substantia nigra and spinal cord. (Rubral connections are outlined in 7.120.)

The main *outflow* is the **rubrospinal tract** (p. 934), from large and small neurons in other mammals and probably so in mankind. As mentioned (p. 934), it is often regarded as unimportant in man by clinical and academic observers, who usually derive it only from the magnocellular element, with axons which do not travel far in the spinal cord. Evidence for this negative view is exiguous; all studies in other mammals, chiefly cats and monkeys, take it to lumbosacral levels. Tract and nuclear origins show somatotopy, those axons ending at cervical levels being from neurons segregated dorsomedially, those for lumbosacral segments ventrolaterally and those for thoracic levels being intermediate. This somatotopy is confirmed by the recording of antidromic impulses evoked in the nucleus by stimulation of the tract. Some efferent axons form a *rubrobulbar tract* to motor nuclei of the trigeminal and facial nerves and perhaps the inferior olivary and oculomotor, trochlear and abducent nuclei; many 'rubrobulbar' fibres may end throughout the brain-stem reticular formation.

In cats *rubrocerebellar* connections to the dentate nucleus have been described (Courville & Brodal 1966). Efferents may also reach ventrolateral thalamic nuclei from the inferior third of the red nucleus. The rubrospinal tract crosses at once in the *ventral tegmental decussation*, which lies ventral to the *tectospinal*

7.120 Simplified diagram of the principal connections of the red nucleus.



decussation, then descends ventral to the *decussation of the superior cerebellar peduncles*, through the reticular formation of the pons and medulla to the spinal cord. Since it ends in almost the same laminae as the corticospinal tract, the *cortico-rubro-spinal* projection is one example of an indirect corticospinal path (p. 934).

Associated with rubrospinal tracts are the *tegmentospinal* fibres from tegmental reticular elements lateral to the red nuclei, probably to be grouped with other medullary and pontine reticulospinal tracts (p. 934).

The **tectospinal** and **tectobulbar tracts** also start at this level, from neurons in the superior colliculi, sweeping ventrally round the central grey matter to decussate ventral to the oculomotor nuclei and medial longitudinal fasciculi as part of the *dorsal tegmental decussations*. The tectospinal tract descends ventral to the medial longitudinal fasciculus as far as the medial lemniscal decussation in the medulla, where it diverges ventrolaterally to reach the spinal ventral white column near the ventral lip of the anterior median fissure. The tectobulbar tract, mainly crossed, descends near the tectospinal, ending in the pontine nuclei and motor nuclei of the cranial nerves, particularly those innervating the orbital muscles. It serves reflex ocular movements (see references to lateral tectotegmentospinal tract, p. 932).

The medial longitudinal fasciculus (7.117, 121), a heavily myelinated composite tract, is ventrolateral to the oculomotor nucleus at this level, where its fibres are more dispersed than at lower levels, though its relation to efferent nuclei is retained. The fasciculus ascends to the *interstitial nucleus* (of Cajal) in the third ventricle's lateral wall, just above the cerebral aqueduct. (Closely related to its upper ends and the decussation of the fasciculi are also the *interstitial* and *dorsal* parts of the nuclear groups *of the posterior commissure* which probably exchange fibres with these complex fasciculi and additionally the *nuclei of Darkschewitsch*, whose status remains uncertain.) The fasciculus retains its position relative to the central grey matter through the midbrain, pons and upper medulla, but is displaced ventrally by successive decussations of the medial lemnisci and lateral corticospinal tracts, to enter the ventral spinal intersegmental fasciculus.

The proximity of the medial longitudinal fasciculus to oculomotor, trochlear and abducent nuclei, emerging facial fibres, dorsal cochlear fibres and the hypoglossal nucleus, makes it a convenient interconnecting route in the brain stem. Continuity with the ventral spinal intersegmental tract provides for connections between these nuclei and cervical motor neurons, especially those innervating the nuchal musculature. For example, co-ordination between facial and hypoglossal nerves in movements of the lips and tongue in speech is often attributed to connections via the medial longitudinal fasciculus; but this is doubtful. Long established are substantial contributions to it by *vestibular nuclei* and, to a lesser extent, the lateral lemniscal nucleus, its chief function being to co-ordinate movements of the eyes and head in response to vestibulocochlear stimulation (Maciewicz et al 1977, Yamamoto et al 1978, and p. 1112). Fascicular lesions may cause partial ophthalmoplegia. Bilateral vestibular connections ascend or descend the fasciculus or divide into ascending and descending branches, which send collaterals to nuclei of the third to sixth cranial nerves and the spinal nucleus of the eleventh (7.121). All four vestibular nuclei contribute ascending fibres, those from the superior remaining uncrossed (McMasters et al 1966), the others

7.121 Simplified diagram of *some* of the components of the *medial longitudinal fasciculus* and of the distribution of its fibres to cranial nerve nuclei.

partly crossed. Some fibres reach the interstitial and posterior commissural nuclei, some decussating to the contralateral nuclei (Mantano 1970, see also p. 1005). Descending axons, from medial vestibular nuclei and perhaps the lateral and inferior, partially decussate and descend in the fasciculus as a *medial vestibulospinal tract* (Brodal et al 1962, and pp. 932, 945). Fibres join from the dorsal trapezoid, lateral lemniscal and posterior commissural nuclei. Therefore the cochlear as well as the vestibular nerve may influence movements of the eyes and head via the fasciculus. Some vestibular fibres may ascend in it up to the thalamus.

Other mesencephalic tracts have been described, some extending in much of the brain stem; only two will be mentioned.

The dorsal longitudinal fasciculus (of Schütz) runs in the central grey matter of the midbrain, pons and medulla, ventrolateral to the aqueduct and fourth ventricle, as a path for descending and ascending connections, largely uncrossed, between hypothalamic and dorsal thalamic and brain-stem nuclei, including the accessory oculomotor, superior collicular, ambigual, salivatory, facial, solitary and hypoglossal (Crosby & Woodburne 1951) and brain-stem reticular nuclei. Some *cholinergic* fibres are described as *descending* from hypothalamic nuclei to enter the cerebellum via its superior peduncle. A *dorsal ascending serotonergic* bundle accompanies the dorsal fasciculus to the diencephalon (p. 994).

The central tegmental fasciculus, prominent in the medulla (p. 956), is more ventral in the midbrain, at first lateral to the medial longitudinal fasciculus and dorsolateral to the red nucleus and decussation of the superior cerebellar peduncles. Descending through the pons into the medulla it swerves laterally to reach and terminate in the inferior olivary complex (Bebin 1956); though few fibres are from the thalamus, it was once called the thalamo-olivary tract. Most descending fibres were said to be from neurons in the central grey zone around the cerebral aqueduct at superior collicular level; but fibres from the basal ganglia and red nucleus also travel in it. Traversing the red nucleus, the ansa lenticularis (p. 1006) and lenticular nucleus, the fasciculus forms a path from the motor cortex to the brain-stem reticular nuclei and inferior olivary nuclear complex. While these components are still largely accepted, additional information has accumulated. Many fibres have proved to be ascending, descending (or both) axons from brain-stem reticular formation, their collaterals and terminals innervating other 'reticular' or adjacent 'specific' nuclei (p. 988). Newer staining techniques have also identified in the fasciculus: *dorsal* and *ventral ascending noradrenergic bundles*, a *ventral ascending serotonergic bundle* and some fibres of *dorsal* and *ventral ascending cholinergic bundles* (pp. 993, 994, 995).

The brachium of the inferior colliculus is a rounded superficial lateral strand in the upper midbrain (7.135A) ascending from the inferior colliculus and lateral lemniscus to the medial geniculate body. It separates dorsolateral fibres of the medial lemniscus from the surface. Quantitative examination by Ferraro & Minckler (1977) in 28 autopsy specimens (from newborn to 97 years) revealed a fibre density of about 68 000/mm², with little variation between left and right and no significant diminution until the ninth decade. The total fibres in an average brachium were 354 314 (right) and 346 810 (left) near the inferior colliculus, rising to 557 122 (right) and 561 359 (left) near the medial geniculate body. These totals must be treated with reserve; the brachium was dissected away from the brain stem. Ramón-Moliner & Dansereau (1974) have examined the 'peribrachial' region at the pontomesencephalic junction and proposed an arbitrary topological division of this part of the tegmental brain stem.

TECTUM OF THE MIDBRAIN

Though the tectum exhibits dorsal swellings from the earliest vertebrate stages, differentiation into superior and inferior colliculi (corpora quadrigemina) appears only in mammals (7.115, 116). In prototherian monotremes, still only a single pair of swellings exists, the *optic lobes* (corpora bigemina). Optic lobes are highly developed in fishes and are larger than the olfactory lobes in Osteichthyes. At this and later levels of vertebrate evolution the olfactory lobes are, in volume, the major *forebrain* developments; with the emergence of cerebral hemispheres, i.e. further forebrain development with more than olfactory connections, the optic lobes are relatively smaller but still remain substantial in amphibians, reptiles and birds. Their connections and functions show a progressive forward neural migration, passing from reptiles to mammals, a process called *telencephalization*. This initial dominance of the optic lobes (in earlier vertebrates probably concerned with *all* sensory modalities other than olfactory) gradually diminishes, perhaps coupled with a decrease in complexity of their cytoarchitecture. These processes are considered to reach their acme in primates, in whom the highly developed cerebrum has taken over much primal tectal activity. Differentiation of the optic lobes into superior and inferior colliculi appears in eutherian mammals, both being perhaps derivatives of primary optic lobes. Though it is usual to simply link the superior colliculi with visual and the inferior colliculi with auditory behaviour, to accept this as *exclusive* is likely to mislead; superior colliculi in particular are concerned in other ascending paths, from cutaneous receptors and perhaps auditory connections. Inferior colliculi are interconnected with the superior. (See below for many further connections.)

The inferior colliculus has a central ovoid main nucleus, derived from periaqueductual grey matter, with which it preserves some continuity. The nucleus is surrounded by a laminar zone of nerve fibres; many from the lateral lemniscus (p. 959) terminate in it. Small and medium-sized neurons predominate, many stellate or multipolar, and some are scattered in the surrounding nerve bundles, particularly on its lateral and medial aspects; sometimes the latter are regarded as a separate nuclear entity; they almost certainly have a different origin, being continuous with the superficial lamina of the *superior* colliculus. Nuclear and neuronal organization have been detailed in cats (Morest 1966, Geniec & Morest 1971, Rockell & Jones 1973, Meininger & Baudrimont 1977) and to a lesser extent in man. It is accepted that the *central nucleus* has *dorsomedial* and *ventrolateral* zones, chiefly differing in neuronal types. The 'laminar zone', noted above, is lateral and peripheral in cats. Disagreements concern the distribution of different sizes of neuron; Meininger & Baudrimont (1977), by using stereological techniques in a small series of cats, described the dorsomedial nucleus as containing small neurons, those in the ventrolateral being larger. The inferior colliculi are connected by a substantial *commissure* of axons from their own neurons and also crossed lateral lemniscal fibres. The main afferent fibre bundle is the lateral lemniscus (p. 959); efferent fibres largely traverse the inferior brachium to the ipsilateral medial geniculate body; a crossed connection, via the intercollicular commissure, may exist (Ades 1944). Lemniscal fibres relay only in the main collicular nucleus (Goldberg & Moore 1967); some pass without relay to the medial geniculate body; similarly some colliculogeniculate fibres do not relay in the geniculate body but continue with those which do via the auditory radiation (p. 1112) to the auditory cortex, area 42. As in other sensory systems a *descending* projection from this cortical area reaches the inferior colliculus via the medial geniculate body, which some fibres may traverse without relay. This descending path may produce effects at levels from the medial geniculate body downwards; it probably links with efferent cochlear fibres, through the superior olivary and cochlear nuclei (p. 960). Tonotopical projection of lateral lemnisci on the inferior colliculi has been described in cats; some similar orderly arrangement probably pervades *all* auditory connections, ascending and descending (Moore & Goldberg 1966 and p. 1005).

Inferior collicular projections to the brain stem and spinal cord appear to first traverse the superior colliculi, thereby connecting with the origins of tectospinal and tectotegmental tracts. These projections are relatively small; the customary view of the inferior colliculi as reflex centres for auditory responses may require revision. There is, however, much evidence that they are concerned in the ability to localize the source of sounds (Masterton et al 1967).

The superior colliculus (unlike the inferior which is fully developed in mammals) is generally regarded as simplified in higher vertebrates, particularly in primates; but nevertheless in man it still exhibits much of the complex laminar organization of

earlier forms. At least six laminae are described in human superior colliculi and even more intricate arrangements in some mammals (Cajal 1909–11, Angaut & Reperant 1976). In this laminar pattern the superior colliculus closely resembles the cerebellar and cerebral cortex which, indeed, it surpasses in complexity in the lower vertebrates. This has prompted the view that the optic lobes, from which superior colliculi are derived, were the first suprasegmental development in vertebrate brains, mediating summation and integration more widely than the term 'optic' indicates. Such considerations are a corrective to the widely current teaching that superior colliculi are exclusively visual in their activities.

Human collicular laminae have been variously termed. From the exterior there are at successive depths the strata zonale, cinereum, opticum and lemnisci. The stratum lemnisci itself is often divided into the strata griseum medium, album medium, griseum profundum and album profundum. These *seven layers* have also been termed: zonal, superficial grey, optic, intermediate grey, deep grey, deep white and periventricular strata (Crosby et al 1962). The two schemes do not completely accord; but as a generalization, layers may be considered alternately composed of neurons or their fibres and dendrites, though some admixture occurs. For example, the *zonal layer* consists chiefly of myelinated and non-myelinated fibres from the occipital cortex (areas 17, 18 and 19, p. 1060), arriving as the *external corticotectal tract*; but among these fibres are a few small neurons, horizontally arrayed. The *superficial grey layer* (stratum cinereum) has many small multipolar interneurons, with which cortical fibres partly synapse, the whole being a cap-shaped lamina, centrally thicker, over the deeper layers. The *optic layer* consists partly of fibres from the optic tract, a much diminished afferent element in higher primates; as they terminate, they invade adjacent layers with numerous collateral branches. The layer also contains some large multipolar neurons; efferent fibres to the retina are said to start in this layer (Wolter & Liss 1956) in man and other mammals. The internal four layers are sometimes considered together as a stratum lemnisci but will be briefly outlined. The next two, *intermediate grey* and *white layers*, are collectively the main reception zone, consisting of neurons of various sizes mixed with axons and dendrites. Its main afferent source is the *medial corticotectal path* from the occipital cortex (area 18) and possibly the preoccipital cortex (area 7), areas concerned with ocular following movements (p. 1060). These layers also receive spinal afferents through spinotectal and spinothalamic routes and probably from the inferior colliculus. The *deep grey* and *deep white* layers, adjacent to the periaqueductual grey substance, again contain a mixture of neurons with dendrites extending peripherally to the optic layer, but their axons form many of the collicular efferents. (For details of the neonatal superior colliculus consult Labrida & Laemle 1977.)

The superior colliculus thus receives *afferents* from a wide area (Wolter & Liss 1956, Meikle & Sprague 1964), including the retina, spinal cord, inferior colliculus and occipital and temporal cortex, the first three of these pathways conveying visual, tactile and probably thermal, pain and auditory impulses, the cortical projection acting as a 'command' and possibly modulating path. Collicular *efferents* pass to the retina and a wide array of brainstem and spinal neurons; *tecto-oculomotor* fibres project to the motor nuclei of ocular muscles. In cats (Edwards & Henkel 1978) neurons in the upper third project to the periaqueductual grey substance dorsal to the upper end of the oculomotor complex, some also synapsing directly with dendrites of oculomotor neurons. Neurons in this central grey region also project to both abducent nuclei. *Tectospinal* fibres (p. 985) descend to cervical segments while *tectotegmental* fibres reach various tegmental reticular nuclei and also the substantia nigra, red nucleus and probably the spinal cord. *Tectopontine* fibres, probably descending with the tectospinal tract, terminate in dorsolateral pontine nuclei, with a relay to the cerebellum (p. 985). *All* descending fibres *cross*, mostly in the *dorsal tegmental decussation*, but to a lesser extent through an intercollicular commissure. Kawamura et al (1974), reviewing these connections, have studied tectoreticular projection in cats by collicular lesions, producing degeneration in ipsilateral mesencephalic and contralateral pontomedullary reticular nuclei (nuclei reticularis gigantocellularis, reticularis pontis caudalis, reticularis pontis oralis and others). Distribution of these projections corresponded to those from cortical, fastigial and vestibular neurons and thus to the main sources of reticulospinal fibres. A tecto-olivary projection, from deeper collicular laminae to the upper third of the medial accessory olivary nucleus, exists in primates (Frankfurter et al 1976); it is crossed and links with the posterior vermis in ocular movements.

The relative paucity of retinal projection to the primate superior colliculus weakens the common view of it as mediating largely visual reflexes, though it so acts in many other mammals. The projection of retinal quadrants on superior colliculi in cats and rodents has been established, by degeneration and stimulation; but results in monkeys are less definite, perhaps due to a greatly reduced retinocollicular projection in primates. Clinical evidence merely suggests a similar limited human pattern of association of the superomedial half of a colliculus with the inferior retinal quadrants and the inferolateral half with superior retinal quadrants. Even the connections to ocular motor nuclei, held to accord with collicular pattern, are uncertain in cats, though perhaps merely interrupted by a pretectal relay. For the present they remain sub judice.

Attention has been much focused on behavioural changes after damage to subcortical parts of the visual pathway (Ingle & Schneider 1969); visual field projection on the optic tectum has also been mapped and compared by recording techniques in vertebrates from fish to mammal. A similar pattern of retinal representation exists even in different classes, the chief difference in mammals being the degree of *ipsilateral* projection. This accords with observations of movement elicited by tectal stimulation; e.g. central collicular stimulation produces 'normal' contralateral head movement in cats (Hess et al 1946). Many similar responses like those of intact animals have been observed in several species, involving the eyes, ears, head, trunk and limbs, thus implicating the superior colliculus in complex integrations between vision and widespread bodily activity (Schaefer & Schneider 1968). In view of the bilateral representation of retinae in the colliculi, results of brain-splitting experiments are of special interest; e.g. tegmental division leads in cats to profound changes in visual behaviour, not so much in reflex responses as in the ability to interpret the environment and adapt to it (Voneida 1965). Response to threatening stimuli and an ability to locate edges and follow them are lost. Similar results appear in monkeys and resemble those of the split-brain syndrome in human patients (p. 1066).

A descending projection from the *auditory cortex* has been described in some mammals, including cats (Diamond et al 1969) and monkeys (Whitlock & Nauta 1956). Paula-Barbosa & Sousa-Pinto (1973) have confirmed this and explored the projection in greater detail in cats, in which a bilateral projection from secondary auditory areas (AII) reaches the superficial laminae in both superior colliculi; no such projection from the primary auditory area (AI) was observed. Though these are from parts of the auditory cortex which, as far as is known, have no visual connections, this corticocollicular pathway may be involved, via known connections between superior and inferior colliculi, in integrations between visual and auditory behaviour.

The pretectal nucleus is a poorly defined mass of neurons at the junction of the mesencephalon and diencephalon, extending from a position dorsolateral to the posterior commissure towards the superior colliculus, with which it is partly continuous. It receives fibres through the superior brachium from the occipital and preoccipital cortex and the lateral root of the optic tract (Kuhlenbeck & Miller 1949, p. 1014). Its efferent fibres reach both accessory oculomotor nuclei (Ranson & Magoun 1933); those which decussate pass ventral to the aqueduct or through the posterior commissure. By this autonomic outflow, with a relay in ciliary ganglia (p. 1097), sphincters of the iris in *both* eyes are made to contract in response to impulses from either (7.139). This bilateral light reflex may be the sole activity of the pretectal nucleus but some of its efferent axons are said to enter the tectobulbar and tectospinal tracts. The significance of the cortical projection is not established.

EXTRAGENICULATE VISUAL PATHWAYS

As a corrective codicil to the above it is apposite to refer briefly to data accumulated in regard to visual paths in mammals (Jones 1974) and particularly birds (Webster 1974). It is almost certain that the vertebrate visual system was primarily mesencephalic in its connections. The concept of 'telencephalization' is part of a greater process of 'encephalization', the evolutionary cranial migration of 'centres' mediating sensorimotor activities, from spinal to *encephalic* levels. Intrusion of visual projections into the *telencephalon* via the thalamus in mammals, with a reciprocal reduction in *mesencephalic* visual connection, remains the major example of *telencephalization*. The change is often regarded as more advanced in mammals, especially primates, than in birds. Compared with mammalian conditions, avian colliculi or optic lobes are relatively larger and more complex in laminar pattern, and the avian corpus striatum is more developed than the superincumbent cortex, proportions apparently reversed in mammalian cerebral hemispheres. The generalizations thus engendered have tended to assign avian and mammalian visual systems to opposite balances in a supposed *duality of pathways*: one integrated at mesencephalic level, vaguely termed 'reflex', the other telencephalic and loosely labelled 'perceptual'. This is an oversimplification. Avian visual structure and function show that both types of path, whether through the midbrain tectum or direct to the dorsolateral thalamus, involve thalamic and cortical projection and striatal connections. In mammals *both* paths exist, in particular a pretectal route (in addition to the superior collicular path) via the pulvinar of the thalamus to the occipital cortex. Functional studies also show that it is erroneous to consider the two visual paths, either in birds or mammals, as being in the one case perceptual and in the other reflexive. In both vertebrate classes the mesencephalic level appears involved in perception and not merely as a level for ocular reflexes; e.g. in avian brains neurons of a tecto-striate projection exhibit responses to movement *and* to colour, though not to shape or orientation. In contrast, a more direct route via the thalamus to a cortical region known as the '*wulst*' in birds (equivalent to the mammalian geniculostriate pathway) has not been shown to evince any special sensitivities, except perhaps to movement. In mammals, including mankind perhaps more than in birds, the complex paths of visual information and multiplicity of collateral and descending interconnections provide a 'system' of intricate projection and 'feed-back' which remains speculative. Despite a mass of data particularly concerning the peculiarities of response in individual neurons at every level, it is difficult to ascribe aspects of visual information to identifiable neuronal groups; perhaps it is misleading to seek to do so. Even in man, clinical evidence from injury to the visual cortex suggests that the customary assignment of 'conscious' vision to cortical levels may impede recognition of the intimate interactions between the occipital cortex, tectum and pretectum. Though no functional synthesis can be discerned in the structural and physiological findings so far amassed, visual function must involve most widespread networks of neurons at all levels.

The cerebral aqueduct, a narrow canal about 15 mm long, connects the third and fourth ventricles. (Being in the midbrain and conducting no fluid to the cerebrum, it is misnamed.) In transverse section it varies, being T-shape below, triangular above and between these oval and slightly dilated (Flyger & Hjelmquist 1957). It is lined by ependyma (with specialized areas, pp. 894, 1005), surrounded by *central grey matter* continuous with the floor of the fourth ventricle and walls of the third. Remains of a *sulcus limitans*, apparent on each lateral wall in the embryonic period, may persist. Dorsally it is separated partly from the collicular grey matter by fibres of the stratum lemnisci; ventral are the medial longitudinal fasciculi and midbrain reticular formation. Scattered through the central grey matter are many and various neurons embedded in fine fibres; it also contains the mesencephalic trigeminal, oculomotor and trochlear nuclei.

THE RETICULAR FORMATION

Long recognized among the more conspicuous tracts and nuclei throughout the brain stem are extensive fields of intermingled neurons and nerve fibres collectively termed the **reticular formation**. Accounts of the central nervous system contain numerous but usually scattered references to this 'system', but it requires a more orderly and overall description. It has attracted a large literature, e.g. Moruzzi & Magoun (1949), Meessen & Olszewski (1949), Olszewski (1954), Olszewski & Baxter (1954), Brodal (1957), Jasper et al (1958), Taber (1961), Valverde (1961a, b, 1962), Ramón-Moliner & Nauta (1966), Horridge (1968), Brazier (1969), Scheibel & Scheibel (1970) and Webster (1978).

GENERAL CONSIDERATIONS

Strict criteria for the designation of nervous regions as 'reticular' are difficult to postulate. Simple inspection of sections allows some measure of identification: many areas in vertebrate nervous systems areas are *predominantly* of grey or white matter (p. 866), their neurons and axons having recognizable, quantitative cytological features, consistently orientated. Thus, many regions of white matter contain fascicles with recognizable spectra of fibre diameters, definable in their directions and conducting between well-defined origins and destinations. Many areas of grey matter contain neuronal populations with somata, axon collaterals, dendritic trees and synapses in distinctive three-dimensional arrays; they also appear to have 'boundaries'. Such are the main nuclei, cortical formations and tracts of the central nervous system, exemplified by well-defined columns and laminae in dorsal and ventral spinal appendages (p. 925), their brain-stem homologues, many brain-stem, diencephalic and telencephalic nuclei, cerebral and cerebellar cortices, tectum and tracts recognized throughout the central nervous system; all are individually described elsewhere. Between these obviously organized *non-reticular* regions are those where grey and white matter intermingle, fascicles of nerve fibres crisscrossing in many directions, dividing neurons in scattered, ill-defined groups; these are the *reticular regions*. Though many agree to the geometric arrangement and non-reticular structure of most main nuclei and tracts, the status of some remains uncertain. Structural extremes of a precise, repeating geometric organization on the one hand and a truly random network on the other are abstractions. Even the highly regular cerebellar cortex shows quantitative variation when examined critically (p. 972) and the most 'reticular' regions show some locally regular structure. A graded range of structural organization exists; inevitably, more diffuse regions are more difficult to investigate. For these reasons, coupled with the sparseness of quantitative data about neuronal forms and connections, views diverge as to which regions should be included in the *reticular formation*. Most agree to the inclusion of parts of the medulla, pons and midbrain (vide infra); some would restrict the term to these. The status of other parts in these regions, such as the olivary complex, parvocellular red nucleus, pars reticularis of the substantia nigra, dorsal commissural nucleus, interstitial nucleus, intracerebellar nuclei and others, is not agreed. Further disagreement concerns the inclusion of central regions of the spinal grey matter, the 'reticular core' of some (p. 946) or inclusion of non-specific thalamic nuclei (p. 1003) and certain hypothalamic nuclei. These debates merely emphasize the undesirability of rigid categorization and need of further research, which may invalidate such controversial parcelling. Precise boundaries between such areas will not be attempted here; but it is emphasized that *all* levels of the neuraxis, spinal cord, brain stem and diencephalon have regions with high levels

of ordered structure *interlocked* topographically and functionally with the surrounding reticular regions, where organization is less orderly. Obviously reticular regions are often regarded as phylogenetically ancient, representing a supposed primitive 'random nerve network', upon which background more organized, selective routes have appeared during evolution. But, as noted elsewhere (p. 865), the most primitive nervous systems show *both* diffuse and highly organized regions, which co-operate in response to different demands. Clearly *both* evolved together, each providing *indispensable* and *interdependent* contributions to the total response of the organism.

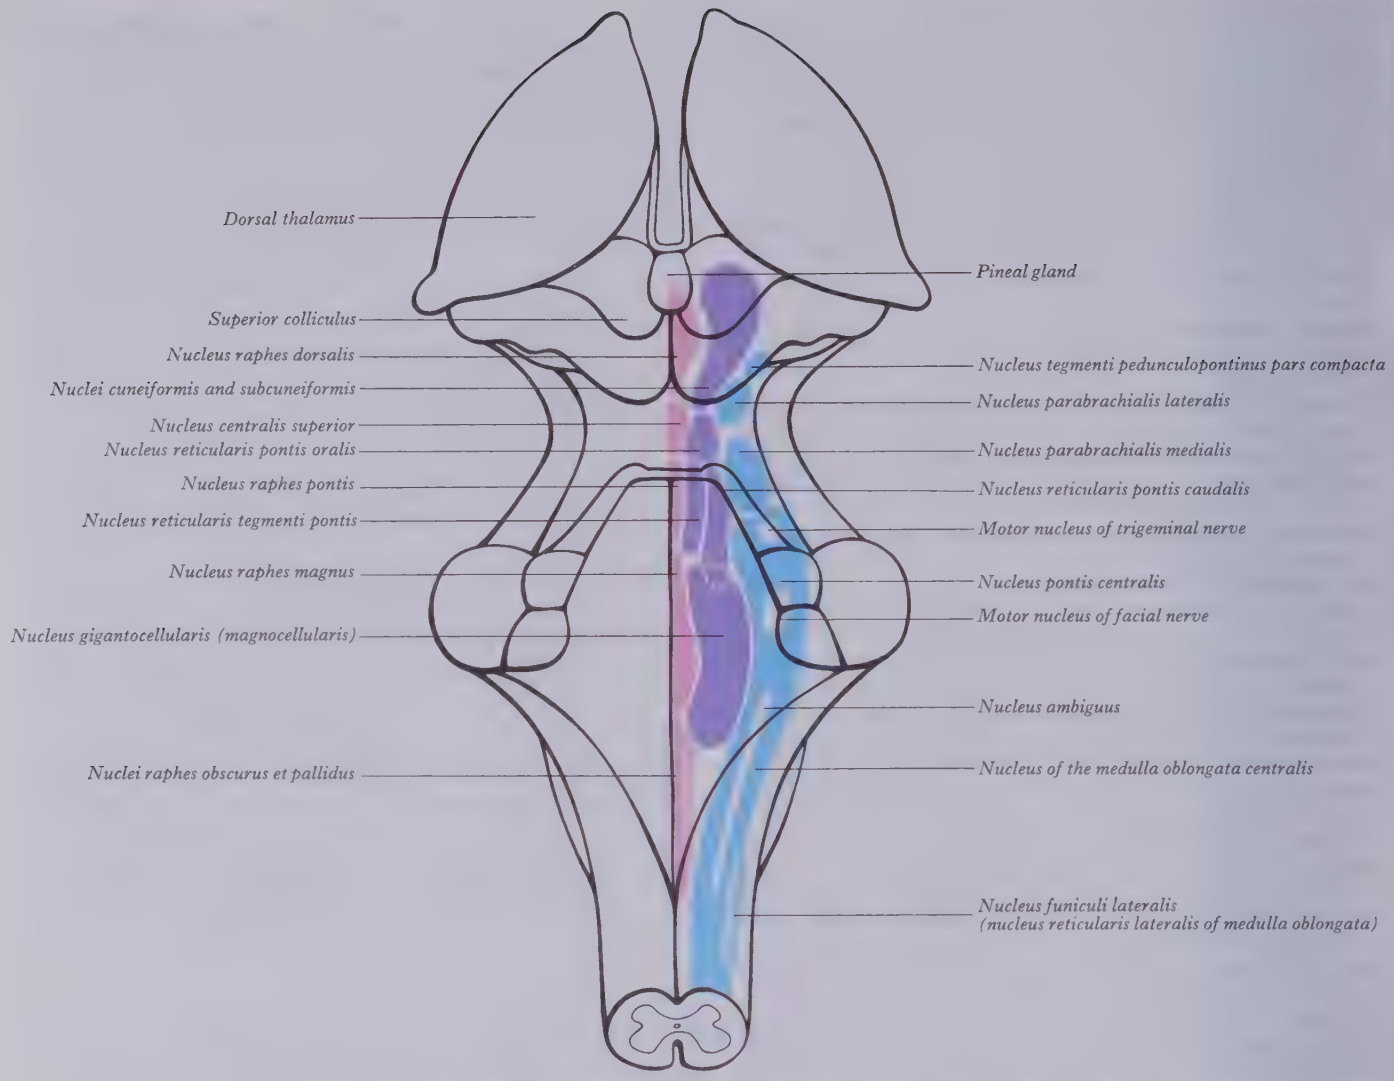
RETICULAR REGIONS OF THE CENTRAL NERVOUS SYSTEM

The general characteristics of reticular regions are: (1) deeply placed, ill-defined collections of neurons and fibres with diffuse connections; (2) conduction paths which are difficult and often impossible to define, but indicated by physiological evidence as complex and often *polysynaptic*; (3) *ascending* and *descending* components which are (4) partly *crossed* and *uncrossed*, unilateral stimulation often resulting in bilateral responses; (5) possessing *somatic* and *visceral* components.

Earlier investigators reported little structural variation in the different regions, simply dubbing all but well-known nuclei and tracts as 'reticular'. More critical studies have emphasized regional variation in structure (and presumably function), including differences in neuronal size, number, packing density, geometry of neurites, cytochemistry (including putative neurotransmitter production) and in connections. By such criteria (much dependent on the technique employed) many *reticular nuclei* have been named in a variety of animals. However, their limits are often ill-defined, dendritic fields interweaving over wide areas. Interspecific variation exists; varying technique and criteria also yield variable results. The data of electrophysiological or pharmacological exploration, focal stimulation or ablation, must be scrutinized; even greater caution is needed in ascribing functions to reticular zones or nuclei. Complex arrays of reticular neurites has been studied mainly by Golgi techniques which, combined with the cytoarchitectonics of the form and deployment of somata, have defined major zones and nuclei. Smaller groups and variations cannot be pursued here; for these consult the references quoted.

Studies with the Golgi technique (Ramón-Moliner & Nauta 1966, Horridge 1968, Brazier 1969, Scheibel & Scheibel 1967, 1970) show that few brain-stem reticular neurons are classic Golgi type II, with short axons branching locally (vide infra); their dendrites are long and usually spread *across* the brain stem's long axis in transverse sheets. Usually dendrites have a simple pattern likened to 'spokes of a rimless wheel', classified as the *isodendritic configuration* by Ramón-Moliner & Nauta (1966) and described as forming an *isodendritic core*, its territory encompassing many ill-defined, 'diffusely' connected reticular nuclei. Their radiating dendrites may spread into 50% of the cross-sectional area of their half of the brain stem. These dendritic trees are crossed by, and may synapse with, a complex of ascending and descending fibres, the *central tegmental fasciculus*. This has many components, the most prominent being axons of the reticular neurons themselves; their main stems usually ascend or descend or bifurcate to do both, travelling far, perhaps through the whole brain stem and even beyond. As an extreme example, an axon from the magnocellular medullary nucleus (vide infra) may bifurcate, its ascending branch traversing the upper medulla, pons, midbrain tegmentum, subthalamus, hypothalamus or dorsal thalamus, while its other branch descends in the reticular core of the lower medulla and may reach the cervical spinal intermediate grey matter (laminae V and VI). Many reticular neurons have unidirectional, shorter axons, synapsing with the radiating dendrites of innumerable other neurons en route, and also collaterals which synapse with cells in 'specific' brain-stem nuclei or cortical formations, such as the cerebellum. Multitudes of afferent fibres converging on individual neurons and their myriad synapses and destinations provide the structural basis for the polymodal responses elicited by experiment, and also for such terms as 'diffuse' and 'non-specific'. These arrangements perplex investigators; it is misleading to attach single, or even complex, functional labels to individual neurons or to small groups, because the innumerable routes for convergence and divergence in this reticular core make it unwise to assign specific functions to specific structures.

A contrasting dendritic form is an *idiodendritic configuration*, in which dendrites are short, sinuous or curved, branch profusely and pursue re-entrant courses at the perimeter of a nuclear group, defining a boundary between it and its environs. Such neurons are typical of: nuclei of the cranial nerves, basilar pontine nuclei, olivary complexes, nuclei of 'specific' sensory pathways, medullary nucleus funiculi lateralis (the so-called lateral 'reticular' nucleus of the medulla), and mesencephalic tegmental nuclei. Neurons of an intermediate dendritic complexity occur in and near such nuclei and vary in density in much of the remaining reticular formation, being termed *allodendritic*. In different zones the proportion of different sizes of neuronal somata varies, some regions containing only small to intermediate multipolar cells (*parvocellular* regions), while in a few these mingle with large multipolar neurons in '*gigantocellular*' or '*magnocellular*' nuclei.



In *general terms* the reticular formation is a continuous isodendritic core traversing the whole brain stem, continuous below with the reticular intermediate spinal grey laminae and merging above into the subthalamus and parts of the hypothalamus and dorsal thalamus. Adjacent to or embedded in it are many well-defined nuclei, a few termed reticular (Leontovich & Zhukova 1963, Ramón-Moliner & Nauta 1966). The reticular formation may thus be described as a 'diffuse network' divisible into three bilateral *longitudinal columns*: one median, a second medial (containing mostly large reticular neurons) and a third lateral (containing mostly small to intermediate neurons) columns. Regional localization resides solely in overlapping zones of terminal afferents (vide infra) and sources of efferents. A corollary is that the application of elementary functional localization to individual neurons, small groups named reticular nuclei or groups of nuclei, is absent; the 'system' operates as a whole, enhancing or depressing the 'general background' in the central nervous system. (For a stimulating discussion see Webster 1978.)

In contrast, parcelling reticular formation into named nuclei by cytoarchitectonics has been zealously pursued, the most extreme exponent being Olszewski who described over 40 such nuclei in the mammalian brain stem (Olszewski & Baxter 1954, consult also Brodal 1957). Such entities may be useful for experimenters (if dependable) but a few only have reliably specific patterns of connectivity; hence their individual functional significance is largely obscure.

Details of cytoarchitectonics, neuritic arrays, overall topography, and connectivity in such a plethora of named nuclei would be inappropriate and of dubious value here. A brief summary of principal nuclear groups (identifed by ordinary techniques) with a diagram of their approximate territories (7.122) is sufficient here. Their positions and extents need examination in serial sections, hence their omission in the preceding general description of the brain stem. For details consult Olszewski & Baxter (1954), Brodal (1957), Ungerstedt (1971), Jasper et al (1978), Nieuwenhuys et al (1978).

The median column of reticular nuclei, extended throughout the medulla, pons and midbrain, contains neurons largely aggregated in bilateral, vertical sheets, blended in the midline and occupying the paramedian zones; collectively they are *nuclei of the raphe*. In the upper two-thirds of the medulla and crossing the pontomedullary junction is the *nucleus raphes obscurus* (and associated *nucleus raphes pallidus*); partly overlapping this and ascending into the pons is the *nucleus raphes magnus* and above it the *nucleus raphes pontis*. Also pontine is the *nucleus raphes centralis superior*; finally the *nucleus raphes dorsalis* (*rostralis*) ascends, expanding then narrowing through much of the midbrain. Some neurons in rapheal nuclei are *monoaminergic* (*serotonergic*); some of their connections will be mentioned below.

The medial column of reticular nuclei has a background of reticular neurons of medium size but in some regions they are the largest such neurons; most are isodendritic. In the lower medulla the column is unclear, perhaps represented by the thin lamina

7.122 An outline of the human brain stem (black) extending from the caudal end of the medulla to the dorsal thalami: note the margins of the rhomboid fossa, the lateral angles of which indicate the pontomedullary junction; note also the profiles of the transected surfaces of the cerebellar peduncles, the colliculi and pineal gland. The principal nuclear derivatives of the brain stem reticular formation are indicated in approximate outline, those from the median and paramedian nuclear column are in magenta; medial column derivatives are purple, lateral column derivatives blue. In reality, of course, considerable overlap of the nuclear profiles would be present when the third dimension is considered. A number of 'non-reticular' nuclei are also included.

lateral to the raphael nuclei; in the upper medulla, however, it expands into the *medullary gigantocellular (magnocellular) nucleus*, lateral to the rapheal nuclei, ventrolateral and ventral to the hypoglossal and dorsal vagal nuclei and dorsal to the inferior olivary complex. Ascending further the column continues as the *pontine gigantocellular (magnocellular) nucleus* lying medially in the tegmentum; its neurons suddenly diminish in size forming, in upward order, the almost co-extensive nuclei *reticulares tegmenti pontis* and *pontis caudalis*, then the *nucleus reticularis pontis oralis*, from which the medial column expands into the *nucleus cuneiformis* and *nucleus subcuneiformis*, fading away in the midbrain tegmentum. Other nuclei sometimes classified with the medial column are nuclei coeruleus (p. 980) and subcoeruleus, which cross the pontomesencephalic junction (p. 980); near this, adjoining the mesencephalic dorsal and medial longitudinal fasciculi, are the *dorsal* and *deep tegmental nuclei*, together with numerous groups in the *mesencephalic circumaqueductal grey matter*.

The lateral column of reticular nuclei contains little but scattered *small* neurons, hence often termed the *parvocellular reticular column*, with its contained *parvocellular 'nuclei'*; its neurons are allodendritic or idiodendritic (vide supra). The column extends through the brain stem as a poorly defined 'background' with few 'reticular' nuclei; in or invading it are clearcut 'specific' nuclei, which many exclude from the reticular formation (sometimes on arbitrary criteria). Descending through the lower two-thirds of the lateral pontine tegmentum and upper medulla, the column lies between the gigantocellular nucleus (medial) and sensory trigeminal nuclei (lateral); continuing caudally, it expands to form most of the reticular formation lateral to the rapheal nuclei and continues into the cervical intermediate grey laminae. Its medullary part is sometimes considered as *central and ventral medullary reticular nuclei*, which are confluent and enclose the nucleus ambiguus (pp. 954, 1113). Lateral to them is the *nucleus of the lateral funiculus*, often named *the lateral medullary reticular nucleus*, despite its cytoarchitecture. Similarly, the *nucleus of the ventral funiculus* is often called *the medullary nucleus reticularis paramedianus*. The *pontine parvocellular column* or *nucleus* embraces the motor nuclei of the facial and trigeminal nerves; the column, it is claimed, ascends from the pons into the mesencephalic tegmentum, differentiating here into large, inappropriately named, *lateral* and *medial parabrachial nuclei*. Above inferior collicular level the lateral column is less marked; but lateral to the decussating superior cerebellar peduncles is the magnocellular *nucleus tegmentalis pedunculopontinus, pars compacta*, above which the parvocellular *pars dissipata* gradually merges into the nuclei cuneiformis and subcuneiformis of the medial column (vide infra). Their parvocellular confluence blends with many subthalamic, hypothalamic and dorsal thalamic nuclei.

CONNECTIONS OF THE RETICULAR FORMATION

Most reticular connections, based on older neuroanatomical techniques, have already been described and here will be merely listed; for a consideration of more recent studies, vide infra.

Afferent projections reach the reticular formation from: (1) the spinal cord via *spinoreticular paths* and *collateral branches* of *long ascending tracts*, though not as abundantly as once held; (2) collateral branches of some primary and many secondary afferent neurons associated with *cranial nerves*, including the central *vestibular* and *acoustic* pathways; (3) from the *cerebellum* via *cerebelloreticular paths* previously noted (p. 967); (4) indirectly from *visual* and *acoustic* paths and other afferent channels via *tectoreticular fibres*; (5) from *thalamic*, *subthalamic* and *hypothalamic nuclei* (pp. 1003, 1006, 1010); (6) from the *corpus striatum*, directly and indirectly via its complex outflow; (7) direct *corticoreticular fibres* from the *sensorimotor* cerebral cortex and from other cortical areas; an unknown proportion are collaterals of corticofugal tracts such as the corticospinal; (8) from various parts of the *limbic system*, including the *septal areas*, *amygdaloid nuclei* and *hippocampus* via various descending routes.

Multiple afferents thus converge on the reticular formation; while there may be *some* zonal localization at their terminations, much evidence exists for overlap and convergence. Unit recording has strongly supported this view; single 'units' have been studied during the multimodal stimulation of cutaneous receptors and proprioceptors in many regions and in many peripheral nerves, special sense organs and diverse central nervous regions, including the spinal cord, cerebral and cerebellar cortices, hippocampus, corpus striatum, etc. For example, some units respond solely to nociceptive stimuli applied in different regions; others respond to a wide range of cutaneous stimuli, from extensive bilateral fields; others respond to the stimulation of many separate regions of the cerebral cortex, and so forth. Some units also respond to the stimulation of several different channels, e.g. visual, acoustic, cortical, cerebellar, etc. Different afferents also interact, some with mutual enhancement and others mutual inhibition. Though different levels of the reticular formation are *not* uniform in input and output, there is always a convergence of afferent channels and a rich interconnection between reticular neurons. How such a structurally complex and functionally fluctuating array is used to direct co-operative responses remains an intractable problem (Klimer et al 1968, Webster 1978).

Efferent connections of the reticular formation are: (1) to autonomic and locomotor control 'centres' and interneuronal pools of the *spinal cord* via *reticulospinal tracts*; (2) by short descending paths to similar centres in the *brain stem*; (3) to the *cerebellum*; (4) to the *red nucleus*, *substantia nigra* and *tectum*; (5) to numerous nuclei in the *subthalamus*, *thalamus* and *hypothalamus*; (6) indirectly, through radiations of these diencephalic nuclei, to the corpus striatum and cerebral cortex, including *most areas of the neocortex* and many *limbic structures*.

Further comments on reticular connectivity. As already noted, most neurons of the *medial reticular columns* and many *rapheal nuclear neurons* are isodendritic (vide supra), with radiate dendritic trees crossed at right angles (i.e. longitudinally) by innumerable ascending and descending axons synapsing with successive neurons. The dendrites also have connections with ascending spinoreticular fibres (vide infra), cranial nerve sensory nuclei, cerebellar (particularly fastigial) efferents, descending fibres from the limbic forebrain complex and hypothalamus, neocortex and tectum, and medially directed axons from some lateral column parvocellular nuclei. Ascending, descending, or bifurcating axons and collaterals of these isodendritic neurons may remain within the reticular system to complete local reflex loops or as intermediaries in longitudinal polysynaptic chains; others project to spinal, brain-stem and forebrain neurons, i.e. they are the sources of most longer reticular efferent axons. The allodendritic and idiodendritic neurons of parvocellular lateral column nuclei appear to receive mainly afferents from nuclei of the sensory cranial nerves and collaterals of neocortical corticoreticular fibres. Some axons pass medially, presumably to modify activity in the medial column; but most surround, interweave and synapse with motor cranial nerve nuclei, completing reflex loops or mediating corticonuclear control.

As examples of zonal or nuclear varieties of reticular activity we may summarize components assumed to be involved in a so-called *ascending activating system*, and some nuclei with well-defined connections. The *ascending activating system* (vide infra) is widely believed to be the substrate for the *arousal reaction* and *desynchronization* (as shown by electroencephalogram), essential to wakening, attention and 'specific' cortical activities (p. 996). It comprises: (1) spinoreticular inputs, (2) collaterals from other long ascending tracts, (3) afferents from sensory cranial nerves, (4) reticulo-diencephalic projections, and (5) hypothalamo-limbic and diffuse 'non-specific' thalamo-cortical radiations; probably the thalamo-striato-pallido-thalamic connection should be included. Most connections are described elsewhere, but a few points need emphasis. Spinoreticular projections reach most parts of the medial reticular column; but at many levels their terminals are sparse and are only abundant in the medullary gigantocellular nucleus, the oral part of the central medullary reticular nucleus and the nucleus reticularis pontis caudalis (inferior). Similar zones receive most terminals from pontomedullary trigeminal sensory nuclei and the nucleus of the tractus solitarius; but vestibulocochlear and retinotectal inputs are concentrated on mesencephalic reticular nuclei. The origins of reticulospinal tracts and some constituent fascicles making reticulo-diencephalic connections are considered on pp. 1003, 1006, 1010; in general they correspond to the inputs just described.

Certain reticular nuclei have clear limits and definite afferent or efferent projections. Thus the lateral reticular nucleus, magnocellular nucleus and nucleus reticularis paramedianus, all medullary groups, and the nucleus reticularis tegmenti pontis all have precise cerebellar connections. The nucleus coeruleus is described on p. 980; the nucleus tegmenti pedunculopontinus, pars compacta, receives a discrete pallidofugal input.

COMPARTMENTALIZATION IN THE RETICULAR FORMATION

Preceding passages have shown that investigators have, with varying techniques, compartmentalized the reticular formation in contrasting ways, each with apparent advantages and limitations. These range as follows:

(1) A view of the formation as a diffuse, 'non-specific', *random nerve network*, with multiple inputs and outputs, polymodal interaction between neurons: perhaps a suitable 'system' for the 'network theory', combined with computer analysis, initiated by Scheibel & Scheibel (1967).

(2) A view of the formation as a central isodendritic core of the neuraxis extending through (and including) the spinal cord to the diencephalon, surrounded by and surrounding 'islands' of allodendritic and idiodendritic neurons and 'specific' nuclei.

(3) A view that the formation, essentially bilateral but cross-connected, has three bilateral, longitudinal columns: 'median', 'medial' and 'lateral', each with its typical neurons.

(4) An extreme parcelling of the foregoing columns into named nuclei by familiar cytoarchitectonic techniques.

(5) Attempts to locate columnar 'zones', individual nuclei or parts thereof as terminations of definable bundles of afferent fibres or as sources of identifiable efferent bundles with distinct destinations, studied by older degeneration techniques (p. 870) and modern fibre tracing methods (p. 874).

(6) An analysis of the results of micro-recording and the structural and behavioural effects of micro-stimulation or ablation of zones or nuclei. Such manoeuvres often result in spectacular focal effects at nodal points often termed 'centres' by neurophysiologists; but much overlap is often present and the relation to named nuclei is vague.

(7) A fashionable view of the formation as 'a collection of more or less specific neuron populations, largely mixed together rather than separated into spatially isolated groups' (Webster 1978): the criteria employed entail the use of techniques for the mapping of the distribution of groups of neurons producing a common neurotransmitter substance (p. 889). Thus, for a while, terms such as '*cholinergic nervous system*' and '*aminergic nervous system*', etc., were employed with increasing frequency.

(8) The latter terms became redundant with the spectacular recognition of numerous neuroactive substances, in many cases new means for their localization, and the emergence of neural chemoarchitectonics.

CHEMOARCHITECTONICS

The brief references in the 36th edition of this book to the location and projections of cholinergic and monoaminergic neurons, based on early techniques, and the possibility of future 'maps' of the distribution of other neuroactive substances have been in the main confirmed but with greater precision and also massive amplification of the substances studied. The new techniques have permitted, in many but not all cases, the accurate localization of neuronal somata, axons and arborizations associated with one or more neuromediators; the latter term was introduced because of their wide range of activities envisaged. Neuromediators (many, and increasing in number) are grouped as peptidergic or non-peptidergic, some regarded as 'established' others, as yet, 'putative'; the distinctions to be drawn between neurotransmission and neuromodulation, and the great temporo-spatial variation in their production, transport, dissemination, receptor sites, effects on target cells and co-operative interaction are reviewed on pp. 889–891. The Table lists a number of the better investigated neuromediators; although lengthy it is not exhaustive, new substances being evaluated and added quite frequently. Locations in which some mediators are listed are also mentioned in the pages noted. The explosive accumulation of data, particularly in the last decade, has led to the firm establishment of a major subject in its own right, *neural chemoarchitectonics*. In general, the recorded observations concerning the detailed distribution of even a single neuromediator lies beyond the scope of the present volume on general anatomy (and, as yet, even beyond large texts devoted exclusively to neuroanatomy). It is indeed fortunate that Nieuwenhuys (1986) has provided a meticulous monograph *Chemoarchitecture of the Brain*; its 246 pages include a compact, thorough survey of published observations, standardized illustrations of great clarity and over 1200 bibliographical references; this merits consultation when any neural aggregate is being considered. His approach has been to detail the distribution of each neuromediator separately and sequentially, then combining these results to the neuromediators present (numbers and varieties) in different neural 'entities', certain tracts, fasciculi and aggregates of grey matter, making reappraisal of some tenets of classic neuroanatomy mandatory in the future; he concludes with stimulating speculations. If persistently reaffirmed, the main elements of such data will be incorporated at many points throughout the neuroanatomical section in future editions of this volume. At present the review on pp. 889–891 may be supplemented by a few brief paragraphs. Without specifying the particular neuromediators identified, the *numbers* found, as yet, in a limited selection of sites are indicated (brackets). *Nerves, tracts, fasciculi*: spinal nerve, ventral root (1); dorsal root (7); cochlear nerve (3); olivocerebellar tract (1); lateral lemniscus (4); inferior brachium (1); corticospinal tract (1); olfactory tract (6); stria medullaris (7); stria terminalis (13); ventral amygdalofugal tract (12); fornix (9); medial longitudinal fasciculus (1); medial forebrain fasciculus bundle (15); dorsal longitudinal fasciculus (12). Numbers of neuromediators in some major neural entities: olfactory bulb (10); basal telencephalon (23); neostriatum (17); hippocampus (13); neocortex (18); dorsal thalamus (18); preoptica-hypothalamic region (25); superior colliculus (10); cerebellum (6); medial reticular formation (17); spinal dorsal grey column (15). For details of the particular mediators and many other features consult the published tables.

The earlier techniques for localizing cholinergic neurons were unsatisfactory and a brief account is given; the earlier techniques for monoaminergic neurons, however, proved remarkably accurate and have been retained except for a few additional notes or deletions.

CHOLINERGIC NEURONS

α, β and γ motor neurons, autonomic preganglionic (and some postganglionic) neurons are all described elsewhere. The neurons which form the source of the olivocochlear bundle are described on p. 960. In the medial reticular regions of the rhombencephalon and the rostral part of the lateral tegmental rhombencephalon, the nuclei, or parts thereof involved include: the central grey matter, parts of the parabrachial nuclei, nucleus pedunculopontinus, nuclei cuneiformis, subcuneiformis, profundus et dorsalis tegmentalis, raphes dorsalis and the non-dopaminergic part of the substantia nigra. Some lateral parts of the complex are classified as Ch6 and medial parts Ch5, both held to be essential parts of the ascending activating system. These various groups project rostrally as dorsal and ventral fasciculi adjoining the central tegmental fasciculus. The dorsal bundles project to the superior colliculus, pretectal area, medial and lateral geniculate nuclei and various thalamic nuclei (midline, intralamina, medial and anterior). Ventral bundles pass to the ventral tegmental grey matter, interpeduncular nucleus, ventral and anterior thalamic nuclei and most hypothalamic nuclei both medial, lateral, mamillary, supraoptic and pre-optic. The cholinergic medial habenular nucleus is bypassed (vide infra).

The cholinergic basal forebrain comprises groups Ch1–4 and extends from the septal area to the nucleus subthalamicus. Ch1—about 10% of neurons of the medial septal nucleus; Ch2—about 70% of neurons in the (vertical part) nucleus of the diagonal band of Broca; Ch3—a few neurons in the latter's horizontal part; Ch4—a massive concentration in the human brain, consisting of 90% of neurons in the basal forebrain nucleus of Meynert (embedded in the substantia innominata) and continuous above with scattered large cholinergic neurons in the internal and external medullary laminae of the globus pallidus.

Ch1–3 neurons project via the stria medullaris and some end in the cholinergic neurons of the habenular nucleus medialis; the remainder, with accessions of habenular axons continue via the habenulopeduncular (retroflex) tract to the interpeduncular nucleus and tegmental reticular formation. Ch1 and 2 also project through the fornix to the hippocampus (cornu ammonis and dentate gyrus) and Ch2 to nuclei of the lateral hypothalamic region. The smaller anterolateral part of Ch4 projects to the amygdaloid complex; the remainder (i.e. the bulk of) Ch4 has a topically organized projection to the *whole neocortex*. The basal frontal cholinergic parts of the brain receive numerous afferents and are a nodal locus between reticular, limbic and neocortical areas and naturally there have been speculations concerning a host of functional roles. What is established, however, is a correlation between gross diminution of forebrain basal cholinergic neurons and Alzheimer's disease and also Alzheimer-like dementias.

Short axoned cholinergic interneurons are scattered throughout the neostriatum (putamen, caudate nucleus and nucleus accumbens); also, in some species, the neocortex (uncertain in primates), the hippocampus, subiculum and laminae III–VI of the spinal dorsal grey column. Many or all of these sites show positive neuronal immunoreactivity for VIP. The scarcity (or possible absence) of cholinergic interneurons in the primate neocortex re-emphasizes the importance of the cholinergic axonal radiation from the dense basal aggregate Ch4 to the entire neocortex (cf the wide radiations of noradrenergic and serotonergic axons from brain-stem reticular groups) (vide infra).

MONOAMINERGIC NEURONS

The results stemming from earlier fluorescence techniques have been retained not only for historical perspective (e.g. of paracrine effects); despite the greater ease with which monoamines can be individually recognized, the earlier results have been largely confirmed and still form the basis for current *numerical classification*. Any outstanding advances are inserted but for the torrent of subsequent literature consult Nieuwenhuys (1986).

The Falck–Hillarp technique (Falck & Hillarp 1959, Falck 1962, Falck et al 1962) showed that after treatment with formaldehyde neurons and neurites containing certain biogenic monoamines fluoresce in ultraviolet light. Those containing catecholamines, dopamine, noradrenalin or adrenalin, show greenish fluorescence, those containing the indoleamine, serotonin, (5-hydroxytryptamine) a distinct yellow. At first the catecholamines could not be distinguised (except by slight

morphological differences, vide infra); but this became practicable by quantitative photofluorometry combined with pharmacological manipulation (now, of course, completely outdated by specific immunofluorescence). These more reliable techniques have led to a wealth of data of differential distribution of dopaminergic, noradrenergic and serotonergic neurons in the brain stem and diencephalon, usually in rats, cats and monkeys (Dahlstrom & Fuxe 1964, 1965, Pin et al 1968, Ungerstedt 1971, Bjorklund & Nobin 1973, Felton et al 1974, Jacobowitz & Palkovits 1974, Palkovits & Jacobowitz 1974, Lindvall et al 1974, Webster 1978). General confirmation was also effected in adult and fetal human brains (Nobin & Bjorklund 1973, Olson et al 1973a, b). (For application of immunocytochemistry to the human brain stem see Pearson et al 1983.) Some difficulties in interpretation require emphasis: axons of such neurons are extremely fine, often branch much, with minute varicosities from which transmitter is assumed to escape. They form innumerable intermediate synapses and may also perhaps produce miniature 'lakes' of transmitter affecting numerous nearby neurons in a volume of neural tissue, a '*paracrine*' effect (but see also p. 1376). Varicosities on noradrenergic fibres are almost spherical, regularly spaced and exhibit intense greenish fluorescence, whereas those of dopaminergic fibres are usually fusiform, smaller, widely and irregularly spaced and their fluorescence is less obvious. (These remarks are not relevant to immunochemistry.) *Dendrites* of these neurons are also fluorescent and may invade the territories of neighbouring nuclei; and even though they *may* be involved in, e.g. dendrodendritic synapses, they may also give a spurious appearance of an aminergic innervation in a group which is devoid of this.

In rodent brains catecholaminergic groups occur and are classified as A1–15, of which A1–7 are noradrenergic, A8–15 dopaminergic/adrenergic; nine groups contain the indoleamine serotonin and these serotonergic groups are classified B1–9. Considerable correspondence appears amongst all mammals so far studied; but the aminergic groups thus classified accord in extent only rarely with reticular nuclei recognized by classic neuroarchitectonics: usually they are part of, adjacent to or cross the boundaries of one or more of such nuclei.

NORADRENERGIC NEURONS

A brief account of the general location of the main noradrenergic neuronal groups (A1–7) is followed below by a summary of principal projections; such groups were initially identified in rats but mostly have been identified in primates and confined to the medullary and pontine regions.

Group A1, in the lower medulla, is ventral to the lateral reticular nucleus (nucleus of the lateral funiculus, p. 990) and partly extends around it; A2 is part of the *nucleus commissuralis*, a *parahypoglossal* nucleus, dorsolateral to the hypoglossal nucleus and near the fourth ventricle's ependymal floor. More recently it has been described as part of the dorsal vagal and solitary nuclei and intervening regions, partly lying under the area postrema and called the *noradrenergic dorsal medullary group*. Group A3 is part of, and dorsal to, the dorsal accessory olivary nucleus (inferior olivary nuclear complex); its status in primates is unproved. Group A4, the *nucleus pigmentosus tegmentocerebellaris*, is subependymal, embracing the ventricular aspect of the superior cerebellar peduncle. Group A5, ventral to the subcoerulean nucleus, partially invades the superior olivary territory and adjoins the facial nucleus. Group A6 is a compact *core* of the *nucleus coeruleus* (p. 980). Group A7 is the *nucleus subcoeruleus*, in the rostral pontine parvocellular lateral reticular column partly confluent with groups 4 and 6, particularly in primates (Hubbard & Di Carlo 1973).

Among these noradrenergic (and some serotonergic) groups most exhibit both complex *ascending* and *descending* projections to *local* destinations. Because their ascending connections differ it is convenient to consider group A6 first and the other groups separately, though the difference may be less than first supposed.

Group A6 is the central noradrenergic core of the nucleus coeruleus and has been described (p. 980). Its *descending fibres*, joined by some from A7 neurons, provide collaterals to the bulbar nuclei, including the vagal and inferior olivary, then traverse the spinal ventrolateral white column to provide noradrenergic terminals in ventral, intermediate and basal parts of the dorsal grey columns; this is the *ventrolateral coeruleospinal tract*. Local brainstem terminals are largely collaterals of ascending fibres; but a substantial bundle, *the coeruleocerebellar tract*, joins the superior cerebellar peduncle, reaching the cerebellar nuclei and cortex (p. 967). Ascending fibres also form the prominent *dorsal tegmental noradrenergic bundle* (part of the central tegmental fasciculus) traversing the midbrain ventrolateral to the aqueductal grey matter; it continues through the *lateral hypothalamus*, largely in the *medial forebrain bundle*, and thence through the septal region to join the cingulum and supracallosal longitudinal stria; others are transported via the fornix, stria medullaris and stria terminalis. Side branches throughout have, sequentially, terminals in *mesencephalic* aqueductal grey matter, reticular nuclei and the colliculi; *diencephalic* terminals include dorsal thalamic nuclei, geniculate and habenular nuclei; telencephalic terminals include *all* the major *limbic structures*, septal and amygdaloid nuclei, hippocampus, subiculum and cingulate, retrosplenial and parahippocampal gyri; the *neocortex* has *a uniform bilateral input*, fibres of the two dorsal bundles having exchanged fibres in the upper brain stem. It has been claimed that the axon of a *single* coerulean neuron may provide terminals in the spinal cord, brain stem and throughout the forebrain! (Further comments on p. 980.)

Groups A1, 2, 5 and 7 (and perhaps A3 and 4, status being less certain in primates) have ascending branches which converge, termed by some the *ventral tegmental noradrenergic bundle* (part of the central tegmental fasciculus). Traversing the ventral midbrain reticular regions it approaches the dorsal bundle in the upper midbrain; both exchange fibres, the ventral then continuing mainly in the medial forebrain bundle through the lateral hypothalamus; en route it provides collaterals ending at mesencephalic levels in the adjacent reticular nuclei (p. 990) and circumaqueductal grey matter; in the diencephalon it diverges to the *hypothalamic* nuclei, with particularly complex terminals in the dorsomedial, periventricular, tuberal, paraventricular and supra-optic nuclei; it appears to end as terminal sprays in the bed nucleus of the stria terminalis and pre-optic area. The dorsal and ventral tegmental noradrenergic bundles thus mainly differ in diencephalic terminations and the extremely *wide* continuation of the dorsal bundle into *limbic* and *neocortical* areas.

Groups A1 and 2 provide *local* inputs, especially to dorsal vagal and solitary nuclei.

Groups A1, 2, 5 and 7 send *descending* fibres to the spinal cord, described as an *anterior noradrenergic bulbospinal tract*, with terminals in the spinal ventral grey column and a *dorsolateral noradrenergic bulbospinal tract*, with terminals in the intermediolateral grey column and substantia gelatinosa. Both coeruleospinal paths are bilateral, the decussation occurring at spinal levels.

DOPAMINERGIC NEURONS

No dopaminergic nuclei are found in the hindbrain; of eight recognized (A8–15) A8–10 are mesencephalic, A11–14 are diencephalic and A15 is telencephalic.

The three midbrain groups are *interconnected* plates of dopamine-positive neurons and difficult to define. Group A8 lies in the mesencephalic reticular formation and is also known as *the substantia nigra pars lateralis* (p. 982), A9 being the *substantia nigra pars compact*. Group A10, a median complex, abuts ventrally the nucleus interpeduncularis and is also termed the *nucleus linearis*, *nucleus parabrachialis pigmentosus* and *interstitial nucleus of the ventral tegmental decussation*; how far these are synonymous in primates is obscure.

The diencephalic group A11 is subependymal in the caudal hypothalamus, lying low in the third ventricle's wall and partly surrounding the fasciculus retroflexus (habenulopeduncular tract). Group A12 includes the *infundibular* (*arcuate*) *nucleus*; its upward extensions into the rostral periventricular grey matter are classified as A14. Some caudomedial neurons of the zona incerta (p. 1006) form group A13. The solitary telencephalic group (A15) comprised periglomerular neurons of the olfactory bulb (p. 1031).

Some dopaminergic efferents from groups A8 and 9 (subdivisions of the substantia nigra) ascend through the subthalamus and lateral hypothalamus, then diverge and traverse the internal capsular fibres (as part of the *comb* bundle, p. 1017), where they join the ansal system and continue to radiate; they end *throughout* the neostriatum, i.e. the caudate nucleus and putamen, forming a *nigrostriatal dopaminergic system*. But septal fibres from the mesencephalic group A10 ascend more medially via the medial forebrain bundle to other telencephalic structures, including the nucleus accumbens, nucleus of stria terminalis, olfactory tubercle, granular areas of the frontal neocortex, anterior cingulate cortex and entorhinal cortex, forming a *mesolimbic dopaminergic system*. It may be noted that more recent analyses have regarded the mesencephalic aggregates as one complex group giving a major *mesotelencephalic dopaminergic system* from which three prominent radiations arise, namely: *mesostriatal*, *mesolimbic* and *mesocortical*; all are topically organized in the three cardinal planes.

Groups A11,13 and 14 (not classically 'reticular') have short axons confined to the diencephalon; A11 projects to the medial group of hypothalamic nuclei, to the nuclei of the midline of the dorsal thalamus, the habenular nuclei and pretectal area. Axons of A13 and 14 terminate in the caudal regions of the dorsal thalamus, other parts of the zona incerta and nuclei of the dorsal and oral parts of the hypothalamus, collectively termed the *incertohypothalamic dopaminergic system*.

Neurons of A12, with somata mainly in the infundibular nucleus, send axons to the anteroventral part of the median eminence and upper infundibulum, ending in synaptic relation with or merely near axons or terminals of parvocellular releasing-factor neurons, or in relation to tanycytes of the infundibular recess and the median eminence (pp. 1010, 1451). This *tuberoinfundibular dopaminergic system* may influence transport and/or exocytosis of releasing factors and their uptake and the uptake of dopamine itself, by the venous portal system capillaries and the exchange and constitution of cerebrospinal fluid to or from the third ventricle by tanycytes.

Some account of group A15 appears on p. 1030.

Recent evidence indicates the possible occurrence of dopamine in the dorsal vagal nucleus, confirmation of a dopaminergic innervation of the hypothalamic nuclei: supraoptic, paraventricular, and dorsomedial; also the presence of a *dopaminergic hypothalamospinal* projection (as yet shown only in rat and rabbit) passing in lamina 1 of the spinal dorsal column, the posterolateral fasciculus and subependymal central canal, innervating the substantia gelatinosa, neighbouring laminae and the intermediolateral column.

SEROTONERGIC NEURONS

Reticular neurons synthesizing the transmitter serotonin (5-hydroxytryptamine) occur at medullary, pontine and mesencephalic levels; all are in or near the midline (i.e. parts of the rapheal nuclei, vide supra); groups termed B1–9 have been located. B1 is formed by neurons of the nucleus raphes pallidus but also extend laterally, B2 is the nucleus raphae obscurus; both extend ventrolaterally to include neurons of the nucleus paramedianus. Neurons of nuclei raphae pallidus and magnus ascend and converge to the pontomedullary junction, together, there, constituting group B3. Groups B1–3 are thus serotonergic, median or paramedian and largely medullary. Group B4 is in the pontine periventricular grey matter (deep to the upper part of the fourth ventricle); B5 is a subgroup of the nucleus raphae pontis, near the trigeminal motor nucleus; B6 is in the central pontine tegmental reticular grey matter, extending to the pontine superior central nucleus. B7, the largest serotonergic group, occupies much of the mesencephalic nucleus raphae dorsalis, spreading into the periaqueductual grey matter; B8 is a rostral extension of B6 in the nucleus centralis rostralis; B9 is a lamina around the lateral aspect of the nucleus interpeduncularis near the medial lemniscus. Lateral extensions of B6 and 8 pass lateral to the confines of their neighbouring rapheal nuclei and are intermixed with noradrenergic neurons of the locus coeruleus, subcoerulean area and parabrachial nuclei.

Routes and terminations of fibres from serotonergic cell groups resemble the noradrenergic ones, but with some exceptions. They may be classified as (1) descending, (2) local, (3) cerebellar and (4) widespread dorsal and ventral ascending paths. Single serotonergic axons may spread to many destinations, others appear strictly localized. In short, they innervate almost the *entire central nervous system*.

(1) *Descending bulbospinal serotonergic projections* come from medullary groups B1–3, particularly the nucleus raphes magnus; they form two tracts. One traverses the ventral white funiculus with re-entrant terminals to neurons of the ventral grey columns (laminae VIII and IX); the other descends dorsally in the lateral white funiculus, lateral to the corticospinal tract, innervating the intermediolateral column (preganglionic autonomic) and other laminae of the dorsal column (particularly laminae I, II, and V), including the substantia gelatinosa, the latter held to be much concerned with the modulation of *nociceptive inputs*. With respect to the latter it should be noted that *raphespinal* neurons projecting in the manner indicated contain at least five putative neuromediators that may be involved. (Substance P is always present, as are enkephalin-immunoreactive interneurons in the target tissue.) Presynaptic serotonergic terminals on *primary afferents* have been observed and the modulation of mechanoreceptor and thermoreceptor inputs is also under rapheospinal control.

(2) *Intrinsic brain-stem serotonergic projections* involve B3–8; those from B5–8 project to the nucleus coeruleus, tegmental nuclei, with descending fibres to other (probably aminergic and non-aminergic) reticular pontine and medullary zones. Groups B3–5 also connect with adjacent reticular nuclei and perhaps the inferior olivary complex. The largest group, B7, sends the most massive bundle of serotonergic axons yet identified to the largest group of noradrenergic neurons, in the core of the nucleus coeruleus (A6).

(3) The *cerebellar serotonergic path* consists of axons from B5 and 6; entering the ipsilateral middle cerebellar peduncle, they branch and some end in the intracerebellar nuclei but the bulk then diverge widely to reach the cerebellar cortex (cf. the noradrenergic cerebellar path in the inferior peduncle).

(4) The *dorsal ascending serotonergic bundle*, smaller and more restricted in its destinations than the ventral, arises in groups B3–6; its axons converge up and dorsally into the dorsal longitudinal fasciculus (p. 986); ascending in this they give collaterals to the mesencephalic reticular nuclei and the periaqueductual grey matter; on entering the diencephalon, they diverge to their terminations in the nuclei of the caudal zone of the hypothalamus (p. 1009).

The *ventral ascending serotonergic bundle*, relatively massive, stems from B6–8 (rapheal nuclei of the upper pons and midbrain), curves ventrally and up to traverse the ventral midbrain tegmentum in the central tegmental fasciculus, then enters the diencephalon and traverses the hypothalamus laterally in the medial forebrain bundle. Its multiple collaterals radiate widely to diverse destinations: mesencephalic fibres to the substantia nigra, others to the interpeduncular nucleus, some terminating here, the rest continuing in the interpedunculo-habenular tract, to reach the epithalamus and dorsal thalamus; they end in the habenular nuclei, in the medial and median thalamic nuclear groups and its parafascicular nucleus. In the diencephalon, as part of the medial forebrain bundle, its collaterals reach the mamillary and lateral hypothalamic nuclei; others penetrate the hypothalamus obliquely to reach the caudate nucleus and putamen, some continuing to wide areas of the lateral neocortex; a small fascicle enters the postcommissural (column) of the fornix, recurving through its body, crus and fimbria to reach the dentate gyrus and cornu ammonis. At the anterior end of the hypothalamus the ventral serotonergic fasciculus splits into rami, some passing ventrolaterally in the ansa peduncularis to the nucleus of Broca's diagonal band, prepiriform and entorhinal cortex and parts of the amygdaloid complex; some splay out to nuclei of pre-optic and septal areas, to the organum vasculosum of the lamina terminalis (intercolumnar tubercle), to the olfactory tubercle and adjacent grey matter; others continue to the medial frontal neocortex and along the olfactory tract to the olfactory bulb; another contingent radiates to the nucleus accumbens to supply an input to anterior

zones of the caudate nucleus and putamen. The substantial remainder of the fasciculus passes forwards, then dorsally to join the cingulum, arching over the corpus callosum and then curving ventrally to run the length of the temporal lobe. It supplies collaterals to the cingulate, retrosplenial and entorhinal (parahippocampal) cortices and sequentially to the cornu ammonis and subiculum, completing a *dual input* to the hippocampal formation (vide supra).

The serotonergic neurons present in nuclei raphes dorsalis and centralis superior in part, give rise to axons that form a widespread *supra-ependymal serotonergic plexus* which is best developed on the ventricular aspects of the fourth and lateral ventricles and the cerebral aqueduct, patchily developed in the third ventricle and absent over the hypothalamus. It consists of fine, varicose fibres, which presumably release serotonin into the cerebrospinal fluid and on to the ependyma. With other neuromediators, it may be concerned in controlling the production, constitution, flow and regional neural uptake of the fluid with its fluctuating constituents.

Thus the brain-stem serotonergic 'system' projects to: (1) brain-stem reticular nuclei, (2) hypothalamic nuclei, (3) all major limbic structures, (4) some 'limbic' and 'non-specific' nuclei of the dorsal thalamus and epithalamic nuclei, (5) much spinal grey matter, (6) most, perhaps all, areas of the neocortex, (7) the supra-ependymal plexus. Taken together, these have been termed, 'the most expansive neuronal network yet described', Nieuwenhuys (1986).

FUNCTIONAL ASSOCIATIONS OF THE RETICULAR FORMATION

Information converges to the reticular formation from *all* parts of the central nervous system and is projected back to all regions, modulating their activities through complex interactions involving varieties of complex synaptic neurotransmission and local neuroparacrine and wider neuro-endocrine effects. Earlier views of anatomists and physiologists, dismissing the reticular regions as merely ancient 'leftovers', were a product of ignorance and can now be ignored. However, the present has equal problems; for so little do we yet understand the *modus operandi* of the reticular formation that two contrasting and extreme views of it have been advanced. On one hand some find it sufficient to feed into the formation a channel from another neural complex, e.g. the corpus striatum, and to describe the effects elsewhere as *mediated* by the formation, with no attempt to analyse it structurally, as if it were a kind of 'black box'. Similar are those who invoke 'reticular activity' to explain almost *any* phenomenon which cannot be explained by more orderly 'specific systems'. On the other hand, with the present patchy and limited (but rapidly increasing) knowledge it is similarly facile to attach *simple unitary functional labels* to individual neurons or nuclei, by whatever criteria they are 'classified'. The methods available for structural and functional evaluation of this problem have been outlined elsewhere (pp. 870–875); various cytoarchitectonic, impregnational, histochemical, histofluorescent, immunofluorescent, degenerative, autoradiographic and other tracer techniques are beginning to form a picture of its organization and connectivity, albeit incomplete. This provides (as in other neural problems) the reference framework for functional probing, which includes: microelectrode recording, analysis of behavioural changes or deficits due to focal or zonal microstimulation or ablation, pharmacological enhancement or depression of neuromediator action, studies of neuropathological states, genetic and developmental deviations and studies of psychoses. All such have limitations, particularly when applied to such complexities as the reticular formation, hypothalamus, dorsal thalamus, limbic 'system' and cerebral cortex. In the present context real comprehension of the 'reticular' formation would necessitate intimate data of form and flow of information in multitudinous converging channels, including any previous processing and interaction, transformations in the formation itself and the mode of modulation by outflow channels on their multiple destinations, all modifying complex behaviour. We are far from such comprehension. Some of the active fields currently engaging neurobiologists are noted below; they may all be allocated (a persistent theme in living creatures) to some aspect of long, intermediate or short-term homeostasis.

(1) **Somatomotor control.** The reticular formation is part of a complex of subcortical regions influencing patterns of activity in skeletal muscles. These include simple reflex loops, large or fine postural re-adjustments, positioning and scanning by distance receptors, manipulative skills, locomotion and complicated patterns of personal and group communciation involving speech, gesture and facial expression. The degree and timing of involvement of a multiplicity of central nervous regions, intimately concerned in influencing alpha and gamma motor neuron pools and adjacent interneurons, varies with the speed, force and complexity of the movement. Involvement of the reticular formation may be direct or indirect through other neural apparatus. *Direct* spinal influences are via reticulospinal tracts from the lateral two-thirds of the pontomedullary reticular formation; from the pons they are largely ipsilateral, in the ventral white funiculus; from the medulla they are bilateral, via a wide area of the lateral white funiculus. Stimulation and ablation led to concepts of an *inhibitory motor 'centre'* or *'zone'* and a *medullary pontine facilitatory 'centre'*. But inhibition by medullary reticulospinal fibres results from *increased* release of neuromediator from terminals influencing spinal interneurons, alpha and gamma efferents, involving various pre- and postsynaptic mechanisms. However, *on balance*, *reduced* medullary activity would have a facilitatory effect, and in any case during normal activities *continual fluctuations* occur, making this terminology arbitrary. The descending fibres involved stem from multipolar neurons of medullary and pontine gigantocellular nuclei, the central medullary reticular nucleus and nucleus reticularis pontis inferior, including groups A6 and 7, and groups B1–7 in rapheal nuclei. Thus, non-aminergic fibres are mingled with inhibitory noradrenergic and serotonergic fibres; also, the nucleus coeruleus (origin of bulbospinal fibres) receives a serotonergic input from the inferior rapheal nuclei, whose serotonergic bulbospinal fibres may mediate general relaxation of body musculature, typical of rapid eye-movement (REM) sleep. Doubtless other neuromediators are involved. There could be similar direct influences on the motor neuron pools of the cranial nerves and on the groups of reticular neurons which control the diaphragm and intercostal musculature, the latter forming the hierarchy of respiratory 'centres' described by neurophysiologists.

Indirect reticular influences on somatomotor control are numerous, as set out in the relevant sections. They include non-aminergic (presumably many cholinergic) and aminergic fibres (see sections on these 'systems'); but the relative numbers, sites of termination and roles in integration are uncertain. Thus, the *cerebellum* receives reticular inputs through: both inferior and middle peduncles, distributed to its nuclei and cortex; other brain-stem complexes, including the olivary nuclei, colliculi, red nucleus and substantia nigra, corpus striatum, in particular the caudate nucleus and putamen through the comb bundle and central tegmental fasciculus; the nuclei ventralis anterior and lateralis of the dorsal thalamus, zona incerta and other subthalamic nuclei, and from the somatomotor cortex, either directly from the reticular nuclei or indirectly via the many regions just mentioned.

(2) **Somatosensory control.** All lower levels involved in processing somatosensory information are subject to reticular influence. Spinal and brain-stem terminals of primary afferent fibres, nuclear destinations and interneurons, dendrites and somata of neurons projecting to suprasinal centres: all these are subject to reticular influence. Effects may be pre- or postsynaptic, facilitatory or inhibitory. The relevance of such controls to theories of sensory 'gating' mechanisms (p. 944) is of special interest: descending bulbospinal and local bulbar reticular fibres, which are serotonergic, may co-operate with others, which are noradrenergic or contain metenkephalins or substance P, and other neuromodulators (p. 892), in an integration modifying the perception of pain (p. 944) and other modalities. (Compare the diencephalic and limbic distribution of monoaminergic and enkephalin-containing reticular terminal fibres with the distribution of opiate receptors, Guillemin 1978,

Chan-Pham 1978, Nieuwenhuys 1986). 'Higher' centres processing somatosensory information and having a reticular input are sensory relay nuclei of the dorsal thalamus and somatosensory cortices.

Similar considerations apply to special senses; reticular afferents reach cochlear, vestibular, tectal, pretectal and geniculate nuclei, pulvinar and other dorsal thalamic nuclei *and* the visual, auditory and olfactory cortices. Spinoreticular and bulboreticular connections are in themselves held by many to provide bilateral, polysynaptic 'slow pain' pathways, discharging into multiple diencephalic nuclei, for both somatosensory and viscerosensory information.

(3) **Visceromotor control.** Cardiovascular readjustments and the activity of non-striated muscle and glandular cells in thoracico-abdominal viscera are usually controlled by postganglionic autonomic neurons; these, either directly or via local interneurons, are partially controlled by the reticulobulbar and reticulospinal fibres. By focal stimulation and ablation, brain-stem transection and pharmacological manipulation, a concept of, e.g. cardiovascular 'centres', has gained physiological acceptance. Though the sites of sympathetic and parasympathetic preganglionic neurons involved are accepted, functionally related reticular nuclei remain speculative.

Forebrain control of autonomic activities involves the orbitofrontal, cingulate and entorhinal cortex, major limbic structures (pp. 1009, 1028), medial and anterior groups of dorsal thalamic nuclei, hypothalamic nuclei and descending fascicles of various tegmental bundles with reticular destinations, and thence via the reticulobulbar and reticulospinal tracts mentioned above.

(4) **Neuro-endocrine transduction.** Via the complex of bundles ascending with central and dorsal tegmental fasciculi, cholinergic, all varieties of monoaminergic and other neuromediator-profiled fibres pass in collateral paths to almost all hypothalamic nuclei, including infundibular nuclei of the median eminence and habenular nuclei. Thus, directly via other hypothalamic nuclei or via dopaminergic infundibular neurons, reticular neurons are one source of modification of synthesis and probably transport and exocytosis of 'releasing' or 'release-inhibiting' factors by parvocellular neurons in the mediobasal hypothalamus (p. 1007), thus controlling the adenohypophysial activity. Similar mechanisms probably operate on the neurohypophysis. Neural input to the pineal gland involves the sympathetic nerves via the upper thoracic spinal outflow of preganglionic fibres, the superior cervical ganglion and nervus conarii. There is also a neural connection via the habenulopineal tracts. The role of the suprachiasmatic nucleus has been mentioned elsewhere (pp. 1013, 1459). Both main neuro-endocrine transduction centres are hence partly under reticular influence.

(5) **Biological rhythms.** The notion of '*biological clocks*' has now permeated all branches of biology. A time-base exists in all living systems through the turnover rates of macromolecules, including those related to the genetic apparatus, annual seasonal variations and daily environmental changes. Biological 'rhythms' thus involve reproductive *cycles*, development, cell division, cell death and replacement, etc., the list being endless. Many rhythms depend on an intact hypothalamus, with its multiple connections, including those from the reticular formation which are also involved in neural control of the pineal gland, prompting much interest in its neuro-endocrine role in relation to *circadian rhythms*, as these repetitive cycles or biorhythms are now called (pp. 1012, 1459).

(6) **Sleep, arousal, states of consciousness, perception.** Much effort (philosophical, psychological, neurophysiological, neuropharmacological and neuroanatomical) has been expended in defining states of consciousness and their neural arenas, ranging from stuporose conditions, varieties of sleep, arousal and awakening, to attention, perception and active responses. Research on all these fronts is endless; a vast literature has accumulated, beyond the scope of this or any volume (Jouvet 1969, 1972, Ingram 1976). It is necessary to distinguish different *behavioural* states of unconsciousness, sleep and awakening from *electroencephalographic* records of these states, where they exist. The terminology used in such recordings is widely employed. Thus, two principal forms of sleep are recognized: *deep* or *slow wave* (*recuperative*) *sleep* (SWS), in which individuals are deeply but reversibly unconscious, with random changes of limb position and posture, elevation of sensory thresholds and *synchronized*, high-voltage, slow waves; interspersed are periods of *paradoxical* sleep (PS) or *rapid eye-movement* (REM) sleep, in which dreaming normally occurs, with bodily relaxation but rapid oscillatory ocular movement, accompanied by corresponding bursts of electrical activity, similar waveforms being recorded from the pontine reticular formation, dorsal lateral geniculate nucleus and occipital visual cortex (PGO activity). Arousal and awakening is accompanied in intact animals by a rapid, low amplitude, *desynchronized* waveform. An '*ascending activating reticular system*' has already been mentioned (p. 991); it is polysynaptic, with multiple inputs from sensory pathways and via diencephalic synaptic complexes and widespread bilateral radiation to most regions of the neocortex and limbic structures. Investigations indicate that both cholinergic and monoaminergic reticular groups in the upper pons and midbrain are, when stimulated, the most powerful initiators of cortical desynchronization. It is widely assumed that desynchronization is necessary for wakefulness, attention, effective perception and cognition and preparation for appropriate responses. The varieties of sleep are currently considered the result of activity in a *hierarchy* of hypnogenic neuronal groups balanced against the 'activating system', most being monoaminergic. *Slow-wave sleep* depends on serotonin production by rapheal nuclei, whereas *paradoxical sleep*, after priming by serotonin, follows the intermittent activity of cholinergic *and* noradrenergic neurons in the nucleus coeruleus (rostral part), its medial neurons appearing to be a '*pontine pacemaker*', which with the former generates PGO responses. Descending serotonergic bulbospinal fibres from rapheal nuclei, together with noradrenergic fibres from the inferior part of the nucleus coeruleus, are considered responsible for the relaxation of limbs and trunk in paradoxical sleep.

(7) **Spatio-temporal discrimination, cognitive mapping and exploration, reward, learning and memory, emotional content, long-term homeostasis** all depend on an intact hypothalamo-limbic 'system' and will be discussed later. In addition to numerous other afferents, all hypothalamic nuclei and limbic structures receive widespread inputs via aminergic, non-aminergic and numerous other reticular elements; surgical or pharmacological interference with brain-stem reticular elements can have profound effects.

As stated at the outset, the brain-stem's reticular core has reciprocal connections with *all* major parts of the central nervous system and hence influences *all* behaviour.

THE PROSENCEPHALON OR FOREBRAIN

The prosencephalon develops from the foremost primary cerebral vesicle (p. 987). This *forebrain vesicle* and its cavity, the future *third ventricle*, soon differentiate into a caudal *diencephalon* and rostral *telencephalon*. From the latter's sides, right and left diverticula develop into cerebral hemispheres, each with a contained ventricle. The sites of evagination become the interventricular foramina, by which all three ventricles are continuous. Survey scans and sections are provided (7.57, 58, 123, 124, 140). The diencephalon corresponds largely to most of the third ventricle and its adjacent structures; the *telencephalon* comprises a median *telencephalon medium* (*impar*), containing a limited forward extension of the third ventricle and massive *bilateral telencephalic hemispheres*, each containing a lateral ventricle. (For development see p. 189.)

THE DIENCEPHALON OR 'INTERBRAIN'

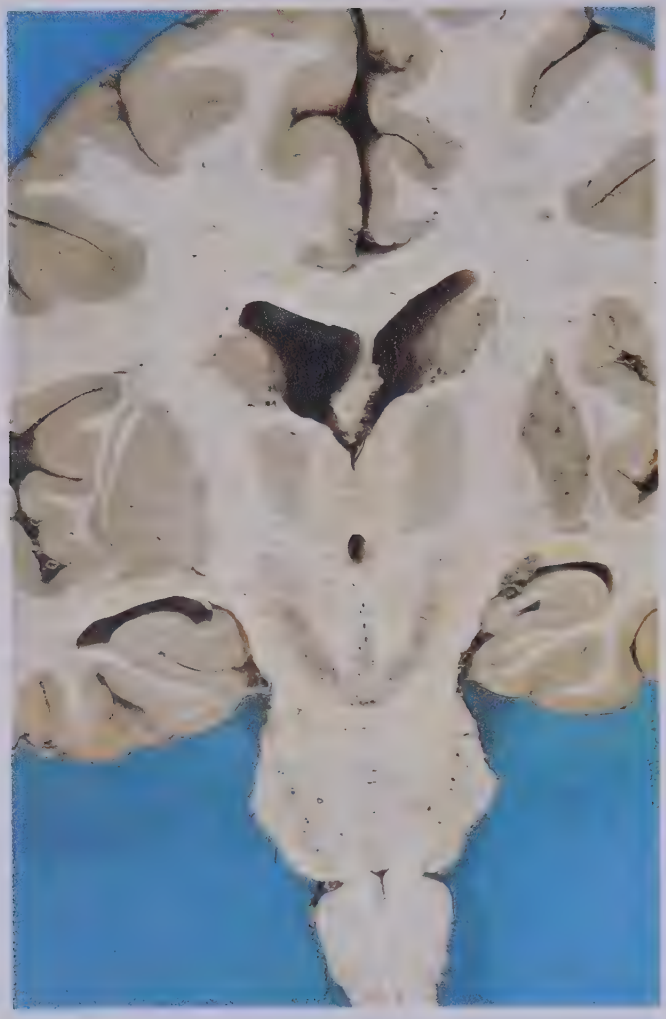
The diencephalic cavity, equal to most of the median slit-like third ventricle, narrows caudally to become the mesencephalic aqueduct and extends rostrally into the median telencephalon (p. 1007). More precise limits of the diencephalon are: caudally, a plane including the posterior commissure and posterior margins of mamillary bodies; rostrally, a plane from the interventricular foramina through the dorsocaudal border of the median part of the optic chiasma, rostral to which are structures of the median telencephalon. While these boundaries have approximate developmental and phylogenetic significance, they are arbitrary descriptive aids, to which function is blind.

The diencephalon, being median, has right and left halves. Across each lateral wall of the third ventricle a *hypothalamic sulcus* extends from the cerebral aqueduct to the interventricular foramen (p. 1019); its line is used to demarcate each lateral half into a **pars dorsalis** and **pars ventralis diencephali**. Each *pars dorsalis* consists of a dorsal thalamus, metathalamus and epithalamus; the *pars ventralis* includes the hypothalamus and ventral thalamus. Dorsal to the hypothalamic sulcus most of each lateral wall is formed by the large ovoid *dorsal thalamus*. The unqualified term *thalamus* is widely used as synonymous with the dorsal thalamus and will frequently be so used here; but the thalamus can be divided into major *parts*, each subdivided into *nuclei*. Postero-inferior to and partly continuous with it are the *medial* and *lateral geniculate bodies*, which contain nuclei also so named, forming the *metathalamus*. The diencephalic roof is largely ependyma, continuous with the third ventricle's lining and apposed in most of its extent to the vascular pia mater, with no nervous tissue between; but caudally in the roof and adjoining the lateral walls are the habendular nuclei and commissure, the epiphysis cerebri or pineal gland and posterior commissure, which together constitute the *epithalamus*.

Some include the whole of the *pars ventralis diencephali* in the hypothalamus, including regions functionally dissimilar; a more restricted definition is preferable. The *hypothalamus* extends axially from the lamina terminalis to a vertical plane caudal to the mamillary bodies and dorsoventrally from the hypothalamic sulcus to include structures in the third venticle's side wall and floor, the latter comprising the mamillary bodies, tuber cinereum and infundibulum, and tissue adjacent to the optic chiasma (7.132, 133). The preoptic region, adjacent to the lamina terminalis and strictly telencephalic, is for functional reasons usually included in the hypothalmus. The remaining zones of the pars ventralis diencephali are partly lateral to the hypothalamus, as a thin sheet ventral to the dorsal thalamus and a thick zone merging caudally with the mesencephalic tegmentum. Collectively these zones are the *ventral thalamus* or *subthalamus*, including upper extensions of the red nucleus and substantia nigra, the subthalamic nucleus, prerubral field, zona incerta and associated complexes of nuclei and tracts.

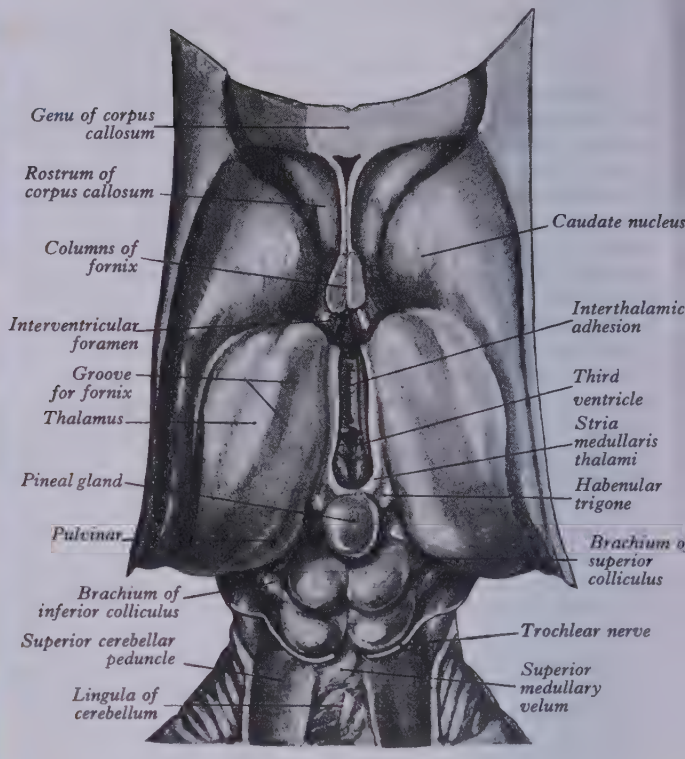
The (Dorsal) Thalamus

The thalami (7.123–126) are large, grey, bilateral, ovoid masses flanking the third ventricle which also extend posterior to it. Each is about 4 cm long with, descriptively, two ends or poles and four surfaces.



The narrow *anterior pole* is near the midline and forms the posterior boundary of the interventricular foramen. The expanded *caudal* (*posterior*) *pole*, the *pulvinar*, directed dorsolaterally, overhangs the superior colliculus and its brachium. Inferolateral to the pulvinar is the lateral geniculate body (p. 1016), a small, oval elevation. Inferiorly the pulvinar is separated from the medial geniculate body (p. 1015) by the brachium of the superior colliculus.

The *dorsal* (*superior*) *surface* (7.125), slightly convex and covered by a white *stratum zonale*, is separated laterally from the lateral ventricular aspect of the caudate nucleus by a white *stria terminalis* and the thalamostriate vein (p. 798); but it is separated medially from its medial surface only by the line of reflexion of the ependyma (*taenia thalami*) forming the third ventricle's roof. The dorsal surface is divided into a lateral region, which is part of the lateral ventricle's floor, covered by its ependymal epithelium and partly hidden by a fringe of choroid plexus (7.126), and a medial region covered by part of the tela choroidea of the third ventricle, separating it from the body of the fornix, the lateral edge of which grooves it. Between the lateral edge of the fornix and the dorsal thalamic surface the lateral edge of the tela choroidea, with its choroid plexus, invaginates into the cavity of the lateral ventricle through the choroidal fissure (7.198–200). Anteriorly, the dorsal surface is separated from the medial surface by a narrow ridge, from which the third ventricular epithelium is reflected to the tela choroidea's ventral surface; the ridge covers a small nervous fascicle, the *stria medullaris thalami* (p. 1004). Thus, anteriorly, the taenia thalami and the stria medullaris thalami are co-incident but progressing posteriorly they diverge, the taenia inclining laterally as the width of the tela expands. The stria medullaris, however, continues subependymally along the dorsomedial rim of the thalamus, then finally turns medially as the anterior limit of the *trigonum habenulae* (7.116, 125), separated from the dorsal thalamic surface by the *sulcus habenulae*.



The *ventral* (inferior) *surface* is continuous with a tegmental prolongation (*subthalamus*) and anterior to this the ventral surface

7.123 The dorsal half of a brain sectioned in an oblique coronal plane which passes through the cerebral hemispheres, diencephalon, midbrain, pons and medulla oblongata, to show the general disposition of main structures, some of which are labelled on 7.126. Note: (1) the complex folding of the cerebral cortical gyri and sulci of the frontoparietal, insular and temporal regions; (2) the sectioned surfaces of the corpus callosum, septum pellucidum, body of the fornix, the corona radiata, internal capsule, ventral pons and medulla oblongata; in the latter, part of the decussation of the corticospinal tracts is visible. Note also: (3) the body and inferior horn of the lateral ventricle; (4) the lentiform and caudate nuclei and the dorsal thalami which are fused across the midline. This illustration includes features referred to at many points in the text which are too numerous to include in a caption; these should be studied as appropriate. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

7.124 The central area of the ventral part of the oblique coronal section of the brain shown in 7.123, photographed at higher magnification to show some structural features in greater detail; compare with 7.126 for appropriate labelling. Note in particular: (1) the anterior, medial and lateral parts of the dorsal thalamus, separated by the internal medullary laminae; (2) the relation of the caudate nucleus to the anterior and inferior horns of the lateral ventricle; (3) the lentiform nucleus, divided into an external putamen and an internal globus pallidus, the latter again divided into internal and external parts; (4) the internal capsule, external capsule, claustrum, extreme capsule and insular cortex; (5) the profiles of the sectioned subthalamic and red nuclei and substantia nigra; (6) the hippocampus projecting into the floor of the inferior horn of the lateral ventricle. Other structural features on this section are referred to at many points throughout the text. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

7.125 Dorsal aspect of the caudate nuclei, thalami, pineal gland and tectum, revealed by removal of most of the corpus callosum, the body of the fornix and of the tela choroidea.

is dorsal (superior) to part of the hypothalamus in the third ventricle's lateral wall.

The *medial surface* (7.140A,B) is the superior ('dorsal') region of the third ventricle's lateral wall, usually (secondarily) connected to the opposite thalamus by a flat, grey *interthalamic adhesion* (*connexus interthalamicus*), behind the interventricular foramen; its anteroposterior dimension averages about 1 cm, is sometimes multiple, occasionally absent and contains neurons, some of their axons crossing the midline, though many recurve back from this. The medial surface is limited below by an often indistinct *hypothalamic sulcus*, which curves from the upper end of the cerebral aqueduct to the interventricular foramen; it is usually considered a continuation of the sulcus limitans of the spinal cord and brain stem, a view strongly challenged (Christ 1969).

On the *lateral surface* is the thick posterior limb of the internal capsule, separating it from the lentiform nucleus (7.123, 124, 126).

The Major Structure of the Thalamus

The thalamus is chiefly grey matter but its superior and lateral aspects are covered respectively by the white *stratum zonale* and *external medullary lamina*. It is incompletely divided into **major parts** by the vertical, white, *internal medullary lamina*, which splits in a Y-shaped manner, dividing the thalamus into *anterior* (rostral), *medial* and *lateral parts*, the lateral being subdivided into dorsolateral and ventromedial regions, all of which contain groups of *thalamic nuclei*, with smaller groups in the lamina and near the medial and lateral thalamic surfaces.

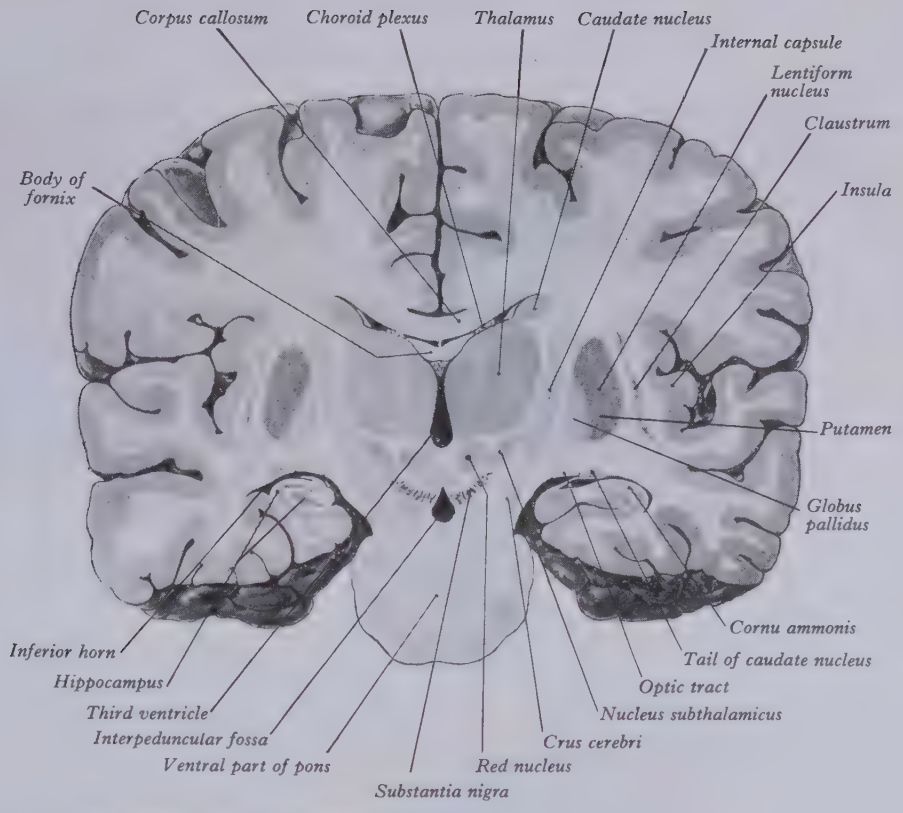
The main nuclear groups are:

(1) *Anterior* (rostral) *group*, forming the anterior part.

(2) *Medial group*, extending medially from the internal medullary lamina almost to (but *not* reaching) the ependymal lining of the third ventricle.

(3) *Lateral group*, dorsolateral moiety of the lateral part, expanding behind as the pulvinar.

(4) *Ventral group*, ventromedial moiety of the lateral part.



(5) *Intralaminar group*, embedded in the internal medullary lamina.

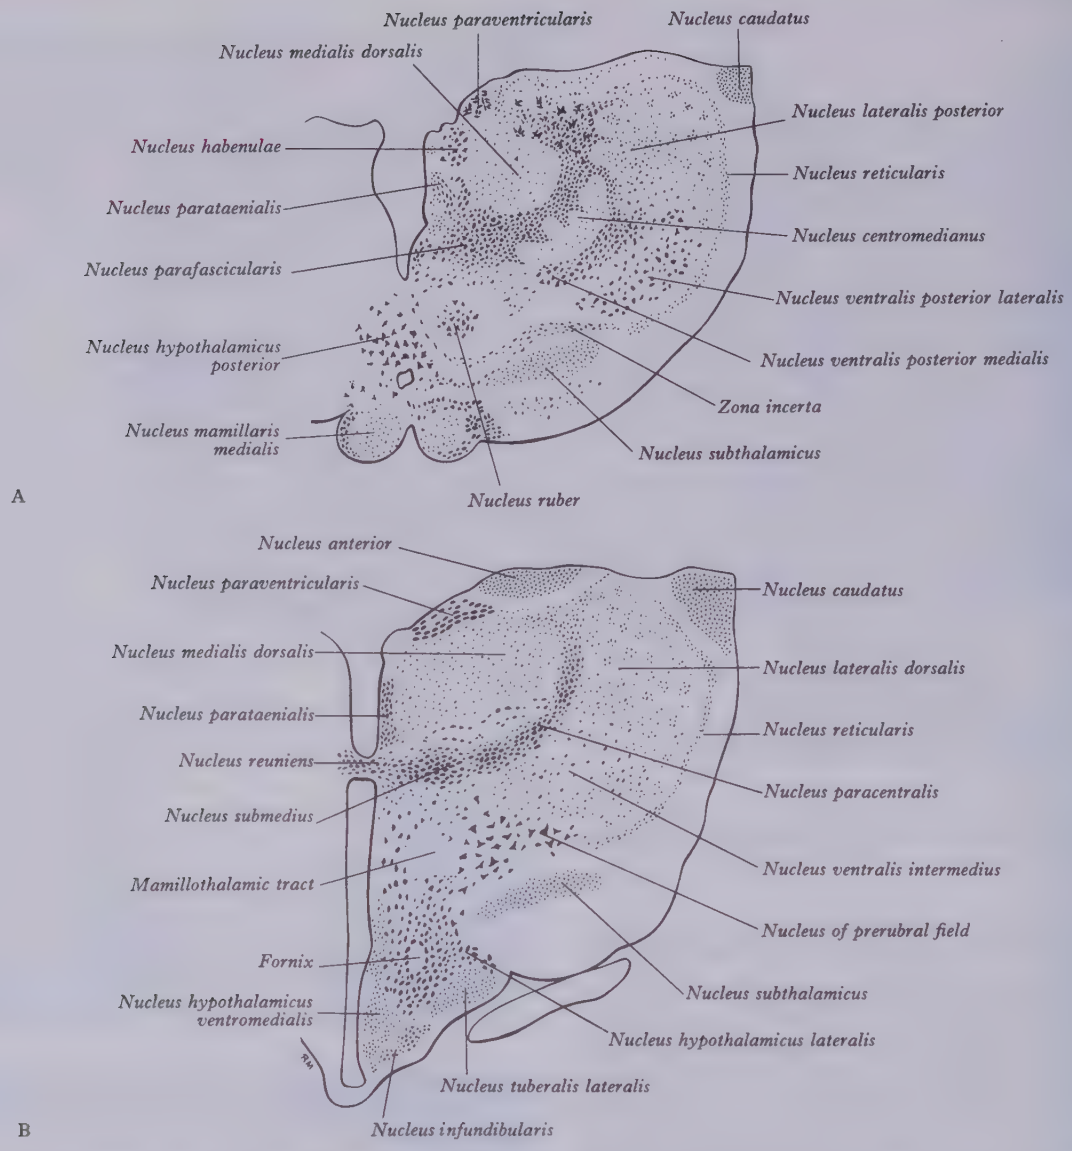
(6) *Nuclei of the midline*, small, interspersed with periventricular fine nerve fibres, part of the grey matter separating the medial thalamic region from the ependyma of the third ventricle and of the variable interthalamic adhesion (p. 1020).

(7) *Reticular thalamic nucleus*, a long, thin, curved lamina, separating the *external* medullary lamina from the posterior limb of the internal capsule.

The thalamic anterior and medial parts, with some smaller nuclear groups, are regarded as phylogenetically older and designated *paleothalamus*, distinguishing it from the lateral *neothalamus*, which reaches full development only in anthropoid apes and mankind; but such evolutionary changes have occurred in the paleothalamus that structural and functional intermingling of various regions of the primate thalamus have left such a division little validity.

Many thalamic regions are connected via the axonal fascicles with the brain stem, spinal cord, cerebellum, hypothalamus and corpus striatum and reciprocally with many cortical areas.

7.126 Coronal section of the brain through the ventral part of the pons.

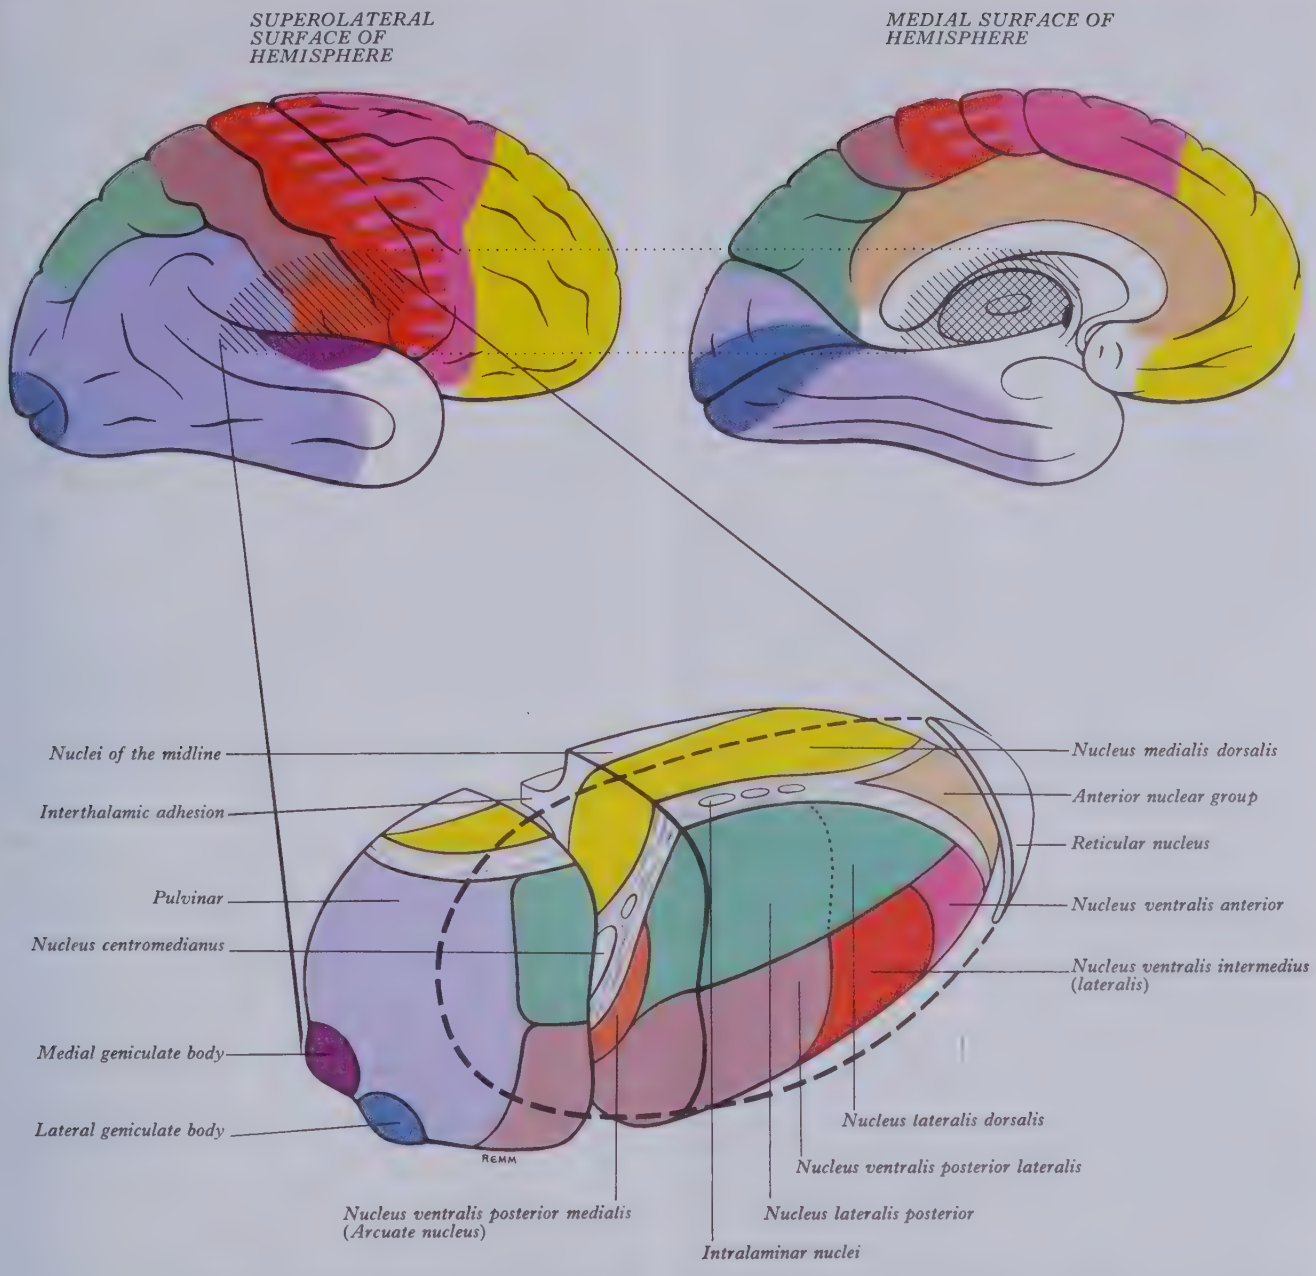


Classically the reciprocal radiations are described as four **thalamic peduncles**, but they form an almost continuous radiation from ventral, dorsal, posterior and ventrolateral thalamic aspects to most cortical regions, forming much of the internal capsule and corona radiata (7.127, 188, p. 1073). The *frontal thalamic peduncle* interconnects the anterior and medial thalamus with much of the frontal cortex; the *dorsal* (superior) *peduncle* interconnects ventral and lateral thalamic regions with pre- and postcentral gyri and adjacent parts of their lobes; the *posterior* (caudal) *peduncle* interconnects posterior regions of the lateral thalamus, including the pulvinar and lateral geniculate body, with the occipital and posterior parietal cortex. The smaller *ventral thalamic peduncle* interconnects the posterior thalamus and medial geniculate body with the temporal cortex.

Thalamic Nuclei and their Connections

The above thalamic nuclear groups have been much investigated in man and other mammalian and submammalian species, and their cytoarchitectonics, general arrangement, neuronal structure and patterns of connection have been established. The effects of selective stimulation and ablation have also been studied; more recently the detailed ultrastructure of synapses, unit recording and distribution of accepted and supposed neurotransmitters have been observed on an increasing scale. Those researches have revealed immense thalamic complexity, with many often interdependent but functionally distinct zones. Though the broad parcelling of thalamic nuclear groups is agreed, often including individual nuclei, no comprehensive structural and functional design has emerged. Difficulties result from the multiplicity of the nuclei, some being very small and closely sited, their afferents and efferents often traversing or skirting adjacent nuclear territories. Stereotactic lesions hence usually damage more than the selected targets. Retrograde degeneration is difficult to assess in small thalamic neurons and is equally difficult for microelectrode techniques; but copious data of thalamic structure have accumulated, briefly summarized here (7.128A,B, 129) (Le Gros Clark 1932, 1933a, b, 1936, 1937, 1949, Walker 1938, Toncray & Kreig 1946, Sheps 1945, Dekaban 1953, Kuhlenbeck 1954, Hassler 1959, Schaltenbrand & Bailey 1959, Ajmone-Marsan 1965, Purpura & Yahr 1966, Scheibel & Scheibel 1966, 1967, Van Buren & Borke 1972).

7.127 After median hemisection of the cerebrum, the left cerebral hemisphere has been dissected from its *medial* aspect to display the fibre bundles of the corona radiata and internal capsule. This entailed the removal of the cingulate gyrus and subjacent white matter, much of the paramedian corpus callosum and fornix, the dorsal thalamus and the head and body of the caudate nucleus. The oval depression previously occupied by the dorsal thalamus can clearly be seen within the curved depression left after removal of the caudate nucleus. Dissection by Andrew Seal, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.



7.128 Drawings of coronal sections through the diencephalon, stained with the method of Nissl to show the main nuclear aggregations of nerve cell somata: A. at the level of the mamillary bodies; B. at the level of the tuber cinereum. Note the variations in cell size, shape and packing density, which characterize the nuclear masses of the dorsal thalamus, subthalamus and hypothalamus at these levels.

A thalamic nucleus may connect with: (1) other thalamic nuclei, (2) adjacent subcortical nuclei, (3) ascending tracts from the brain stem and spinal cord, (4) the cerebral cortex. Intrinsic connections are the most difficult to analyse, and thus are the least clarified. The general thalamic termination of more prominent connections, e.g. long ascending tracts or those from adjacent centres, are well established; but details of their sites and modes of termination and of smaller connections are often uncertain. Many thalamic nuclei degenerate after the removal of certain cortical areas, hence the term *cortically dependent nuclei*. Some nuclei, while locally connected, receive chiefly discrete, often somatotopically ordered inputs with equally ordered cortical projections and are termed *relay nuclei*, in contrast with *association nuclei* which have multiple subcortical connections; but the former are not mere relays as complex transformation is usual in them. By focal thalamic stimulation and cortical recording, thalamic nuclei have been classed as *specific* or *non-specific*. In the former rapid, localized, ipsilateral responses are recorded; in the latter they are widespread, bilateral and with longer latency. Refined methods show that many nuclei, previously considered unconnected with the cerebral cortex, are in fact 'cortically dependent'; also the distinction between specific and non-specific nuclei is fading, as interactions between them become apparent.

SYNAPTIC ORGANIZATION OF THALAMIC 'RELAY' NUCLEI

The ultrastructural organization of main sensory 'relay' nuclei appears complex and analysis of their synaptic patterns is far from complete. A striking feature of all nuclei studied is the *synaptic glomerulus*, an ovoid or irregular unit from 2 μm to 20 μm or more across, which contains a dense mass of diverse axons and dendrites, interconnected by many, usually diverse synapses (Szentágothai 1970, p. 888). Included are the thalamic dendrites and various axonal endings, encapsulated and separated from the surrounding less organized neuropil by extensive astrocytic processes. Specific afferents mainly end in them, e.g. axons of the optic nerve and tract in the lateral geniculate nucleus and medial lemniscal fibres in the nucleus ventralis posterior lateralis. By its synaptic interactions each glomerulus may act as an integrating unit with a corticopetal output, in response to specific afferent impulses, interaction being modified by variable factors such as activity in corticothalamic and other afferent connections and by adjacent specific afferents and glomeruli. Morest (1971) demonstrated *presynaptic dendrites* in thalamic nuclei, containing clusters of synaptic vesicles and synapsing with adjacent dendrites. Some neurons have ordinary and presynaptic dendrites, others resemble amacrine cells of the retina and olfactory bulb, having a

7.129 The main nuclear masses of the dorsal thalamus (below) have been labelled and colour coded and the same colours have been used to indicate the areas of cerebral neocortex interconnected with these nuclei. The lack of colour in the centromedian, intralaminar and reticular nuclei and in restricted areas of the frontal and temporal lobes are *not* related to the colour code. The boundaries of the coloured cortical zones may well need revision in the future as experimental and pathological data accumulate.

single 'dual-purpose' neurite. Electron microscopy (Lieberman & Webster 1972) shows that presynaptic dendrites have end-bulbs full of distinctive disc-like synaptic vesicles, similar to axonal end-bulbs, forming most of the synapses in thalamic glomeruli. Their significance in processing thalamic activities is discussed by Shepherd (1974, 1978), Schmitt et al (1976) and Rakic (1975).

THE ANTERIOR GROUP OF THALAMIC NUCLEI

The anterior group contains three nuclei named: *anterodorsalis* (AD), *anteromedialis* (AM) and *anteroventralis* (AV); the first is the least prominent. They interconnect with medial and lateral thalamic groups and perhaps with the contralateral anterior group. They receive direct fibres from the postcommissural fornix, the substantial ipsilateral mamillothalamic tract (but including a few contralateral fibres), then also return a few thalamomamillary fibres to the mamillary nuclei. The main anterior radiations are the thalamocortical fibres reaching many parts of the gyrus cinguli (areas 23, 24 and 32), with reciprocal corticothalamic projections from the same areas; some observers add the retrosplenial gyrus (areas 29 and 30) in similar reciprocal connection.

Anterior thalamic nuclei thus link the hippocampus and hypothalamus with other thalamic nuclei and limbic cortical areas (p. 1028). Stimulation or ablation of the mamillothalamic tract affect autonomic control and are presumably concerned in homeostatic cycles involving visceral responses. Normal physiological function in the structural train (hippocampus-fornix-mamillary-body/thalamus/limbic cortex) is considered necessary to *recent memory*. In Korsakow's syndrome, typified by loss of memory for recent events, mamillothalamic lesions are common (Talland 1965, Barbizet 1963); but experiments in rats (Krieckhaus 1967, Krieckhaus & Randall 1968) showed no defect of recent memory after such lesions, but suggested that the 'system' assists in determining the balance between repetitive learned behaviour and new responses.

THE MEDIAL GROUP OF THALAMIC NUCLEI

This includes the large *nucleus medialis dorsalis* (MD) and smaller *nuclei parafascicularis, submedius, paracentralis* and *centralis lateralis*, the connections and significance of which are uncertain in man. (These smaller nuclei are often assigned to the intralaminar group, or to the nuclei of the midline, vide infra.) *Nucleus medialis dorsalis* has an anterior (rostral) *pars magnocellularis* and posterolateral *pars parvocellularis*, considered to make intrathalamic connections with almost all other groups; it has connections from the amygdaloid complex (p. 1034) and piriform cortex, establishing reciprocal connections with parts of the corpus striatum (p. 1076), precise regions in the corpus being uncertain. Its clearest connections are with hypothalamic nuclei and the frontal cerebral cortex (vide infra); reciprocal connections with the former may be part of the *periventricular system* of fibres, fine myelinated or non-myelinated axons in these instances, pursuing vertical or oblique courses subependymally in the third ventricles' lateral wall, intermingled with periventricular grey matter. Some periventricular fascicles may be polysynaptic. The 'system' is often described as principally rostrocaudal (anteroposterior), the fascicles connecting different parts of the medial thalamus with the preoptic, tubero-infundibular and mamillary hypothalamic regions (p. 1007). The most posterior fascicles continue via the *dorsal longitudinal fasciculus* in the periaqueductual grey matter to numerous brain-stem reticular nuclei; but some consider details of periventricular thalamohypothalamic connections less certain (Raisman 1966, Szentágothai et al 1968).

Abundant reciprocal connections exist between the nucleus medialis dorsalis and most of the prefrontal cortex anterior to areas 6 and 32 (p. 1040). These radiations show an orderly arrangement, regions of the nucleus and cortex being specifically linked. In essence, therefore, the nucleus medialis dorsalis is an integral part of the **limbic associated structures**, i.e. those listed under the limbic system, the frontal and cingulate neocortex, the hypothalamus and its basal and brain-stem continuations.

Its complex and copious connections show that the medial thalamus is of great functional significance; but simple functional labels cannot be attached. It probably integrates diverse sensory channels (olfactory, visceral and somatic) by the convergence of paths via the hypothalamus, amygdaloid complex, piriform cortex, corpus striatum and prefrontal cortex but also affecting these reciprocally by divergent paths which reach, additionally, many other regions. Stimulation of the dorsomedial thalamic nucleus in monkeys elicits movements even after ablation of the cortical motor areas; but their patterns disappear with loss of the corpus striatum. Stimulation, disease or removal of the human nucleus results in changes in motivational drive, the ability to solve problems, level of consciousness, general 'personality' and subjective feelings or 'affective tone' of the individual. The effects of ablation partly parallel the results of prefrontal lobotomy.

THE VENTRAL GROUP OF THALAMIC NUCLEI

This group is an anteroposterior series of nuclei *ventralis anterior* (VA), *ventralis intermedius* (*lateralis*) (VI or VL) and *ventralis posterior* (VP). The last named is subdivided into nuclei *ventralis posterior lateralis* (VPL) and *ventralis posterior medialis* (VPM), with smaller, less well-defined nuclei ventral and anterior in position. Connections of the three main nuclei include intrinsic ones with adjacent thalamic nuclei (centromedianus and the pulvinar, vide infra) and with the subthalamus and corpus striatum; but their major connections are the medial, spinal and trigeminal lemnisci, gustatory paths and two-way links with the cerebral cortex already described. The VPL receives the medial and spinal lemnisci, the VPM the trigeminal lemniscus and gustatory paths. (The station for trigeminal terminals is the *arcuate* or *semilunar nucleus*; gustatory fibres may end in an *accessory arcuate nucleus*.) Structural and functional localization and interactions during transmission in these nuclei have been much investigated.

Somatotopy is general in the ascending tracts themselves, their thalamic nuclei and the latter's cortical connections. Medial lemniscal and spinothalamic fibres from lower body segments (via the nucleus gracilis for the former) end laterally in the VPL, the fibres from successively higher segments ending progressively medially. The more medial VPM receives trigeminothalamic fibres from the face and head. Most medial are the solitariothalamic gustatory fibres from the solitary nucleus. Though such *lateromedial localization* exists, some consider that the terminals of the various tracts are not simply superimposed but end in a rostrocaudal order; the lateral spinothalamic tract may end in the caudal nuclear regions, followed by intermediate terminals of the medial lemniscal and anterior spinothalamic fibres, while trigeminothalamic fibres have a rostromedial termination.

Medial lemniscal and spinothalamic terminations exhibit further contrasts: the lemniscal fibres are crossed and originate solely from the contralateral gracile and cuneate nuclei; their terminals are confined to the VPL. *Most* spinothalamic fibres also decussate but *some* ascend to the ipsilateral thalamus; though many end in the VPL, others go elsewhere, including parts of the medial geniculate nucleus, suprageniculate nucleus and various 'non-specific' thalamic nuclei, the *posterior* (PO) *group* (Poggio & Mountcastle 1960, 1963), which may receive terminals of high threshold spinal neurons transmitting nociceptive impulses (p. 943). The PO nuclei may have reciprocal connections with the secondary sensory area SmII (p. 1056). The structure of terminals in the VPL, viewed by Golgi technique (Scheibel & Scheibel 1966), shows that spinothalamic and reticulothalamic terminals form diffuse networks, that medial lemniscal fibres end as conical bushy terminals in regular laminae, while corticothalamic terminals are confined to disc-shaped 'sheets' around the territories of many lemniscal fibres. Small local interneurons have been identified in VPL (Tombol 1967); synaptic detail of the nucleus has also been explored (Anderson et al 1964a, b, Lieberman & Webster 1972, Shepherd 1974, Rakic 1975). Unit recordings have been made from neurons in the VPL during activity in the medial lemniscal and spinothalamic tracts in monkeys and in man, before placing stereotactic lesions for types of locomotor disease. Simian units responding to lemniscal impulses show features described previously in gracile and cuneate neurons, the VPL neurons being highly specific for the type and source of stimulus. Units respond to contralateral stimulation by distortion of the skin or hairs, joint movement, static joint position and sinusoidal tissue vibration, but each *only to one* variety of stimulus. The receptive fields are small and localized, the smallest being associated with the terminal segments of the limbs. Units responding to spinothalamic activity generally show larger receptive fields; while some are 'modality specific', others show the interaction of impulses from different patterns of stimulus (p. 944). Transmission in the VPL is thus a complex of events. Many units show *lateral inhibition* or *'inhibitory surround'* (p. 865), greatly enhancing their discrimination. Transmission may be modified by corticothalamic axons and those converging from other thalamic and extrathalamic sources. Presynaptic and postsynaptic inhibitory and facilitatory effects have also been demonstrated in the VPL.

Recordings in the *human* VPL are inevitably restricted in scope, but substantially support simian somatotopy and modal specificity. Nuclear stimulation in conscious patients evokes localized sensations of tingling, numbness, etc. on the opposite side. The main thalamocortical radiations from the VPL and VPM traverse the internal capsule's posterior limb to the primary somatic sensory cortex (postcentral gyrus, areas 1–3) (p. 1051). Throughout these connections the precise somatotopy in their nuclei of origin is preserved. The same areas project back to the nuclei. Thalamic projections to secondary somatic sensory areas are uncertain; some may stem from the PO group (p. 1004).

Nucleus ventralis intermedius (VI, including the nucleus ventralis lateralis, VL, of many authors) has been less investigated. It connects with the adjacent thalamic nuclei but its main input is from the contralateral nucleus dentatus and from the ipsilateral red nucleus (p. 967, 7.120) and also some fascicles from the globose and emboliform nuclei and the globus pallidus. A nigrothalamic connection exists in monkeys (Carpenter et al 1976). These afferents are all in the *thalamic fasciculus* (p. 1007). The main projection from VI is somatotopic and traverses the internal capsule to the motor and premotor cortex (areas 4 and 6). Its posterior part has often been ablated in cases of severe Parkinsonism.

The *nucleus ventralis anterior* (VA) has become prominent, with VI, through destructive lesions placed in or near them for some locomotor disorders. It has many connections with other thalamic nuclei, particularly the *nucleus centromedianus* (vide infra), other *intralaminar nuclei*, *midline nuclei* and the *reticular thalamic nucleus*, i.e. all the so-called 'non-specific' thalamic nuclei. In addition VA has an input from the brain-stem reticular formation and wide connections from the globus pallidus via the *thalamic fasciculus* (p. 1007) and uppermost dentatothalamic fibres in the superior cerebellar peduncle. Carpenter et al (1976) have confirmed a nigrothalamic projection to the VA in monkeys; thalamocortical fibres radiate from it to the premotor cortex (area 6), less so to the motor cortex (area 4); axons to small regions of the insular cortex have been described. Corticothalamic fibres leave areas 6 and 4, converging on the VA. (For a detailed Golgi study see Scheibel & Scheibel 1966.)

The nucleus ventralis anterior (VA) is thus a focus via which the corpus striatum, ascending reticular formation and non-specific thalamic nuclei and a proportion of the cerebellum may powerfully modify the activities of motor and premotor cortices and probably other cortical regions. How far the impulses converging on the VA are integrated before transmission to the cortex is uncertain. Functional views of the VA are changing: some relation to the motor systems is evident; stimulation increases Parkinsonian rigidity and tremor; ablation (with, doubtless, surrounding tissue) may reduce or abolish tremor. Experimental stimulation of the caudate nucleus reduces activity in the VL and VA and their cortical connections, accompanied by a loss of behavioural responses. Stimulation of the VA also desynchronizes the electroencephalogram; this nucleus is regarded increasingly as a link in the '*ascending activating system*' (p. 996).

THE LATERAL GROUP OF THALAMIC NUCLEI

This group is usually divided anteroposteriorly into *nuclei lateralis dorsalis* (LD), *lateralis posterior* (LP) and most caudally the expanded *pulvinar*, occupying almost all the caudal thalamic quarter. The pulvinar is phylogenetically recent, prominent only in higher mammals and especially primates. Some subdivide it but this and its separation from the LP are imprecise; some prefer to describe an *LP–pulvinar complex*.

These three nuclei are presumed to have connections with other thalamic groups, the details being uncertain. Connections from the lateral geniculate nucleus, possibly the medial geniculate nucleus and amygdaloid complex, have been described, as well as a direct *retinothalamic projection* (p. 1016); these require further evidence. Most certain are the reciprocal connections with specific regions of the cortex, the LD with inferior parietal and posterior cingulate regions, the LP with much of the parietal cortex behind the postcentral gyrus and the pulvinar with wide areas of the parietal, occipital and temporal cortex, each pulvinar subnucleus projecting in orderly array to particular cortical areas, which probably reciprocate to the pulvinar; but connections with *primary* sensory areas are sparse or absent. The pulvinar has abundant connections with Wernicke's speech area; it has been implicated in such diverse activities as the perception of chronic pain, oculomotor control, speech control and as a '*multisensory data processor*' involved in general '*gnosis*' (Ingram 1976).

THE 'NON-SPECIFIC' GROUPS OF THALAMIC NUCLEI

Since Moruzzi & Magoun (1949) observed that stimulation or ablation of regions of the brain-stem reticular formation led to wide changes in electroencephalographic synchronization or desynchronization, possible paths from the reticular formation to the cerebral cortex have been a focus of research. Brain-stem reticular 'centres' were soon suggested to be connected to thalamic nuclei, with a *diffuse thalamocortical radiation* to almost all the cortex. Since stimulation of several thalamic nuclei caused extensive, *bilateral* change in cortical electrical activity, typified by a slow onset and progress to a maximum, followed by fluctuations (recruitment), the responses and nuclei were together dubbed *non-specific*. A wide assumption followed that such effects normally maintained cortical preparedness for the effective reception of rapid, localized, ipsilateral patterns from larger *specific relay nuclei*, which have somatotopic, thalamocortical and corticothalamic connections. From the large volume of reports some general concepts remain valid; but it is becoming clear that the *reticulocortical paths* involved are *multiple* and more complex than imagined, some involving the ventral diencephalon. Interaction between specific and non-specific thalamic regions is so extensive that, while some terms retain their general usefulness, they do *not* imply a distinction between the two aspects of thalamic function.

Non-specific nuclear groups usually include the intralaminar nuclei, midline nuclei and the thalamic reticular nucleus.

The Reticular Thalamic Nucleus

This thin curved sheet of neurons lies between the external medullary lamina and the posterior limb of the internal capsule. Hence, all corticothalamic and thalamocortical fibres in the capsule are near this nucleus, which was long regarded a final link in the diffuse thalamocortical radiation mentioned above; wide effects on cortical activity follow its stimulation, and nuclear degeneration follows resection of the cerebral cortex. But the Golgi technique (Scheibel & Scheibel 1966) has shown that its axons run *posteriorly*, with collaterals to many thalamic nuclei and also to the midbrain reticular formation. The whole cerebral cortex projects in an orderly manner to the reticular nucleus (Carman et al 1964); degeneration after cortical resection is now confirmed as transneuronal and not retrograde (Rose 1952). Other afferents are from the brain-stem reticular formation and the globus pallidus. Afferents thus converge from many sources; output is mainly to other thalamic nuclei, both specific and non-specific.

Intralaminar nuclei are the small *nuclei paracentralis*, *centralis lateralis and medialis*, *parafascicularis*, and larger *nucleus centromedianus* (vide infra).

Nuclei of the midline, complex and well-developed in many mammals, are small in man. Recognizable groups are sometimes seen near the taenia thalami, in the interthalamic adhesion when present, and also scattered in the third ventricular wall. They include *nuclei paraventricularis anterior and posterior*, the *nucleus rhomboidalis* and *nucleus reuniens*. They will not be separately described further here.

Non-specific nuclei are difficult to approach for any investigation. They are held to receive terminals from the brain-stem reticular formation, some connecting with the corpus striatum, cerebellum, spinothalamic tracts, hypothalamus and with other specific and non-specific thalamic nuclei on both sides. The most anterior project to the cerebral cortex, including the phylogenetically old prepiriform and entorhinal areas and parieto-occipital and frontal regions.

The nucleus contromedianus, embedded in the internal medullary lamina, is only prominent in primates and easily recognized in the human thalamus; but disagreement concerning its status and connections persists, though most agree that it is *not* connected with the cortex. Various ascending connections are reported, including a few collaterals or terminals from spinal medial and trigeminal lemnisci, ascending reticulothalamic fibres and some from the superior cerebellar peduncle. The main connections are with parts of the corpus striatum, some being topically organized; abundant connections occur with other non-specific nuclei on both sides and with some 'specific' nuclei, particularly the nucleus ventralis anterior.

The dorsal thalamic connections so far mentioned were established by older techniques, but subsequent data accumulated in a variety of mammals by newer tracing techniques (p. 870) (particulary methods locating somata and neurites of cholinergic and monoaminergic neurons, as detailed in pp. 992, 995) are merely noted here. The *dorsal tegmental ascending cholinergic bundle* provides terminals in the geniculate nuclei, dorsal and anterior nuclear groups of the dorsal thalamus and in midline and intralaminar nuclei, especially the nucleus centromedianus. The *ventral tegmental ascending cholinergic bundle* carries terminals into the ventral and anterior nuclear groups. The *dorsal ascending noradrenergic bundle* is afferent to many, perhaps all, dorsal thalamic nuclei. *Dopaminergic neuron group* A11 sends fine axons among the midline nuclei; groups A13

and 14 similarly reach the caudal thalamic nuclei. The *ventral ascending serotonergic bundle* contains axons reaching the medial nuclear group, midline nuclei and parafascicular nucleus. For brief comments on fibres containing metenkephalins, endorphins, substance P and the distribution of opiate receptor sites, see pp. 892, 995 and vide infra.

SUMMARY

The dorsal thalamus is obviously most complex and must be functionally important; but despite much research, concepts of its activities are rudimentary. A very large number of sensory channels *converge* on it and many *integrate* with each other; the results, of even greater range and complexity, *diverge* to many destinations. It is indeed involved in activities of *all* major regions of the central nervous system; the whole sensory system (except olfactory), most of the cerebral cortex, corpus striatum, cerebellum, hypothalamus, subthalamus and brain-stem reticular formation all *project to* the thalamic and metathalamic nuclei, and most *receive* reciprocal thalamic connections.

The thalamus is not essential to olfactory perception, which involves the primary and secondary olfactory areas (p. 1034); but olfactory information, combined with other modalities, reaches it via the amygdaloid complex, piriform lobe and hippocampus via the mamillary body.

Specific relay nuclei, including the geniculate, receive major sensory tracts and, usually after interaction with other channels, somatotopic thalamocortical radiations pass to sensory cortical areas. Complex transformations include the interaction between parallel and converging channels, pre- and postsynaptic facilitatory and inhibitory effects, phenomena of inhibitory 'surround' and 'neural sharpening' and modulation of transmission by corticothalamic and other axons in converging thalamic connections. Some thalamocortical fibres preserve a high specificity for single modalities and peripheral sites, others transmit more complex orders of information derived by integration. Cutting thalamocortical radiations to the somatosensory cortex lessens the ability to localize tactile stimuli, impairs tactile discrimination and appreciation of texture, weight and shape (*astereognosis*) or of position and movement; but awareness of contact and vaguely localized pain and thermal sensations survive if the thalamus itself remains intact. (Webster 1976 has reviewed somaesthetic pathways.) While some appreciation of pain survives loss of the cortex, its involvement in the intact nervous system has not been clarified (Albe-Fessard & Delacour 1968). Disease in the lateral or central thalamus sometimes causes sudden, 'spontaneous' attacks of ill-defined *thalamic pain*. In contrast, in addition to spinal, medullary or mesencephalic tractotomy for the relief of pain, selective ablation of the nucleus ventralis posterior and surrounding regions, or of intralaminar nuclei including the nucleus centromedianus, have sometimes relieved intractable pain. In summary it appears that involved in sensation of pain are the VPL and VPM, PO group (including parts of the medial geniculate, suprageniculate and intralaminar nuclei), the nucleus centromedianus, probably the nucleus medialis dorsalis and the pulvinar, with many hypothalamic nuclei, the globus pallidus, caudate nucleus and limbic structures, such as certain amygdaloid nuclei and the bed nucleus of the stria terminalis; but how they co-operate remains obscure. Many regions (including: spinal laminae I, II, and V, lateral reticular nuclei, the nucleus ambiguus and solitarius, areas of mesencephalic periaqueductual grey and of the pars compacta of substantia nigra) interchange axons which contain monoamines (particularly serotonin), metenkephalin, endorphin, substance P and other neuromediators; hence the proposal that these co-operate in processing pain perception (Nathan 1977, 1978, Wall 1978, Basbaum et al 1976, Webster 1976, 1978, Snyder in: Reichlin et al 1978). (See also notes and references to the *descending analgesia system* p. 943.)

Copious interconnection of *the nucleus dorsalis medialis* with the frontal cortex, hypothalamus and other specific and non-specific thalamic nuclei has already been noted; it is generally regarded as a main centre for the complex *integration of visceral and somatic functions*. By hypothalamic connections it is involved in autonomic and endocrine activities and also in emotional content, subjective feeling and consciousness of 'self'. Ablation or disease here cause changes in personality, emotional drive and level, intellectual performance, etc. and indifference to pain—like the sequelae of frontal corticectomy.

Anterior thalamic nuclei integrate a complex input along the mamillothalamic tracts from many visceral sources, the hypothalamus and limbic structures (including the hippocampus, amygdala and septal areas), with that from other thalamic nuclei and the cingulate cortex; the anterior group has reciprocal connections with all these. Such arrangements are concerned in complex homeostatic mechanisms, possibly in the efficiency of recent memory and in determining a balance between 'repetitive and stereotyped' or 'novel and exploratory' forms of behaviour.

Non-specific nuclear groups (including the nucleus ventralis anterior) have abundant connections with each other and with the specific thalamic nuclei of both sides, receiving from many sensory paths, the cerebellum and corpus striatum; via diffuse cortical projections they have profound effects, the *arousal reaction*, on the background activity in the cerebral cortex. This reaction involves particularly the parietal, orbital, cingulate and occipital association areas, the most marked experimental responses being in prefrontal areas.

The nuclei ventralis anterior and lateralis are sites of interaction of outflows from the corpus striatum and cerebellum with other thalamic nuclei, projecting to motor and premotor cortices and essential to full locomotor control. The activities of most major regions of the cerebral cortex are under thalamic influence, the cortex equally affecting most thalamic nuclei.

The Epithalamus: Pineal Gland and Habenula

Epithalamic structures occupy the posterior diencephalic roof and adjacent areas of the third ventricular walls. They include right and left *habenular nuclei*, each deep to its *habenular trigone* and receiving a complex *stria medullaris thalami*; also included is the median *pineal gland* (epiphysis cerebri) and *habenular* and *posterior commissures* crossing in anterior and posterior laminae of the pineal peduncle. Pineal development is briefly mentioned on p. 190, its structure, neuro-endrocrine roles and innervation on p. 1457 with accompanying illustrations.

The *trigonum habenulae* is a small, bilateral triangular depression, anterior to the superior colliculus, medial to the pulvinar but separated by a *sulcus habenulae*; anteromedial is the posterior end of a ridge occupied by the stria medullaris thalami and by the pineal peduncle.

The habenular nucleus, sometimes described in medial and lateral parts, is, in part, a station on olfactory reflex routes, but probably also concerned with pineal innervation; connections have been described but details are uncertain (see comments on pineal innervation, p. 1457). Many *afferents* to the nucleus run in the **stria medullaris thalami**, formed near the anterior thalamic pole and including connections from the amygdaloid complex via the stria terminalis (p. 1034) and from the hippocampal formation via the fornix (p. 1039); other components are from the olfactory tubercle, anterior perforated substance, preoptic and septal areas and several hypothalamic nuclei. Tectohabenular fibres from the superior colliculi have also been described.

The stria medullaris crosses the superomedial thalamic aspect, skirts medial to the habenular trigone and sends many fibres into the ipsilateral habenular nucleus. The stria has fibres containing seven neuromediators: acetylcholine, noradrenalin, serotonin, GABA, LHRH, somatostatin, vasopressin and oxytocin. Other strial fibres cross in the anterior pineal lamina, decussating as the *habenular commissure* to reach the contralateral habenular nucleus. Some fibres are really commissural and interconnect the amygdaloid complexes and hippocampal cortices; crossed tectohabenular fibres accompany them in the commissure. Additional afferents to the habenular nuclei are fibres containing serotonin (5-hydroxytryptamine) from the *ventral ascending tegmental serotonergic bundle*, which join the habenulopeduncular tract (vide infra) to reach the nuclei; they may exert some control over neurons of the *habenulopineal tract*, thus influencing

innervation of the pinealocytes (p. 1457), as may also the habenular nuclear afferents from the *dorsal ascending tegmental noradrenergic bundle* (pp. 986, 993). Though human habenulae are relatively small, they are a focus of integration of diverse olfactory, visceral and somatic afferent paths.

The main habenular outflow reaches the interpeduncular nucleus, thalamic nucleus medialis dorsalis, mesencephalic tectum and reticular formation, the largest being the *habenulopeduncular tract* or *fasciculus retroflexus* (7.131). This courses ventrally and up, skirts the inferior zone of the thalamic nucleus medialis dorsalis and traverses the superomedial region of the red nucleus to the interpeduncular nucleus; this provides relays to the midbrain reticular formation, from which tectotegmentospinal tracts and dorsal longitudinal fasciculi connect with autonomic preganglionic neurons controlling salivation, gastric and intestinal secretory activity and motility; others pass to motor nuclei for mastication and deglutition. Ablation of habenular complexes causes extensive changes in metabolism, endocrine and thermal regulation (Szentágothai et al 1962).

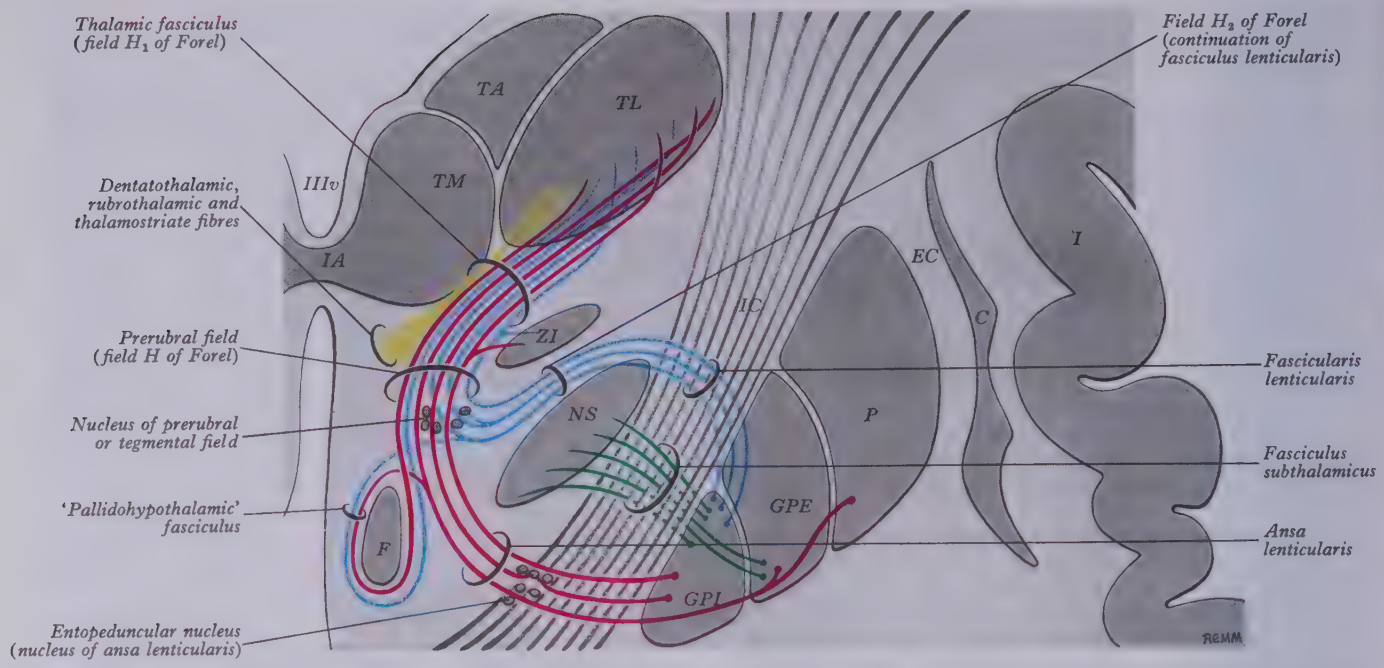
The posterior (dorsal) commissure is a complex fasciculus decussating in the posterior pineal lamina, relatively reduced in primates and of unknown constitution in man. It myelinates early; estimates of fibres in several species have been made (Tomasch & Malpass 1958). Various nuclei are associated with it: small groups scattered along it as the *interstitial nuclei of the posterior commissure*, accumulations in the periventricular grey matter forming *dorsal nuclei of the posterior commissure*, *nucleus of Darkschewitsch* in the periaqueductual grey, and the *interstitial nucleus* (of Cajal) near the upper end of the oculomotor complex, closely linked with the medial longitudinal fasciculus (p. 985). Fibres from all these nuclei and the fasciculus cross in the posterior commissure. Other contributors to it include dorsal thalamic nuclei, pretectal nuclei, superior colliculi and connections between the tectal and habenular nuclei. The destinations and functions of many of these fibres are obscure.

Ventral to and below the posterior commissure (i.e. near the inferior wall of the pineal recess), ependymal cells on the dorsal aspect of the cerebral aqueduct are tall, columnar and ciliated, with granular basophilic cytoplasm and specific histochemical reactions. This patch, possibly secreting into the cerebrospinal fluid, is the *subcommissural organ* (Keene & Hewer 1935, Wislocki & Leduc 1953, Mollgard et al 1973). Its cells may be involved in the transport of materials to the cerebrospinal fluid from adjoining axonal terminals or capillaries; or substances may be transported from fluid to neurons, blood vessels or pinealocytes (p. 1457, and cf the infundibular recess of the third ventricle, pp. 1019, 1451). Possible neuro-endocrine roles of these specialized ependymal *tanycytes* have been reviewed by Knowles (1974), Reichlin et al (1978), Joseph & Knigge (1978), Collins & Woollam (1981). Other patches of similar ependyma project into the third ventricle from its secondary roof (body of fornix) and from its anterior wall between the diverging fornical columns: the *subfornical organ* and the organum vasculosum or *intercolumnar tubercle* respectively. These and, in some vertebrates, other specialized regions of the third ventricular ependyma are collectively termed **circumventricular organs**. For a review of the disposition, ultrastructure and possible functional roles of circumventricular organs see Collins & Woollam (1981); they indicate that circumventricular organs (CVOs) are a mosaic of *three* main cell varieties: 'basic' ciliated ependymal cells, secretory cells and tanycytes, the latter, however, varying in their ultrastructure as each is location specific. In summary, a generalized mammalian brain displays, in median section, the following specialized ependymal CVOs: the median eminence (ME), and variable infundibular recess (IR); the collicular recess organ (CRO); the aqueductal recess organ (ARO); the subcommissural organ (SCO); the habenular ependyma (HE); the habenular commissural organ (HCO); the subfornical organ (SFO); the organum vasculosum of the lamina terminalis (OVLT) or intercolumnar tubercle (IT). Recall, also, the area postrema and funiculus separans in the fourth ventricle (p. 979).

The Ventral Thalamus or Subthalamus

The pars ventralis diencephali, ventral and posterior to the hypothalamic sulcus, may be divided into the *hypothalamus* and the *ventral thalamus* (*subthalamus*). The hypothalamus, including structures forming the third ventricular floor as far back as, and including, the mamillary bodies and also structures in its anteroventral side wall, will be described later. The rest of the pars ventralis diencephali is the *subthalamus*, merging below with the midbrain tegmentum; upper extensions of substantia nigra and the red nucleus project into its lower end and large tracts pass between the two regions (7.130, 131). Dorsal are the ventral nuclei of the *dorsal thalamus* and anteromedially the subdivisions of the *hypothalamus* (7.128A,B). Ventrolaterally the subthalamus adjoins an expanding, twisting junctional zone where each cerebral peduncle merges into its internal capsule; the capsules separate the subthalamus from the medial aspect of each globus pallidus.

The main neuronal groups are: (1) the upper pole of the red nucleus, (2) the upper end of the substantia nigra, (3) the nucleus subthalamicus, (4) the zona incerta, (5) the nucleus of the prerubral or tegmental field, (6) the entopeduncular nucleus (nucleus of ansa lenticularis); all, of course, are bilateral.



The main subthalamic tracts are: (1) the upper parts of the medial, spinal and trigeminal lemnisci and the solitariothalamic tract, approaching their terminations in the thalamic nuclei; (2) the dentatothalamic tract from the contralateral superior cerebellar peduncle accompanied by ipsilateral rubrothalamic fibres; (3) the fasciculus retroflexus; (4) the fasciculus lenticularis; (5) the fasciculus subthalamicus; (6) the ansa lenticularis; (7) fascicles from the prerubral field (H field of Forel); (8) the continuation of the fasciculus lenticularis (in the H_2 field of Forel); (9) the fasciculus thalamicus (the H_1 field of Forel); all, of course, are bilateral.

Subthalamic topography is complex and best appreciated in solid models or in coronal and sagittal serial sections. A parallel study of the corpus striatum (p. 1075), from which prominent subthalamic tracts are derived, is also helpful. Figure 7.130 may clarify the region's complicated terminology but three-dimensional topography is difficult to appreciate from flat (two-dimensional) diagrams.

As the upper ends of the red nucleus and substantia nigra pass into the subthalamus they diminish in area, ending a little below the mamillary bodies. The changing relation of the lemnisci to the red nucleus and substantia nigra as they ascend in the midbrain has been described (p. 983). Lemniscal fibres enter the subthalamus largely *lateral* to the red nucleus; as they ascend they approach the *dorsal* aspect of the nucleus to reach the *ventral* surface of the thalamic nucleus ventralis posterior, in which most fibres end. Dentatothalamic and rubrothalamic run with pallidothalamic fibres in the *thalamic fasciculus*, which ascends beyond the lemnisci to distribute largely to the thalamic nuclei ventralis intermedius and anterior (pp. 1002, 1003, and vide infra).

The nucleus subthalamicus, absent in submammalian forms, is small in most mammals and is prominent only in primates. The human nucleus, containing medium to large multipolar neurons, is biconvex in coronal sections. It is inferior in the subthalamus, extending below into the midbrain, where it is dorsolateral to the upper end of the substantia nigra and lateral to the red nucleus. It is near the medial aspect of the internal capsule, which separates it from the globus pallidus. Medially, the nucleus adjoins the hypothalamic region and is dorsally separated from the ventral thalamic nuclei by the thin *zona incerta*, interposed between continuations of lenticular and thalamic fasciculi (7.130, and vide infra).

Connections are numerous, some established and many less certain, the principal being with the corpus striatum; reciprocal connections by several routes link the globus pallidus and subthalamic nucleus. Connections with the putamen and caudate nucleus have been described but are less documented. Other reported connections include the contralateral subthalamic nucleus and globus pallidus, ipsilateral red nucleus, substantia nigra, mesencephalic reticular formation, zona incerta and other

7.130 The nuclear masses of grey matter and fibre tract systems associated with, or closely related topographically to, parts of the dorsal thalamus, subthalamus and globus pallidus. The information presented is compounded from a series of closely spaced coronal sections through this region, attempts being made to include what are essentially three-dimensional structures in a two-dimensional diagram; it must be emphasized that all the structures shown would not appear on the same single coronal section. The significance of the letters is as follows: IIIv = third ventricle; M = medial nuclear group of thalamus; TA = anterior nuclear group of thalamus; TL = lateral nuclear group of thalamus; IA = interthalamic adhesion; ZI = zona incerta; F = column of fornix; NS = nucleus subthalamicus; IC = internal capsule; GPI and GPE = internal and external parts of globus pallidus; P = putamen; EC = external capsule; C = claustrum; I = cortex of insula.

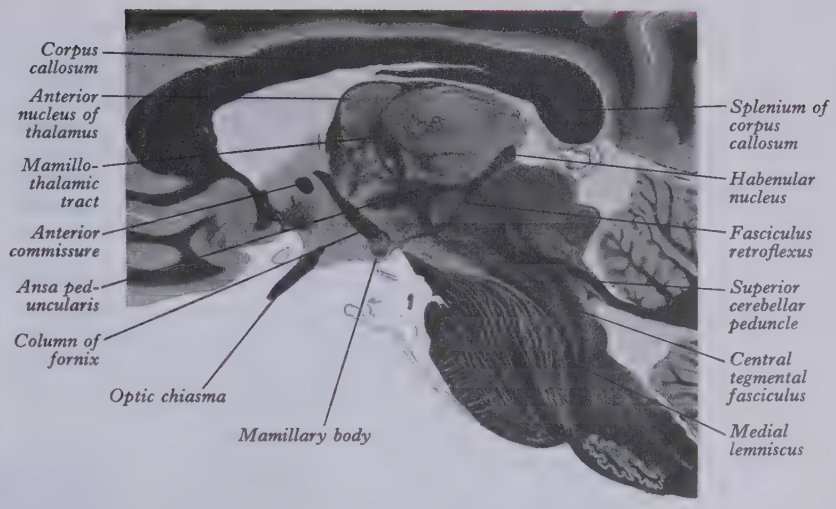
small subthalamic nuclei, various hypothalamic and thalamic nuclei and possibly regions of the cerebral cortex. Some afferent fibres are derived from the *ventral ascending tegmental cholinergic pathway* and probably the *incerto-hypothalamic dopaminergic system*; their functional roles remain obscure.

The subthalamic nucleus is clearly a site of integration of motor control centres, particularly by its connections with the corpus striatum and mesencephalic tegmentum. Discrete lesions of one human subthalamic nucleus result in *hemiballismus*, with contralateral, uncontrollable, violent, torsional movements, choreiform in type, often continuing for long periods and usually affecting the proximal musculature of one or both contralateral limbs; facial and trunk muscles are less often involved. Unlike other *dyskinesias*, hemiballismus can be reproduced experimentally; in monkeys it follows the ablation of a quarter or more of the nucleus, provided adjacent fibres of the globus pallidus are intact; it is unaffected by ablation of the rubrospinal, vestibulospinal and reticulospinal tracts or cortical area 6, but *is* abolished by ablation of the globus pallidus or its outflow, or of the thalamic nucleus ventralis anterior, area 4 of the cerebral cortex or the corticospinal tract. This suggests that the nucleus inhibits the globus pallidus and its main outflow via the thalamus to the motor cortex, i.e. the principal origin of the crossed corticospinal tract (Whittier & Mettler 1949, Carpenter 1950, Carpenter et al 1950, 1951, 1958, 1960).

The zona incerta is a thin grey lamina among the fascicles of fine fibres extending through most of the diencephalon a little ventral to the thalamus, separated from it by the thalamic fasciculus (vide infra). On each side it continues laterally into the thalamic reticular nucleus; ventral is the fasciculus lenticularis (vide infra). Functionally associated are neurons grouped along its inferomedial border, collectively the *nucleus of the prerubral* or *tegmental field*, and other groups between fascicles of the ansa lenticularis (vide infra), sometimes regarded as 'detached' parts of the globus pallidus but collectively termed the *entopeduncular nucleus*. These nuclei are mainly relays on discharge pathways from the globus pallidus to the mesencephalic reticular formation; some of their fibres descend in the central tegmental fasciculus to the inferior olivary complex (p. 956), numerous branches leaving to innervate the 'reticular' and 'non-reticular' brain-stem nuclei. Cortical projections to the zona incerta may exist; various subthalamic groups probably also interconnect with the main nucleus, intralaminar and ventral thalamic nuclei and red nucleus. The zona incerta also has afferents from the *ventral tegmental ascending cholinergic pathway* and is involved in the *incertohypothalamic dopaminergic system* (pp. 992, 994).

In addition to terminal parts of the lemniscal, dentatothalamic and rubrothalamic tracts (p. 1002), the subthalamus is typified by white fascicles, often containing small groups of neurons and of complex topography. Conflicting terminologies have been proposed. The approach adopted here is to consider the fascicles in relation to the main striatal outflows (p. 1078). These are derived partly from the putamen but mostly from the globus pallidus and appear at the latter's surface, fanning out medially; the radiation's dorsal and intermediate fibres intersect those of the internal capsule, while the ventral ones curve round the capsule's posteroventral border. Earlier investigators (von Monakow 1882) termed the whole radiation the *ansa lenticularis*, with dorsal, intermediate and ventral divisions, a term now restricted to the ventral radiation, the intermediate radiation being the fasciculus subthalamicus, the dorsal radiation the fasciculus lenticularis (7.130).

The fasciculus lenticularis is the dorsal division of pallidofugal fibres traversing the internal capsule; it turns medially near the capsule's medial aspect, partly intermingled with the dorsal zone of the subthalamic nucleus and ventral part of the zona incerta, where the fasciculus traverses the *H_2 field of Forel*. Reaching the medial border of the zona incerta, the fasciculus intermingles with fibres of the ansa lenticularis, scattered elements of the prerubral nucleus and with dentatothalamic and rubrothalamic fibres. This merging of diverse pathways and associated cell groups is variously called the *prerubral*, *tegmental* or *H field of Forel*.



The ansa lenticularis has a complex origin from both parts of the globus pallidus, from the putamen and possibly other adjacent structures; its fibres partly relay in neurons along its course, the *entopeduncular nucleus*. It curves medially round the internal capsule's ventral border, continuing dorsomedially to mingle with other fibres noted above in the prerubral field. Some fibres in both fasciculus lenticularis and ansa lenticularis synapse in the nucleus subthalamicus, prerubral field and zona incerta; the remainder

continue laterally with other fascicles into the thalamic nuclei, particularly the nuclei ventralis anterior intermedius and centromedianus.

The thalamic fasciculus is a complex extending from the prerubral field, dorsal to and also partly traversing the zona incerta and related dorsally to the ventral thalamic nuclei. It contains continuations of the fasciculus lenticularis and ansa lenticularis, dentatothalamic and rubrothalamic fibres and thalamostriate fibres. Its territory is sometimes termed the H_1 *field of Forel.*

The 'pallidohypothalamic' fasciculus leaves the main pallidofugal system in the prerubral field and pursues a curious course, curving ventromedially round the column of the fornix towards the hypothalamus (Bard & Rioch 1937, Vidal 1940, Ingram 1940), where it was long assumed to end in the dorsomedial nucleus. But evidence is inconclusive and experiments in monkeys (Nauta & Mehler 1966) show that it recurves laterally below the column, turning dorsally to rejoin the H_1 field of Forel.

The fasciculus subthalamicus is an abundant two-way array of fibres traversing the internal capsule, interweaving with it at right angles, to connect the nucleus subthalamicus with the globus pallidus and, to a lesser extent, the putamen.

7.131 Sagittal section of the right cerebral hemisphere through the mamillary body, viewed from the left. Myelin stain. The fasciculus retroflexus is seen crossing the medial side of the red nucleus, which is surrounded by a capsule of white fibres derived chiefly from the superior peduncle. After Foix & Nicolesco 1925.

The Hypothalamus

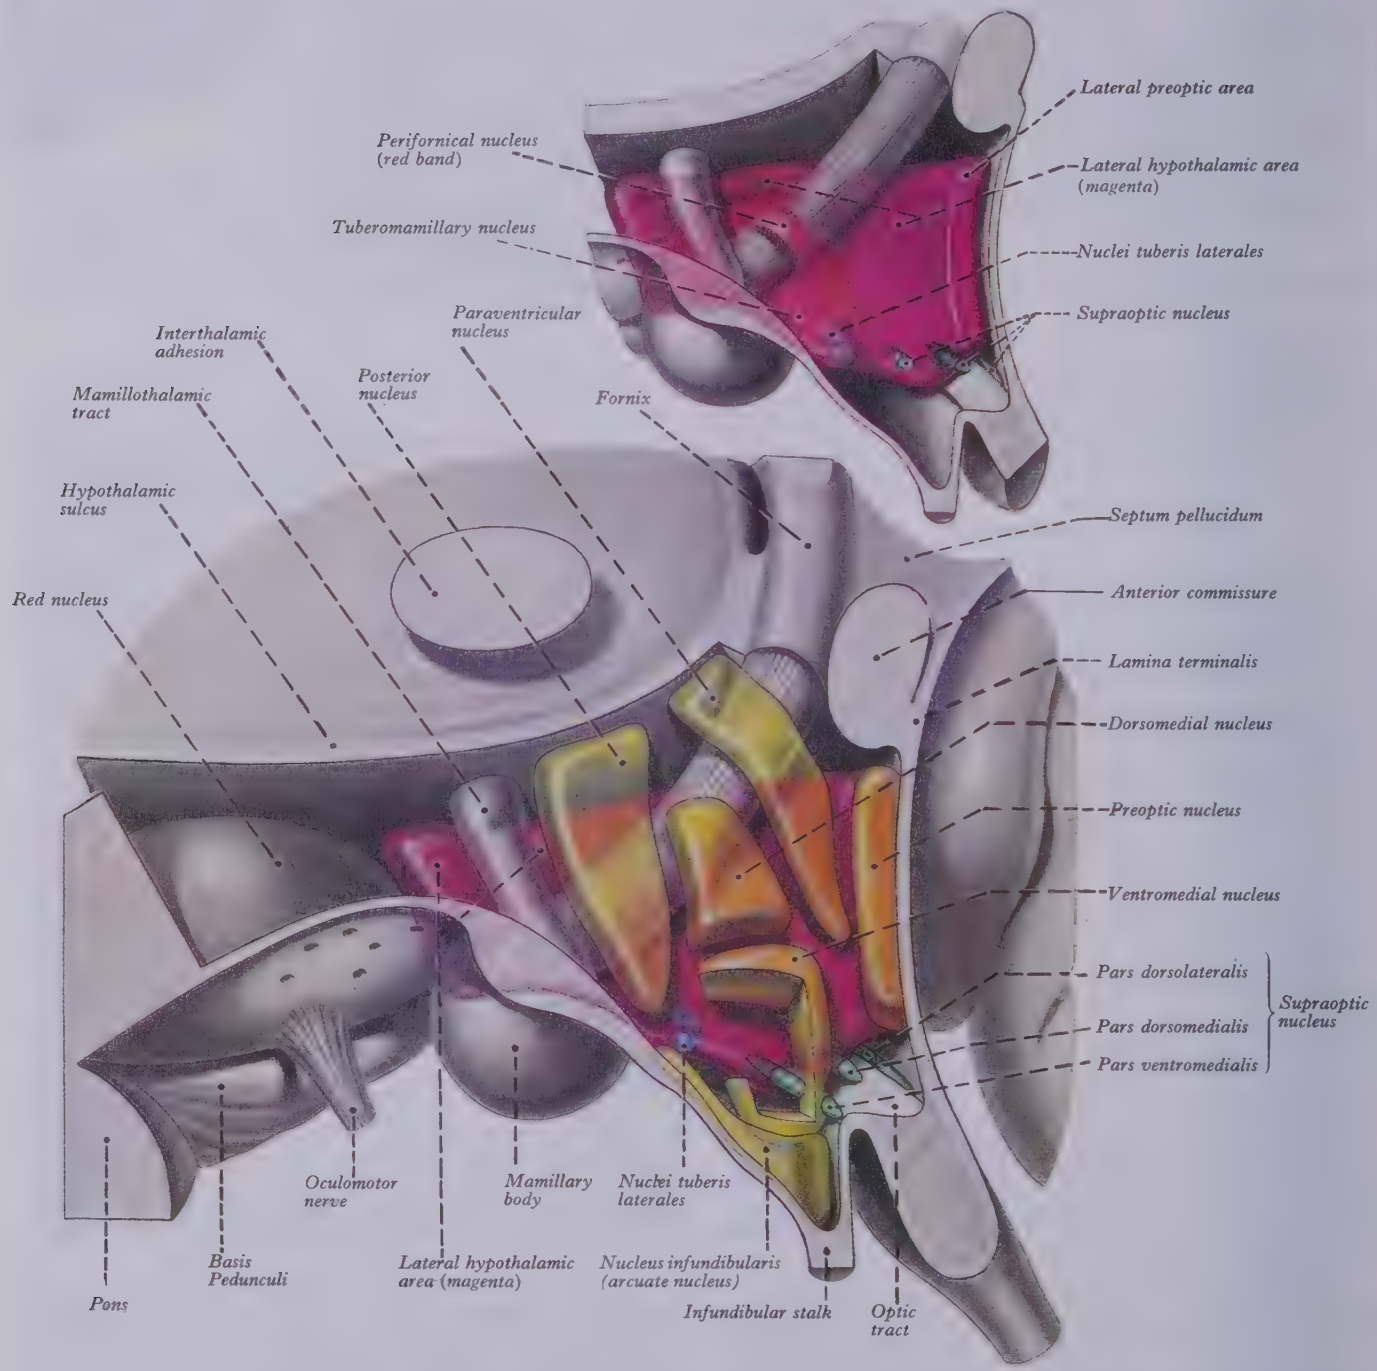
The general position and extent of the hypothalamus have been noted (p. 997). It extends from the lamina terminalis to a vertical plane posterior to the mamillary bodies and from the hypothalamic sulcus to the pial surface of the third ventricle's floor. Strictly, this region's anterior part, the preoptic area, belongs to the telencephalon impar but is here included for functional reasons. *Lateral* are the anterior part of the subthalamus, internal capsule and optic tract; *posteriorly* the tegmental part of the subthalamus continues into the mesencephalic tegmentum; *dorsal* are nuclei of the dorsal thalamus; anteriorly the optic chiasma, lamina terminalis and anterior commissure separate the preoptic area from the precommissural septum, i.e. the continuation of the diagonal band into the paraterminal gyrus (p. 1033), anterior to which is the parolfactory gyrus. These 'boundaries' are arbitrary and functionally continuous 'systems' cross many of them.

Structures in the third ventricle's floor reach the pial surface in the **interpeduncular fossa** (7.132); from front to back they are: (1) the optic chiasma, (2) the tuber cinereum, tuberal eminences and the infundibular stalk, (3) the mamillary bodies, (4) the posterior perforated substance, included here for convenience.

The posterior perforated substance, a small grey depression, lies posteriorly in the interval between the diverging crura cerebri, pierced by small apertures for central branches of posterior cerebral arteries. Deep within it is the *interpeduncular nucleus,* small in man and homologous with a more extensive complex in submammalian forms. It receives looped terminals of the fasciculus retroflexus (p. 1005) of both sides and has other connections with the mesencephalic reticular formation and mamillary bodies.

The mamillary bodies are smooth, hemispherical and about the size of two small peas, side by side in the interpeduncular fossa's floor, anterior to the posterior perforated substance, each enclosed in white fascicles largely from the fornix. Internally are a number of nuclei (vide infra).

The tuber cinereum, between the mamillary bodies and the optic chiasma, is a convex mass of grey matter; its ventral aspect is not completely smooth but presents a series of eminences with intervening grooves of varying depth. Behind the optic chiasma a median, conical, hollow **infundibulum** depends ventrally to the solid posterior lobe of the hypophysis cerebri (p. 1451). Around the infundibular base is a **median eminence,** superficially marked by a shallow *tubero-infundibular sulcus* along their junction. The tuber cinereum also has a pair of **lateral eminences** and a median **postinfundibular eminence;** posterolaterally, on each side, is a row of two or three minute projections between the tuber cinereum and mamillary bodies.



7.132 The interpeduncular fossa and surrounding structures. Note from above downwards: (1) the gyri recti of the frontal lobes and the olfactory tracts, trigones and anterior perforated substances; (2) the optic nerves, chiasma and diverging optic tracts which disappear beneath the medial borders of the unci hippocampi; (3) the tuber cinereum with the attached superior part of the infundibular stem; (4) the mamillary bodies; (5) the deep recess between the mamillary bodies, the diverging crura cerebri and the cranial border of the pons, the floor of which is the posterior perforated substance; (6) on each side the prominent oculomotor nerves, more laterally the slender trochlear nerves and, bordering the pons, the thick trigeminal nerves are visible. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

HYPOTHALMIC DIVISIONS AND NUCLEI

Most of the hypothalamus contains neuronal groups classified by phylogenetic, developmental, cytoarchitectonic, synaptic and histochemical data into nuclei with specific names, some more clearly defined than others. Several tracts are also visible, the remaining regions being filled by complex connections: afferent, efferent, intrinsic or in transit, some established, others uncertain. This small but complex region is difficult to study, and different classificatory criteria have been applied, with varied terminology. Only major nuclei and connections need be noted. For details consult Le Gros Clark et al (1938), Crosby & Woodburne (1940), Harris (1955), Haymaker et al (1959), Szentágothai et al (1962) and Reichlin et al (1978).

The hypothalamus may be viewed as a median anteroposterior sequence of *supraoptic, infundibulotuberal* and *mamillary* zones, or as having *lateral* and *medial zones* on each side separated by a paramedian plane, which includes the column of the fornix, the mamillothalamic tract and fasciculus retroflexus. Some prefer to subdivide the medial region into a subependymal *periventricular zone* and a thicker *intermediate* (medial) *zone*. The main nuclear groups are illustrated in 7.133; a more complete list is given

7.133 Schemata of the hypothalamic region of the left cerebral hemisphere from the medial aspect to display the major hypothalamic nuclei. In the upper diagram the medially placed nuclear groups have been removed, whilst in the lower diagram both lateral and medial groups are included. Lateral to the fornix and the mamillothalamic tract is the lateral hypothalamic region (magenta), in which the tuberomamillary nucleus is situated. Situated rostrally in this area is the lateral preoptic nucleus. Surrounding the fornix is the perifornical nucleus (red band), which joins the lateral hypothalamic area with the posterior hypothalamic nucleus. The medially situated nuclei (yellow) fill in much of the region between the mamillothalamic tract and the lamina terminalis, but also project caudal to the tract. The nuclei tuberis laterales (blue) are situated ventrally, largely in the lateral hypothalamic area. The supraoptic nucleus (green) consists of three parts. See text for further description. From Nauta & Haymaker 1969, by courtesy of the authors and the publishers.

below. Many are small, poorly localized but sometimes subdivided further. Each zone may be considered an anteroposterior nuclear sequence, with some dorsoventral overlap; preoptic grey matter is common to all zones.

The periventricular zone consists of: (1) part of the *preoptic* nucleus, (2) a small *suprachiasmatic* nucleus (vide infra), (3) a large *paraventricular* nucleus, (4) the *infundibular* nucleus, (5) the *posterior* nucleus. In general, they are dispersed between the periventricular fibres (pp. 1001, 1010) with which some are connected. Most prominent and functionally best understood is the paraventricular nucleus (vide infra).

The intermediate zone (medial zone) consists of: (1) part of the *preoptic* nucleus, (2) the *anterior* nucleus, (3) the *dorsomedial* nucleus, (4) the *ventromedial* nucleus, (5) small *premamillary* nuclei.

The lateral zone consists of: (1) part of the *preoptic* nucleus, (2) the *supraoptic* nucleus, (3) the *lateral* nucleus, (4) the *tuberomamillary* nucleus, (5) *lateral tuberal* nuclei.

The mamillary body, with its main *medial* and *lateral mamillary* nuclei and adjacent smaller groups, is between the intermediate and lateral zones, but overlaps both.

These nuclei will not be individually described here; for details see the references quoted. However, some outstanding features must be noted. The preoptic, anterior, dorsomedial and ventromedial nuclei, and part of the posterior, are mainly of small or medium neurons and are ill-defined in man. Larger neurons scattered amongst smaller ones typify the rest of the posterior and much of the lateral nucleus. Lateral tuberal nuclei, though small, are well-defined, encapsulated by fine fibres; each lies in one of the posterolateral projections between the tuber cinereum and mamillary body. The large size of the medial mamillary nucleus is a human characteristic. The supraoptic nucleus, dorsal to the lateral part of the optic chiasma, and the large subependymal paraventricular nucleus are well vascularized and have common distinctive cytological features; they are partly composed of large, bipolar or multipolar neurons, sometimes multinucleate and Nissl-staining more densely than neurons in adjacent nuclei. Their cytoplasm contains granules of neurosecretory material (p. 1010).

Modern tracing techniques, initially employing formaldehyde histofluorescence (p. 992) and now replaced by the extensive use of immunofluorescence (p. 993), have vastly stimulated neuroendocrinology. An immense literature can only be briefly noted. Useful references are included with: neuro- and adenohypophysis (pp. 1451–1454), the latter's circulatory system (p. 1451), the 'diffuse neuro-endocrine system' and the APUD concept (p. 1376), the habenulopineal system and neuro-endocrine transduction (p. 1005). See also Reichlin et al (1978) and Hokfelt and coworkers (1978).

The neuronal somata, axons and the fibre terminals in the preoptico-hypothalamic region contain in toto (and in many subregions) 25 separate neuromediators, each (within technical limits) having been localized ('mapped') and each with a large and increasing literature. These include: angiotensin II, dynorphin, enkephalin, endorphin and MSH, αMSH, ACTH, vasopressin and oxytocin, TRH, somatostatin, LHRH, CRF, neurotensin, CCK, VIP, substance P, glycine, glutamate and aspartate, GABA, histamine, serotonin, adrenalin, noradrenalin, dopamine and acetyl choline. Clearly, it is not possible to describe their locations individually in this volume. (For review see Nieuwenhuys 1986.)

CONNECTIONS OF THE HYPOTHALAMUS

As noted, some hypothalamic connections are discrete fascicles, others diffuse; they are difficult to study and hence uncertain in origin and termination. Broadly, *afferent* hypothalamic axons include the ascending visceral and somatic sensory connections, olfactory paths and numerous tracts from the midbrain, diencephalon, 'limbic' structures and neocortex. *Efferent* paths are reciprocal to many such sources; in particular efferents reach the origins of *peripheral autonomic nerve fibres*. The hypothalamus also controls the secretory cycles of *hypophysis* and *epiphysis cerebri* and, through these, the *endocrine system*. More precisely, different hypothalamic parts connect with: (1) the tegmentum and periaqueductal grey of the midbrain, (2) the subthalamic nuclei and indirectly the globus pallidus, (3) some thalamic nuclei, (4) the hippocampal formation, (5) the anterior olfactory areas, (6) the amygdaloid nuclear complex, (7) the septal areas, (8) the prefrontal cerebral cortex, (9) the hypophysis cerebri, (10) direct retinal fascicles (vide infra), (11) possibly accessions from the superior cerebellar peduncle and globus pallidus, (12) numerous afferents from pontine and medullary reticular nuclei (pp. 988–996). Some will be briefly outlined.

Afferent Connections

Ascending paths include collaterals of lemniscal somatic afferents but are largely polysynaptic routes for visceral and gustatory impulses from the spinal cord and brain stem, including the **mamillary peduncle**, a convergence of fibres in the mid-brain tegmentum into a discrete fasciculus ending in the mamillary body; afferents also ascend in the **dorsal longitudinal fasciculus** (p. 986 and vide infra) and from the **brain-stem reticular formation**, already described (pp. 991, 996 and below). *Direct* projections reach the hypothalamus from ipsilateral and contralateral subthalamic nuclei and zonae incertae, the latter via supraoptic decussations. Connections pass from the thalamic nucleus medialis dorsalis to many hypothalamic nuclei by **periventricular fibres** previously described (p. 1009), probably also via the medial part of the **inferior thalamic peduncle**.

Certain forebrain structures, many of which were once regarded as mainly olfactory but now recognized as much wider in function, are often grouped as the **limbic system** (p. 1028). These include the hippocampal formation, amygdaloid and septal complexes, piriform lobe and the adjacent regions of the neocortex. Limbic structures have prominent paths to the hypothalamus: the *fornix*, *stria terminalis*, *medial forebrain bundle* and *ventral amygdalofugal tracts*.

The fornix is complex in structure (p. 1039); it contains diverse commissural and other connections. It is the main outflow from the hippocampal neuronal laminae; as these fibres curve ventrally towards the anterior commissure they are joined by fascicles from the cingulate gyrus and indusium griseum and the septal areas. Continuing ventroposteriorly the fornix divides around the anterior commissure into pre- and postcommissural parts. The *precommissural fornix* distributes in part to preoptic hypothalamic regions; in its descent the *postcommissural (column of the) fornix* connects with dorsal, lateral and periventricular hypothalamic regions before its main termination in the mamillary nuclei. The fornix is further described on p. 1039; its fibres, in diverse bundles, carry at least nine different neuromediators.

Amygdaloid nuclei project to the preoptic area and most hypothalamic nuclei anterior to the mamillary bodies. These **amygdalohypothalamic fibres** have two routes: the complex curved *stria terminalis* and a *ventral amygdalofugal route*; the latter is a diffuse array of fibres, inferior to the lentiform nucleus, which traverse the anterior perforated substance to reach the hypothalamus. The amygdaloid complex and stria terminalis are described below (p. 1034).

The medial forebrain bundle, another complex fasciculus, is reduced in human brains, but is still the principal longitudinal hypothalamic fascicle (7.155). With ascending, descending, transverse but mainly longitudinal components, it connects anterior olfactory, hypothalamic and mid-brain tegmental regions and traverses the lateral hypothalamic zone, exchanging small fascicles throughout its course. Descending afferents include numerous *septohypothalamic fibres* from the septal area (p. 1035), *olfactohypothalamic fibres* from the piriform cortex and *corticohypothalamic fibres* from the orbitofrontal cortex. Visceral afferents *ascend* in the posterior part of the medial forebrain bundle, which also contains *descending* fibres which are continuations beyond the main anterior terminations of both the fornix and stria terminalis. Some of these connections are known only in subprimate brains; but their existence in human brains is almost certain. Some of the bundle's connections have been partly clarified by newer fibre-tracing and immunofluorescence techniques (p. 876 and vide supra). Fascicles from the *ventral tegmental ascending cholinergic pathway* are in or adjoin it; most if not all hypothalamic nuclei thus receive a cholinergic input. The *ventral*

tegmental noradrenergic bundle does the same, with branches to dorsomedial, periventricular, paraventricular, supraoptic and lateral hypothalamic nuclei. A *mesolimbic dopaminergic system* (p. 994) traverses the hypothalamus in the medial forebrain bundle: dopaminergic group A12, in the infundibular (arcuate) nucleus, has terminals in the median eminence and infundibulum, group A11 innervates the medial hypothalamic nuclei, and groups A13 and 14 supply the dorsal and rostral hypothalamic nuclei (p. 994 and **8**.224). The medial forebrain bundle in a recent review (Nieuwenhuys 1986) has been shown to have a fibre bundle containing 15 different neuromediators (also confirming those mentioned above). These are: acetylcholine, dopamine, noradrenalin, adrenalin, serotonin, histamine, substance P, VIP, CCK, neurotensin, CRF, LHRH, somatostatin, ACTH and enkephalin.

Corticohypothalamic fibres reach the hypothalamus from much of the prefrontal cortex by direct and indirect routes, in uncertain relative numbers. *Indirect* cortical fibres converge on the thalamic nucleus medialis dorsalis and relay to the hypothalamus by periventricular routes in some animals; in others *direct* corticohypothalamic fibres may end in lateral, dorsomedial, mamillary and posterior hypothalamic nuclei; some of these connections are questioned by some authors. (For detailed reviews see Nauta & Haymaker 1969, Reichlin et al 1978.)

Efferent Connections

Hypothalamic efferents include: (1) reciprocal paths to the limbic system, (2) descending polysynaptic paths to autonomic and somatic motor neurons, (3) neurovascular links with the hypophysis cerebri. Septal areas and the amygdaloid complex have reciprocal hypothalamic connections along the paths described above. The medial mamillary nucleus produces a large ascending fascicle which diverges into: (a) a *mamillothalamic tract* (7.148) which continues to ascend and ends in all parts of the anterior thalamic nuclei, whence massive projections radiate to the cingulate gyrus (pp. 1003, 1062); and (b) a *mamillotegmental tract*, which curves inferiorly into the midbrain ventral to the medial longitudinal fasciculus and is distributed to tegmental reticular nuclei. Small *mamillosubthalamic fascicles* reach the subthalamic prerubral field, their destinations uncertain. Descending hypothalamic fibres also reach the mesencephalic tegmentum in the *dorsal longitudinal fasciculus* and inferior extension of the *medial forebrain bundle*.

Connections of the hypothalamus with the hypophysis cerebri. In summary these are: (1) *nerve fibres* from hypothalamic neurons ending throughout the median eminence, infundibulum and *posterior lobe* and (2) long and short *portal blood vessels* between sinusoids in the median eminence and infundibulum and plexuses in the hypophysial *anterior lobe* (p. 1451 and **8**.224, 229). Certain points need emphasis: the anterior lobe receives no major nerve supply; almost all its blood comes from hypothalamohypophysial portal vessels; direct observation shows that the predominant direction of flow is from tufts of sinusoids in the median eminence and infundibulum via portal vessels to sinusoids between glandular cells in the anterior lobe. However (p. 1452), *flow reversal* may occur, with widespread neuroendocrine effects.

Neurosecretion is involved in the production and release of posterior lobar *oxytocin* and *vasopressin* and their related proteins: transport *neurophysins* in neurovascular control of the glandular cells of the anterior lobe. Hypothalamic neurons, whose axons end in the median eminence, upper infundibulum or posterior lobe, have their somata in the supraoptic, paraventicular, infundibular nuclei and partly in the ventromedial nuclei.

The supraoptic nucleus, curved over the lateral part of the optic chiasma, is sometimes considered as having three or more subsidiaries; it has a uniform population of large neurons. **The paraventricular nucleus** is a visible bulge into the third ventricle, extending from the hypothalamic sulcus across the medial aspect of the column of the fornix; its ventrolateral angle reaches towards the supraoptic nucleus, whose neurons some of its own resemble, with intermediate and small ones of varying shape. **The infundibular (arcuate) nucleus** is median in the postinfundibular part of the tuber cinereum, extending into the median eminence and almost encircling the infundibular base; but it is deficient above, where the infundibulum adjoins the median part of the optic chiasma. No glial layer intervenes between the nucleus and the tanycytic lining of the *infundibular recess*. (For the neuroendocrine role of tanycytes consult Knowles 1974, Joseph & Knigge 1978, and pp. 894, 1453.) Its numerous neurons are all small and round in coronal, oval or fusiform in sagittal section.

Thus neurons projecting into or via the infundibulum form two groups: (a) **magnocellular**, including the large and intermediate neurons in the paraventricular nucleus, large cells in the supraoptic, with small groups or rows of internuclear neurons; (b) **parvocellular**, including small infundibular neurons and some in various adjacent nuclei (Nieuwenhuys 1986). Large neurons contain neurosecretory material (vide infra) but both groups are true neurons, each with a soma, dendrites, axon and collateral branches and the usual neuronal organelles. They have axodendritic and axosomatic synapses from unknown sources. Their axons conduct impulses and terminate in the posterior hypophysial lobe and infundibulum at end-bulbs containing mitochondria and vesicles of about 40–60 nm diameter, many being applied to the capillary basement membranes without intervening neuroglia. Neural connections exist to influence the activities of these nuclei, probably from other hypothalamic nuclei and via paths converging on the hypothalamus from other sources, the precise connections remaining uncertain; likewise, the functions of impulses in these neurons and of presynaptic vesicles are not clear: no clear relation to neurosecretion has been shown.

The terminology of neuro-endocrine paths has changed with the increasing knowledge, resulting in an array of imprecise terms. For example *supra-opticohypophysial tract*, often used for *all* fibres entering the infundibulum of whatever origin or destination, is now often restricted to axons from supraoptic and paraventricular nuclei; since these differ in cytology and connections, some authors differentiate *supra-opticohypophysial* and *paraventriculohypophysial tracts*. But many of their fibres reach the infundibulum, not the posterior lobe; *tuberohypophysial* or more precisely **tubero-infundibular tract** denotes fibres of small neurons in infundibular and related nuclei of the ventromedial hypothalamus (vide infra) which end in the infundibulum.

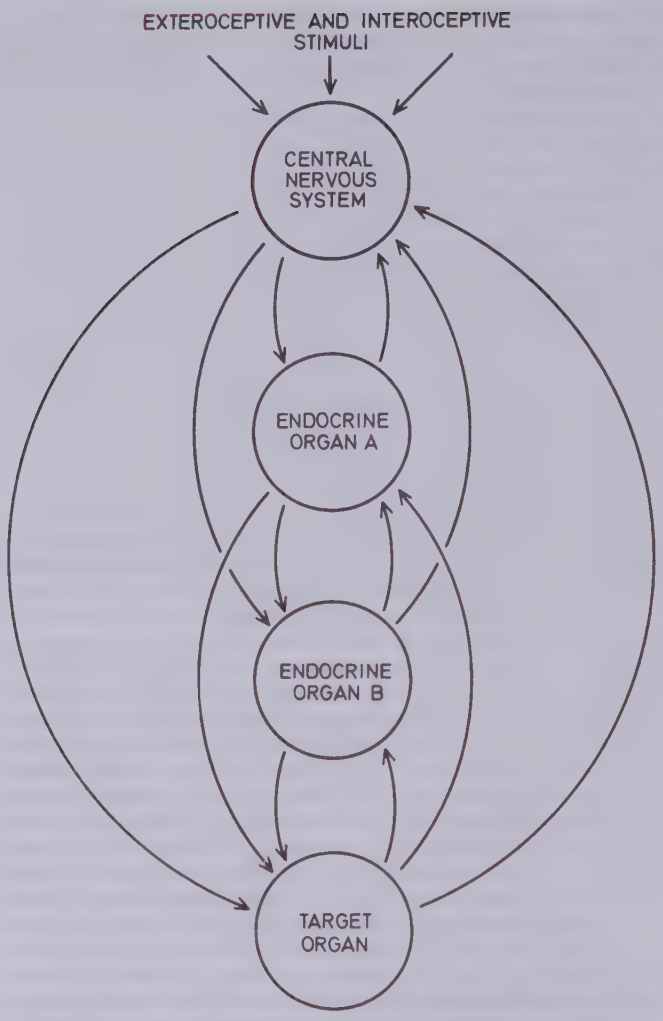
Neuronal somata and axons of **magnocellular neurosecretory** paths from the supraoptic and paraventricular nuclei, internuclear neurons and (some contend) occasional neurons in the suprachiasmatic nucleus, all contain what were first termed *colloid droplets*. These vary in size, sometimes appear between somata and fibres and have an affinity for Gomori's chrome-alum haematoxylin stain, which reveals, in fine axons and branches, rows of stained masses distending them like rosaries. Terminals irregularly distended by masses of neurosecretory material are termed *Herring bodies*. Electron microscopy shows in them membrane-bound aggregations of dense granules from 200–300 nm in diameter. Transection of the infundibulum, hypophysial transplantation, the culture of neurohypophysial explants, autoradiography with labelled cysteine, fractionation and extraction with biological assay or chemical analysis, the effects of dehydration, hydration, drugs and stress, chemical and electrical stimulation and ablation of focal points, all have led to agreement that neurosecretory material is synthesized in the large neuronal somata of supraoptic, paraventricular and adjacent neurons, near their endoplasmic reticulum; also that it is then elaborated in Golgi complexes, transported along axons and branches, released at terminals and absorbed into adjacent capillaries. While *both* supraoptic and paraventricular nuclei are involved in the production of vasopressin *and* oxytocin, vasopressin is *predominantly* a product of the supraoptic oxytocin of the paraventricular nucleus. By immunofluorescence the precise three-dimensional distribution of neurons containing oxytocin and vasopressin has been analysed in several mammals; marked regional and specific differences exist. Many questions that persisted for a time (Donovan 1970, Knowles 1974) are now answered, e.g. the exact chemical constitution of neurosecretory material is now determined; the chemically related hormones, oxytocin and vasopressin (nonapeptides), are transported in an inactive form and conjugated with a specific low molecular weight protein, a

neurophysin. The rate and mode of transport, presumably by fast axoplasmic flow, however, remain speculative. Details of exocytotic release at axonal terminals are few, but calcium ions and the local synaptic release of acetylcholine may be involved. The vascular relations of supraoptic and paraventricular nuclei are discussed below. (For reviews see Defendini & Zimmerman 1978, Silverman & Zimmerman 1983.)

Neurosecretory paths may also aid the control of anterior hypophysial secretion. Groups of hypothalamic cells produce *peptidergic-releasing hormones*, transported along their axons and discharged into the portal system's upper radicles; the portal vessels carry them to the anterior lobe's dense capillary plexus to influence the appropriate glandular cells. *Releasing hormones* is an inappropriate term; some *inhibit* hormonal release from anterior lobar cells while others stimulate synthesis and promote release. They include *releasing hormones* for corticotropin, luteinizing hormone, follicle-stimulating hormones, thyrotropin and somatotropin and *release-inhibiting hormones* for prolactin, melanocyte-stimulating hormone and somatostatin. The **parvocellular neurosecretory pathway** of the '*tubero-infundibular tract*' is proposed as the main route for the synthesis of releasing hormones and transmission to portal blood. Immunofluorescence has localized some of these peptides (p. 891, table on p. 1451, Renaud 1978). For example: corticotropin-releasing factor is localized to small neurons in paraventricular, anterior and dorsal hypothalamic nuclei, thyrotropin-releasing factor to nuclei dorsomedialis and ventromedialis, luteinizing hormone-releasing factor to nucleus infundibularis (arcuatus), somatotropin-releasing factor to anterior and posterior hypothalamic nuclei and somatostatin to certain periventricular nuclei. Some tubero-infundibular fibres also have high concentrations of acetylcholine, others of catecholamines, in accord with the ultrastructure of their end-bulbs (p. 1451), some containing small clear synaptic vesicles, others larger dense-cored vesicles and some a mixture. There is no evidence of large, electron-dense, membrane-bound granules typical of the magnocellular path. The tubero-infundibular tract may carry releasing hormones in dispersed, active form and also catecholamines or acetylcholine. For such widespread origins *tubero-infundibular* is too narrow a term. Already noted (p. 1010) it is a possible role of tubero-infundibular dopaminergic (and other monoaminergic) paths to regulate synthesis, transport and exocytosis of releasing or release-inhibiting factors and the activities of tancytes (p. 1010 and 8.225). According to Renaud (1978) tubero-infundibular neurosecretory parvocellular neurons have *afferents* from the amygdala, preoptic nuclei and hippocampus, their *efferent* axons returning collaterals to these structures and to the medial nuclei of the *dorsal thalamus* and other *hypothalamic* and numerous *brain-stem reticular* nuclei, in addition to their better known *infundibular* terminals.

Many axonal terminals of the magnocellular path end in the proximal infundibulum and are perhaps also involved in control of the anterior hypophysial lobe. Thus, magnocellular and parvocellular paths may not be as functionally independent as is sometimes stated.

FUNCTIONS OF THE HYPOTHALAMUS



Hypothalamic lesions have long been linked with widespread and bizarre endocrine syndromes and with metabolic, visceral and motor disturbances; it has been widely assumed that these result from interruption of the paths mediating such 'functions', which, though largely independent, are structurally associated in the hypothalamic region. Though the endocrine role of the hypophysis cerebri was emerging in the late nineteenth and early twentieth centuries (Cushing 1912), the *interrelation* of hypophysis and nervous system has been much more recently established (Harris 1955) with the emergence of *neuroendocrinology* (Scharrer & Scharrer 1963, Heller & Clark 1962, Gabe 1966, Donovan 1970, Knowles 1974, Reichlin et al 1978), which has rapidly progressed, enlarging the accepted role of the hypothalamus as the 'head ganglion' of the autonomic nervous system (Sherrington 1947). Research has confirmed in greater detail the hypothalamic effects on the *endocrine system* and *lower autonomic centres*, also emphasizing the hypothalamic action's dependence on afferent channels, nervous and vascular, interlocking it structurally and functionally with the higher regions, including the complex of structures in the *limbic lobe* (p. 1028) and prefrontal cortex.

One approach to the general study of nervous systems, mentioned earlier (p. 860), depends on their control of *homeostatic cycles* to preserve individual and species in a changeable environment. The mammalian frontal cortex, limbic system, hypothalamus, lower brain stem and spinal cord are regarded as a hierarchy in such cycles, mediated peripherally by the autonomic nervous and endocrine systems through their effector patterns. This concept is germane to widespread use of the terms *lower*, *intermediate* and *higher* '*centres*' for visceral and somatic locomotor controls. 'Centre' is a product of methods of analysing central nervous activities by focal stimulation or destruction of localized topographical targets. Such manoeuvres are then combined with other observations: cytological, biochemical, metabolic, developmental or behavioural, electrophysiological and so forth. Focal stimulation or obliteration causes dramatic changes in certain responses; some regions exhibit apparently spontaneous, sometimes rhythmic electrical changes when isolated; but this does not establish them as autonomous 'centres' controlling particular activities. Most evidence indicates that 'centres' are best regarded as *nodal regions* which, by chemical constitution, structure and intrinsic and extrinsic connections, nervous or vascular, are essential foci in a range of responses following the appropriate stimulus. Hence other regions whose afferents converge on the 'centre', though often less dramatic in their effect on responses when individually disturbed, are collectively as essential as the so-called centre itself. Especially in a confined region such as the hypothalamus, with numerous converging and diverging connections and ill-defined neuronal groups (often with diffuse connections), the putative 'centres' of different investigators may overlap or coincide. Therefore many prefer to discuss the effects of stimulation or ablation of general hypothalamic *zones*, e.g. lateral, preoptic, mamillary, etc., rather than ascribing functions to specific nuclei. Exceptions are the accepted neurosecretory nuclei with their specific products although afferent neurovascular connections are not fully clarified even in these.

Experimental transections generally show that as progressively higher levels are included with the spinal cord below the section, more effective homeostasis is retained (Anand 1970). After transection at upper mesencephalic levels, minor reflex readjustments of cardiovascular, respiratory and alimentary systems survive but are not integrated, nor is normal temperature maintained. After transection above the hypothalamus, separating it from the limbic system but leaving the connections between the hypothalamus, hypophysis, brain stem and spinal cord, a very different picture emerges: effective homeostasis is maintained in a moderate range of conditions; visceral and endocrine control integrates the patterns of responses; 'innate drives' and 'motivated behaviour' are preserved, including feeding, drinking, apparent satiation, and copulatory responses; but homeostasis fails if environmental stresses exceed a certain range e.g. persistently high or low temperatures. Motivated behaviour also becomes abnormal under stress; animals may attack, try to eat, drink or copulate with inappropriate objects. But if the connections between the limbic system (p. 1028) and the hypothalamus survive and the neocortex only is cut off, normal homeostasis is preserved even in a wide range of adverse conditions.

An unwieldy literature has amassed on the functions of the hypothalamus and aspects of neuroendocrinology, unprofitable to detail here; the references quoted here contain extensive bibliographies. To summarize, much experimentation has revealed an intimate involvement of the hypothalamus in the following activities.

(1) **Endocrine control** is effected by releasing or release-inhibiting factors which influence the production of thyrotropin, corticotropin, somatotropin, somatostatin, prolactin, luteinizing hormone, follicle-stimulating hormone and melanocyte-stimulation hormone by cells of the *anterior hypophysis*. Some of these affect target cells in general tissues directly, others through a second endocrine organ, e.g. the thyroid gland, adrenal cortex and gonads, in the sequences summarized in 7.134. Neural paths

7.134 A flow diagram showing a stimulus pattern impinging on the central nervous system and the possible interactions of the latter with endocrine organs A and B and a target tissue. Note the different orders of feed-forward and feed-back pathways envisaged. From Scharrer & Scharrer 1963, by courtesy of the authors and publishers.

converge to be integrated in the hypothalamus (Nieuwenhuys 1986), modifying the production of all its factors (p. 1011), which in turn influence endocrine glands and, ultimately, target tissues. Each intermediate link may be modified by negative or positive feed-back loops depending on the circulatory levels of secretory products of other links in the chain (Haymaker et al 1969, Donovan 1970, Bargmann & Scharrer 1970, Knowles 1974, Reichlin et al 1978).

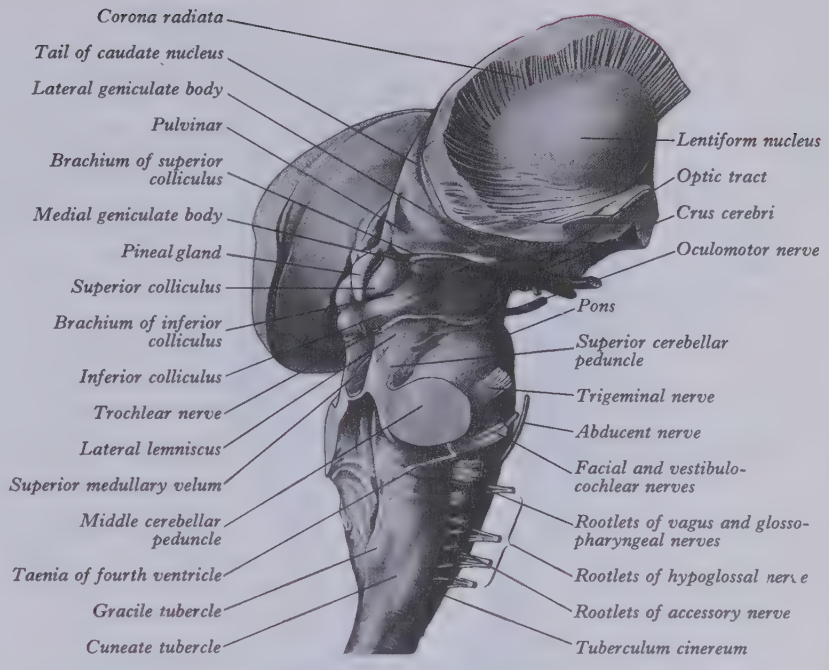
(2) **Neurosecretion** of oxytocin and vasopressin (antidiuretic hormone, ADH) is directly into blood in the infundibulum and hypophysial posterior lobe. Vasopressin's effect on vascular non-striated muscle remains uncertain; but it has a powerful effect on renal reabsorption of water. Oxytocin causes contraction of the uterine and mammary muscle, with roles in coitus, parturition and suckling. Stimulation of the nipples and genitalia increases oxytocin release. Vasopressin's rate of release is partly determined by the tonicity and osmotic pressure of the blood traversing *osmoreceptor sites* in the hypothalamus (Verney 1947) and peripheral circulation, probably in the hepatic portal vein (Haberich 1968), from which the impulses generated reach the hypothalamus. Reduced blood volume is believed to stimulate *volume receptors* in the great veins and atrial walls, increasing the release of vasopressin (Gauer 1968); pain, emotional states and stress also modify its rate of release.

(3) **The general autonomic effects** of anterior hypothalamic zones, mediating general parasympathetic activity, and of the posterior zones, mediating sympathetic activity, have been long suspected. While a preponderance of one or other effect in these zones is undoubted, interaction and overlap occurs; a rigid distinction between parasympathetic and sympathetic 'centres' cannot be maintained. Focal hypothalamic stimulation and ablation intimately affect *cardiovascular*, *respiratory* and *alimentary* control, often causing profound changes in heart rate, cardiac output, vasomotor tone, peripheral resistance, blood pressure, differential flow in organs, the frequency and depth of respiration, motility and secretion in the stomach and intestines.

(4) **Temperature regulation.** In all homeothermic animals production and loss of heat are balanced, the hypothalamus providing a central regulator. Raised temperature is reduced by vasodilatation with increased cutaneous flow, sweating, panting and depressed production of heat; at lower temperatures the reactions are reversed, with shivering and increased thyroid activity. Signals of body temperature reach the hypothalamus from peripheral *thermo-detectors* and also from intrinsic hypothalamic thermo-detector neurons responding to temperature changes in the blood of the hypothalamic circulation. Other hypothalamic neurons react specifically to blood-borne viruses, toxins, pyrogenic drugs, etc. The signals converge to regions of the hypothalamus which evoke the appropriate autonomic, endocrine and muscular responses. An '*anti-rise*' region is hypothecated in the anterior hypothalamus to control vasodilatation, sweating, panting and possibly to depress the production of heat, the posterior hypothalamus containing an '*anti-drop*' region controlling vasoconstriction, shivering and other means of producing heat. The sites and even the distinction of such a *dual hypothalamic thermostat* are obscure. Some investigators (Myers 1969) propose a *dual chemical* '*thermostat*' between the inflow of signals and 'antirise' and 'antidrop' regions, consisting of neurons containing 5-hydroxytryptamine or noradrenalin (possibly dopamine). Warmer blood, impulses from heat receptors, antipyretic substances or anaesthetics are all supposed to release noradrenalin (or dopamine) to stimulate 'anti-rise' mechanisms; cooler blood, impulses from cold receptors and pyrogenic substances stimulate the release of 5-hydroxytryptamine, activating 'anti-drop' mechanisms.

(5) **Regulation of the intake of food and water.** Experiments show (Anand & Brobeck 1951, Anand 1961) that regions with opposing actions exist in the medial and lateral hypothalamic zones: ablation of the medial zone promotes over-eating (*hyperphagia*), leading to gross obesity, while ablation of the lateral zone promotes *hypophagia* or complete *aphagia*, with death from starvation. Conversely, stimulation of the medial zone reduces eating, lateral stimulation increases and prolongs it. Hence, a lateral '*hunger*' or '*feeding centre*' balanced against a medial '*satiety centre*' have been proposed. Neurons sensitive to the glucose level in circulating blood exist in the medial zone, the supposed 'satiety centre'.

Water balance and haemal osmolality are partly controlled by an '*osmoreceptor/volume receptor—vasopressin—renal system*' described previously, which determines the rate of water loss in urine. Allied to this is a '*thirst*' or '*drinking centre*' in the lateral zone, regulating water intake; stimulation of this causes copious drinking and, if stimulation persists, gross hyperhydration.



(6) **Sexual behaviour and reproduction.** Through the hypophysial control of gonadotrophin production the hypothalamus controls aspects of reproduction, including gametogenesis, cyclic variations and the development and maintenance of secondary sexual features. Hypothalamic stimulation may induce receptivity in females and simple copulatory movements in males. Some hypothalamic neurons are sensitive to circulating oestrogen or testosterone.

Though elementary *drives* of hunger, thirst and reproduction may stem in part from an intact hypothalamus, full integration into behaviour requires reciprocation between the hypothalamus and the limbic system (p. 1028). Such behaviour includes searching out and procuring food, drink and mate, home-building, rearing of young, etc.

(7) **Biological clocks.** Many tissues and organs show cyclic variation in function, with a period of about 24 hours. Examples of such *circadian rhythms* include fluctuations in temperature, concentrations of several plasma constituents, the eosinophil count, adrenocortical secretory activity and renal secretion. In

some the rhythm is partly intrinsic to the organ or tissue but in many overall control is exerted by an intact hypothalamus. Lesions in other parts of the brain leave this variety of biological timing unaffected; hypothalamic lesions alone cause serious disturbances. The suprachiasmatic nucleus appears in many animals to act as an *endogenous neural pacemaker*, whose rhythmic activity may respond to changes in the level of light (p. 1459). Though it occurs throughout vertebrates (Joseph & Knigge 1978), some doubts have been expressed concerning the prominence (or even presence) of a discrete human suprachiasmatic nucleus (Defendini & Zimmerman 1978). Bilateral experimental destruction permanently interferes with circadian rhythms of, e.g. adrenocorticosterone secretion (Moore & Eichler 1972), drinking and locomotion (Stephan & Zucker 1972), sleeping and wakefulness (Ibuka & Kawamura 1975) and pineal N-acetyltransferase activity (Moore & Klein 1974). Concerning pineal activity Nishino et al (1976) have shown that activity in suprachiasmatic neurons is increased by visual stimulation and that this inhibits the sympathetic neurons supplying pinealocytes, resulting in a decrease in secretion (p. 1459). Though this is still controversial, there is experimental evidence of direct retinosuprachiasmatic connections, perhaps involved in human photic regulation of circadian rhythms. Retinal terminals in the nucleus have been demonstrated by autoradiography after intraocular injection of tritiated amino acids in mammals, from tree-shrew to macaque (Moore 1973), supporting degeneration studies (Moore & Len 1972, Printz & Hall 1974); further evidence is provided by cobalt precipitation techniques (Mason & Lincoln 1976), by electron microscopy (Wenisch 1976) and electrophysiology (Sawaki 1977). *Retinal projections* to the anterior region of the infundibular (arcuate) nucleus have also been shown to exist (Mason & Lincoln 1976). Efferents have been traced from the suprachiasmatic nucleus to ventromedial, dorsomedial and arcuate hypothalamic nuclei, suggesting that their fine control by an endogenous circadian regulator is sensitive.

Alternation of sleep and wakefulness is an outstanding circadian rhythm. Sleep has been much investigated (Jouvet 1962, 1964, 1965, Rossi 1964, Koella 1969); it is no longer regarded as passive 'switching off' or the simple depression of a cerebral activating system. *Two* main types of sleep are recognized. During the waking state, electroencephalograms show a low-amplitude undulatory pattern at about 10 cycles per second, upon which bursts of irregular 'random' activity occur. In sleep the pattern becomes *synchronized*, larger in amplitude and slower. From this *deep* or '*slow-wave sleep*' (SWS) the subject can be aroused easily; it is dreamless. It may be interrupted by periods of *paradoxical sleep* (PS), with a fast, low-amplitude waveform; muscle tone is generally reduced, especially in the neck, and *rapid eye movements* occur (REM sleep); the subject is difficult to rouse and dreams; the electroencephalographic pattern corresponds to ocular oscillation. Three or four spells of REM sleep occur each night. The general view is that the level and type of sleep depend on a *balance* between opposing systems, deployed through much of the brain stem and parts of the thalamus, hypothalamus and limbic system. On one hand is the *reticular activating, arousal system*, with extensions to the cerebral cortex, stimulation of which leads to wakefulness and desynchronization of activity. On the other is a postulated series of *hypnogenic zones* in the medulla, pons, midbrain, thalamus, hypothalamus and basal limbic structures, stimulation of which leads to synchronization of cortical activity and a *variety* of sleep-like states, differing in detailed traits. How these opposing 'hierarchies' of sleep-controlling regions interact is unknown; but the thalamohypothalamic 'centres' seem dominant and those in the medulla, pons and midbrain subordinate, as would be expected. Intact centres in the nucleus coeruleus, rich in noradrenergic and cholinergic neurons, appear important in the generation of paradoxical sleep. Overall the circadian rhythm of sleep and waking is disturbed by lesions in the anterior hypothalamus, with fluctuations in the concentration of serotonin in hypnogenic zones of the brain stem and diencephalon. Whether serotonin functions as a humoral, sleep-inducing factor or a neural transmitter in the 'hypnogenic system' is undetermined. (Further comments appear on p. 996.)

7.135B Right lateral view of the brain stem; compare with 7.135A. Dissection by E. L. Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

(8) **Emotions: fear, rage, aversion, pleasure and reward.** Emotional states contain two main elements: *subjective feeling* or *affective tone* and *objective physical accompaniments*, together forming *emotional expression*. For the full integration of both during changes in the internal and external environment and other cerebral activities, essential structures are an intact hypothalamus, limbic system and prefrontal cortex. In such a complex array it is impossible to specify the functional roles to punctate subregions. Some basic information is gained by focal stimulation or ablation of the hypothalamus in intact animals by removal of the 'higher centres' and by observations during human operations. Classic experiments were carried out in decorticate dogs (Goltz 1892) and subsequently analysed in decorticate cats

7.136 A ventral dissection of the brain showing the metathalamus and the optic tracts. On the right side of the figure the inferior horn of the ventricle is exposed. The floor has been removed but the choroid plexus is in situ and obscures most of the roof.

(Cannon & Britton 1925), where mild peripheral stimulation evoked *sham rage*, with hissing, growling, baring of claws and fangs, piloerection, arching of the back, dilatation of pupils and lashing of the tail; 'sham' because it was assumed that emotional *feelings* could not occur in decorticate animals. Sham rage was shown later to be abolished by obliteration of the posterior hypothalamus and elicited by stimulation of it in intact animals.

7.137 An oblique view of the dorsal aspect of the brain stem looking cranially. In the foreground is the floor of the rhomboid fossa, bounded laterally by the sectioned white matter of the cerebellum containing the dentate nuclei; the cranial recess of the fourth ventricle passes inferior to the superior medullary velum to continue into the aqueduct of the midbrain. More cranially, the emerging trochlear nerves, the colliculi, superior and inferior brachia, the medial and lateral geniculate bodies and the pineal gland may be identified. Lateral to the pineal gland on each side is the rounded pulvinar of the dorsal thalamus, skirted laterally by the curving body and tail of the caudate nucleus, whilst most laterally is the cut surface of the corona radiata. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

Subsequent studies showed that stimulation or ablation of the different hypothalamic regions cause changes in emotional expression of the basic drives (thirst, hunger and reproduction), other regions being related to behavioural (and subjective) aspects of rage, fear and pleasure. The existence of broadly opposed 'centres' (*positive* and *negative* '*reward*' *centres*) has been popularized. Stimulation of the former ('*pleasure centres*') leads to presumed 'pleasurable sensations' or gratification of a biological drive; in the appropriate experimental situations an animal will *self-stimulate* its hypothalamus until exhausted, ignoring food and drink even after prolonged deprivation. The main regions from which this can be elicited include parts of the catecholaminergic complex of the brain stem, the medial forebrain bundle of the hypothalamus, septal areas, orbitofrontal and parahippocampal (entorhinal) areas of the neocortex. Most effective, in earlier studies, was the medial forebrain bundle (p. 1009), in which ascending and descending fascicles, multiple in source and destination, intermingle with noradrenergic, dopaminergic, serotonergic and non-aminergic paths, which are in close relation. This field has been surveyed, with personal contributions, by Wanquier & Rolls (1976), Olds (1977) and also Routhenberg & Santos-Anderson (1977) who concluded that intact dopaminergic paths ascending from the pars compacta of the substantia nigra were essential to 'normal' patterns of self-stimulation. Stimulation in mankind often causes sensations of well-being, with sometimes a strong erotic content. Such *positive reinforcement* is used to expedite the responses of animals in experiments which demand *learning*. In this regard note the forward projection of *mesolimbic dopaminergic paths* to multiple endings in the limbic system (p. 1028), with a possible relevance to forming memory patterns. Stimulation of negative reward centres presumably causes pain or 'displeasure'; experimental animals make complex efforts to avoid repetitive stimulation.

The Metathalamus and Visual Pathway

The optic chiasma (7.136, 139), a flat, almost quadrilateral mass of decussating nerve fibres at the junction of the anterior wall and floor of the third ventricle, has anterolateral angles continuous with the optic nerves and the posterolateral angles with the optic tracts. The lamina terminalis (p. 1019), continuous with its upper surface, is crossed, dorsal to the chiasma, by the anterior communicating artery. Ventral is the diaphragma sellae, a little behind the 'optic' groove of the sphenoid bone; in about one subject in 10 the chiasma is either in the groove or altogether posterior. It is always near the hypophysis (p. 1451). Posterior to the chiasma are the tuber cinereum and infundibulum, with the third ventricle dorsal to them. Lateral is the end of the internal carotid artery and anterior perforated substance. The third ventricle's optic recess passes over its superior surface to reach the lamina terminalis (**8**.223A).

Most chiasmatic fibres start in the retina and arrive via the optic nerves; fibres from the nasal half of each retina, including half the macula, cross to the contralateral optic tract, fibres from temporal retinae continuing into the ipsilateral tract. Decussating fibres loop a little, backwards into their ipsilateral optic *tract before* crossing and forwards into the contralateral optic *nerve after* crossing. Macular fibres and those from an adjacent central area form a flat band occupying almost two-thirds of the central chiasma, dorsal to all peripheral decussating fibres, ventral to which are fibres from the extramacular parts of both nasal half retinae; most ventral are the nasal fibres concerned with monocular fringes of the binocular field. Dorsal to and in the chiasma are fascicles not derived from the optic nerve, forming no part of the visual pathways. Though collectively termed *supraoptic commissures*, they are really decussations. One, the *supraoptic commissure* (of Gudden), was incorrectly believed to connect the medial geniculate bodies. Its connections are not close but evidence from mammals suggests that it arises in the brain stem and spinal cord; its existence, in man, is denied by some. It is only one of at least three dorsal connections described in the optic chiasma and reputed to end in various hypothalamic and subthalamic nuclei in some animals, e.g. cats; but it is improbable that they are associated

with vision. Yet there *is* convincing evidence of a retinal projection to the suprachiasmatic nucleus, the ventral part of the infundibular (arcuate) nucleus and perhaps the supraoptic nucleus in rats; though not concerned with perceptual vision, these connections mediate, by pineal projection (p. 1459), the influence of light and dark on hypothalamic, pineal and autonomic activity in circadian rhythms. Detached bands of nerve fibres have been noted to leave the optic tract and pass across the cerebral peduncle ventral to the tract; such *transverse peduncular tracts* and other *accessory optic tracts*, present in some lower mammals, have been denied in primates (but see p. 982); in this view *all* myelinated fibres of human optic tracts reach either the lateral geniculate body or the superior colliculus and pretectal nucleus (Polyak 1957). But as noted above and elsewhere (p. 1009), much evidence indicates that the suprachiasmatic and ventral part of infundibular (arcuate) nuclei and a thin lamina in the pulvinar, receive fibres from the optic tract, i.e. as *retinohypothalamic* and *retinothalamic projections*.

The optic chiasma is supplied from a pial plexus receiving branches from the superior hypophysial, internal carotid, posterior communicating, anterior cerebral and anterior communicating arteries; its veins drain into basal and anterior cerebral vessels.

The optic tracts (7.136, 139) continue dorsolaterally from the chiasma, each passing between the anterior perforated substance and tuber cinereum as the ventrolateral boundary of the interpeduncular fossa. Each flattens and curves round its cerebral peduncle, to which it adheres, hidden from view on the ventral cerebral surface by the uncus and parahippocampal gyrus. Reaching the lateral geniculate body it divides into medial and lateral rami ('roots'), the medial believed to contain supraoptic commissural fibres and the lateral consisting of fibres derived from the retina and partially decussating in the chiasma, as described, but also containing a few fine efferent fibres ending in the retinae. Most fibres in the lateral root end in the lateral geniculate body (p. 1016), but some sweep medially ventral to the pulvinar to reach the superior colliculus and pretectal nucleus (p. 987); the termination of some of these in the pulvinar in various mammals, including primates (Campos-Ortega et al 1972) and cats (Berman & Jones 1977), suggests a more direct route to cortical areas outside the striate cortex; the latter workers describe the projection as ending in a thin pulvinar zone lateral to the lateral geniculate nucleus. The arrangement of retinal fibres in the optic chiasma and tract has been minutely detailed in monkeys (Polyak 1957); clinical observations have long suggested similar human organization (Traquair 1948). Figure 7.139 shows these details. A notable feature is that macular nerve fibres are central in the optic nerve and chiasma but assume an eccentric, dorsolateral location in the tract, fibres from both retinae having intermingled. As detailed later, this rearrangement is a prelude to spatial representation in the lateral geniculate body (p. 1017), superior colliculus and visual cortex (p. 1058).

A relay of fibres from neurons in the lateral geniculate nucleus traverses the posterior limb of the internal capsule, emerging as a broad *optic radiation* of axons of secondary visual neurons, curving dorsomedially to the occipital cortex (p. 1058). They are separated from the posterior cornu of the lateral ventricle only by the tapetum of the corpus callosum.

Some fibres in the optic radiation, from neurons in the occipital cortex, descend to the superior colliculus, which therefore receives *cortical and retinal paths*. From this a relay travels by tectobulbar tracts to motor nuclei of the third, fourth, sixth and eleventh cranial nerves and the spinal anterior grey column. Recent studies question such 'oculomotor' connections in primates, including man (p. 987).

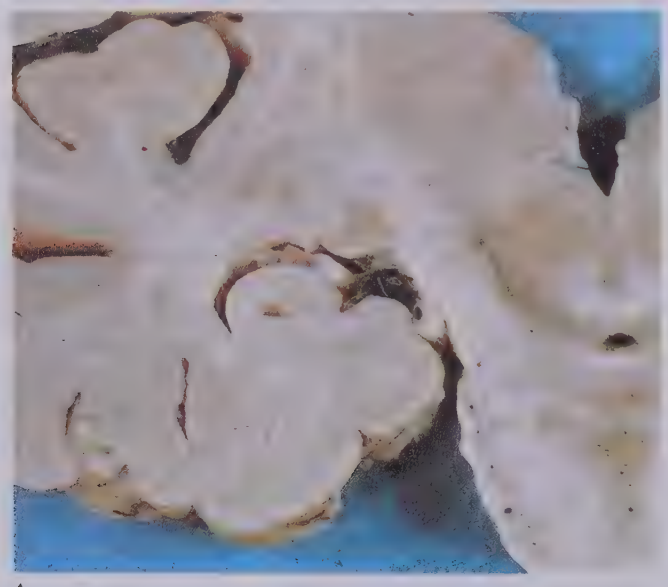
Metathalamus: the Geniculate Bodies

The metathalamus (7.136, 137) comprises the *medial* and *lateral geniculate bodies*, bilateral eminences on the posterior parts of the ventral thalamic aspects lateral to each side of the midbrain. Each eminence overlies the subjacent nuclear aggregates. As the collective term suggests, they are late developments in the vertebrate thalamus. Their basic roles as relay nuclei on the acoustic (medial geniculate) and visual (lateral geniculate) paths are long recognized; subsequent evidence shows that their connections, and hence functions, are much more complex. In both paths, as in most sensory projections, there is a *corticofugal* component modulating *centripetal* inputs and they are no longer regarded as in receipt of simple arrays of impulses from peripheral receptors, proceeding along independent parallel channels. For example, neuronal connections exist, as elsewhere, for collateral inhibition and probably for interaction between different sensory modalities.

THE MEDIAL GENICULATE BODY

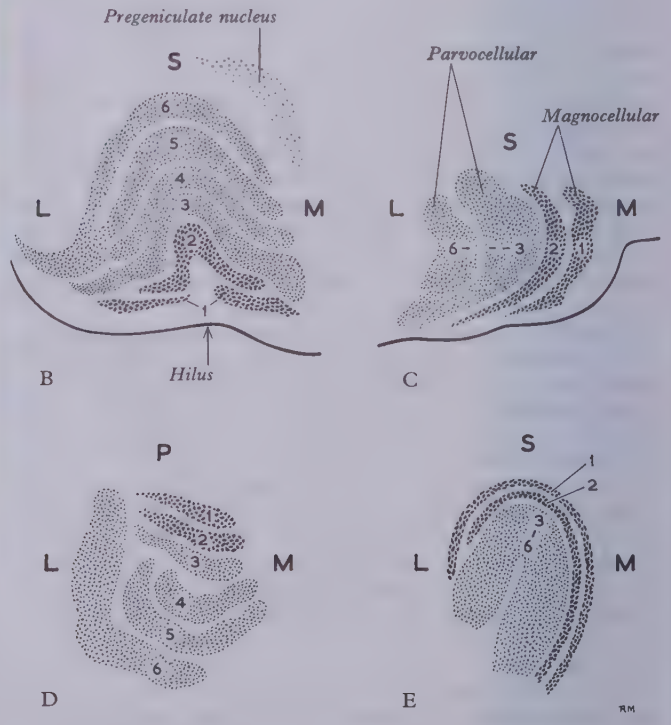
The medial geniculate body (7.116, 152) projects ventrally from the thalamic pulvinar (7.116), lies lateral to the superior colliculus and is ovoid in contour, with its long axis ventrolateral. The superior brachium extends from the superior colliculus to the lateral geniculate body and passes between the pulvinar and medial geniculate body. The inferior brachium (p. 981) ascends anterolaterally to reach the medial geniculate body; it contains fibres from the ipsilateral lateral lemniscus (with its complex *bilateral* nuclear origins: cochlear, trapezoid, superior olivary, intrinsic lateral lemniscal and inferior collicular, see pp. 959, 960, 1112).

In **internal structure** the medial geniculate nucleus has no clear subdivisions; the entire mass has a knee-shaped profile in section, hence its name. By size its neurons are largely segregated into a *dorsal pars parvocellularis* or *principal division* and a smaller *ventromedial division*, the *pars magnocellularis*, which also contains some neurons. Wedged between the pulvinar and pretectal region, dorsomedial to the medial geniculate body, is a small *suprageniculate nucleus* (in some species); its connections are uncertain. It may receive fibres from reticular nuclei in the lateral midbrain and pontine tegmentum, concerned in other modalities, including pain (p. 952). Closer study of the medial geniculate neurons, particularly of their dendritic organization and connections, has prompted partition into regions and component nuclei (Morest 1964, 1965). In cats it has been ascribed *dorsal*, *ventral* and *medial divisions*, with further subdivisons; one part of the ventral division, the *'ventral nucleus'*, has a laminar structure, a detail of special interest because this receives most of the inferior collicular projection *in cats* (Moore & Goldberg 1963); moreover, the lateral geniculate nucleus is also laminated, a pattern associated with the spatial organization of sensory terminals. In the feline schema, the medial division appears to be the terminus of direct lateral lemniscal fibres which are probably, in cats and monkeys, spinal afferents concerned in modalities other than acoustic, ending in magnocellular parts of the medial geniculate and suggesting that this, and perhaps the suprageniculate nucleus, may integrate visual, auditory, general somatic and even visceral inputs.



The role of the medial geniculate body in acoustic paths is still partly obscure, apart from being a relay, largely due to its relative inaccessibility to the recording electrode or destructive probe. By analogy, the laminar appearance in its ventral division and a tonotopical organization at cortical level suggest similar arrangements in the medial geniculate body; the evidence is, however, equivocal in experimental animals. It is clearly premature to suggest tonotopical representation in the human structure. The cortical projection is considered to be direct from small-celled regions of the nucleus, terminating in the temporal lobe in an area in monkeys corresponding to human area 41 (p. 1060), in the superior temporal gyrus. Other acoustic areas, as shown by experiment, may also exist in mankind (p. 1060). A primary acoustic area (AI) in cats is directly connected to the medial geniculate body; secondary acoustic areas (AII and others) may receive projections from the parvocellular parts of the geniculate complex (Niimi & Naito 1974). All areas may be concerned in aspects of acoustic function (p. 1061); there is strong evidence of tonotopical representation of the cochlear spiral organ in area A1. The role of the medial geniculate body in the determination of frequencies remains sub judice, evidence being largely negative (Whitfield 1967). Lesions in it do not cause pronounced deafness unless

bilateral; *both* cochlear organs are represented in *each* lateral lemniscus (p. 959). As in most receptive areas, the auditory cortex projects to the lower centres. Cajal first suggested a cortico-geniculate projection, demonstrated in monkeys by Whitlock & Nauta (1956). Pontes et al (1975) have detailed projections in cats from A1 and adjoining areas to medial geniculate nuclei (dorsal and magnocellular) and have summarized previous work; they confirm a *descending auditory pathway* (see Rasmussen 1967, and pp. 1005, 1112).



THE LATERAL GENICULATE BODY

The lateral geniculate body is a small nuclear complex visible on the surface as a small ovoid ventral projection from the posterior thalamic region (7.136, 152), its long axis approximately sagittal. Its anterior pole blends with the larger, lateral moiety of the optic tract, the medial ramus (or 'root') of which separates the lateral geniculate elevation from the lateral aspect of the crus cerebri. The medial geniculate is, of course, medial but also dorsal. Superficial aspects of both are overlapped by the temporal lobe, its parahippocampal gyrus being the immediate relation (p. 1029). Proceeding dorsally from the posteromedial part of the lateral geniculate body to reach the pretectal area and lateral side of the superior colliculus, is the *superior brachium* (7.135). This contains uninterrupted retinal nerve fibres mediating optic reflexes through the pretectal nucleus and colliculi and thence the oculomotor nuclei and nerves and the efferent descending tectal tracts (p. 987). The superior brachium passes largely between the medial geniculate body and the pulvinar. From a comparison of the lateral ramus of the optic tract and the superior brachium whose relative sizes represent a balance between forebrain and midbrain optic destinations, it is obvious that the phylogenetically older, mesencephalic termination is reduced in man, as in other primates, but less so in other mammals. The lateral geniculate body emerged during submammalian evolution, when the optic tracts contained only contralateral retinal fibres. This decussation is basic in vertebrates; explanations of it (like other decussations) remain hypothetical (Duke-Elder 1932, Polyak 1957). The advent of uncrossed retinal connections in mammals, especially developed in primates and others with forward-looking eyes and overlapping visual fields, is coupled with increasing specialization in the *dorsal part of the primitive lateral geniculate body*, by volume its major part in higher mammals. In this dorsal region *laminar organization* appears, perhaps associated with combined bilateral termination of retinal projections (vide infra). The *ventral part* is also known as the *pregeniculate nucleus*, represented in man by a small but not exiguous neuronal group (Le Gros Clark 1932), medial to the ventral third of the main, laminar nucleus. Medially, pregeniculate neurons are scattered towards the subthalamic region, marking the evolutionary and embryonic origin of this part of the complex. It has a bilateral retinal projection (possibly by collaterals of fibres passing to the tectum and main nucleus); these are said to be limited in origin to the central retinal region and part of the light reflex route by a *pregeniculo-mesencephalic connection* (Polyak 1957). The arrangement has clinical interest in the Argyll–Robertson phenomenon (p. 1215). However, Pierson & Carpenter (1974) found no evidence of involvement of this nucleus in the light reflex in monkeys subjected to various lesions in ocular, geniculate and pretectal sites. A cortical connection with the pregeniculate nucleus has not been established. Some deny termination of optic nerve fibres in the primate nucleus, which is, however, a definable entity though not as well developed as in ungulates and carnivores (Niimi et al 1963).

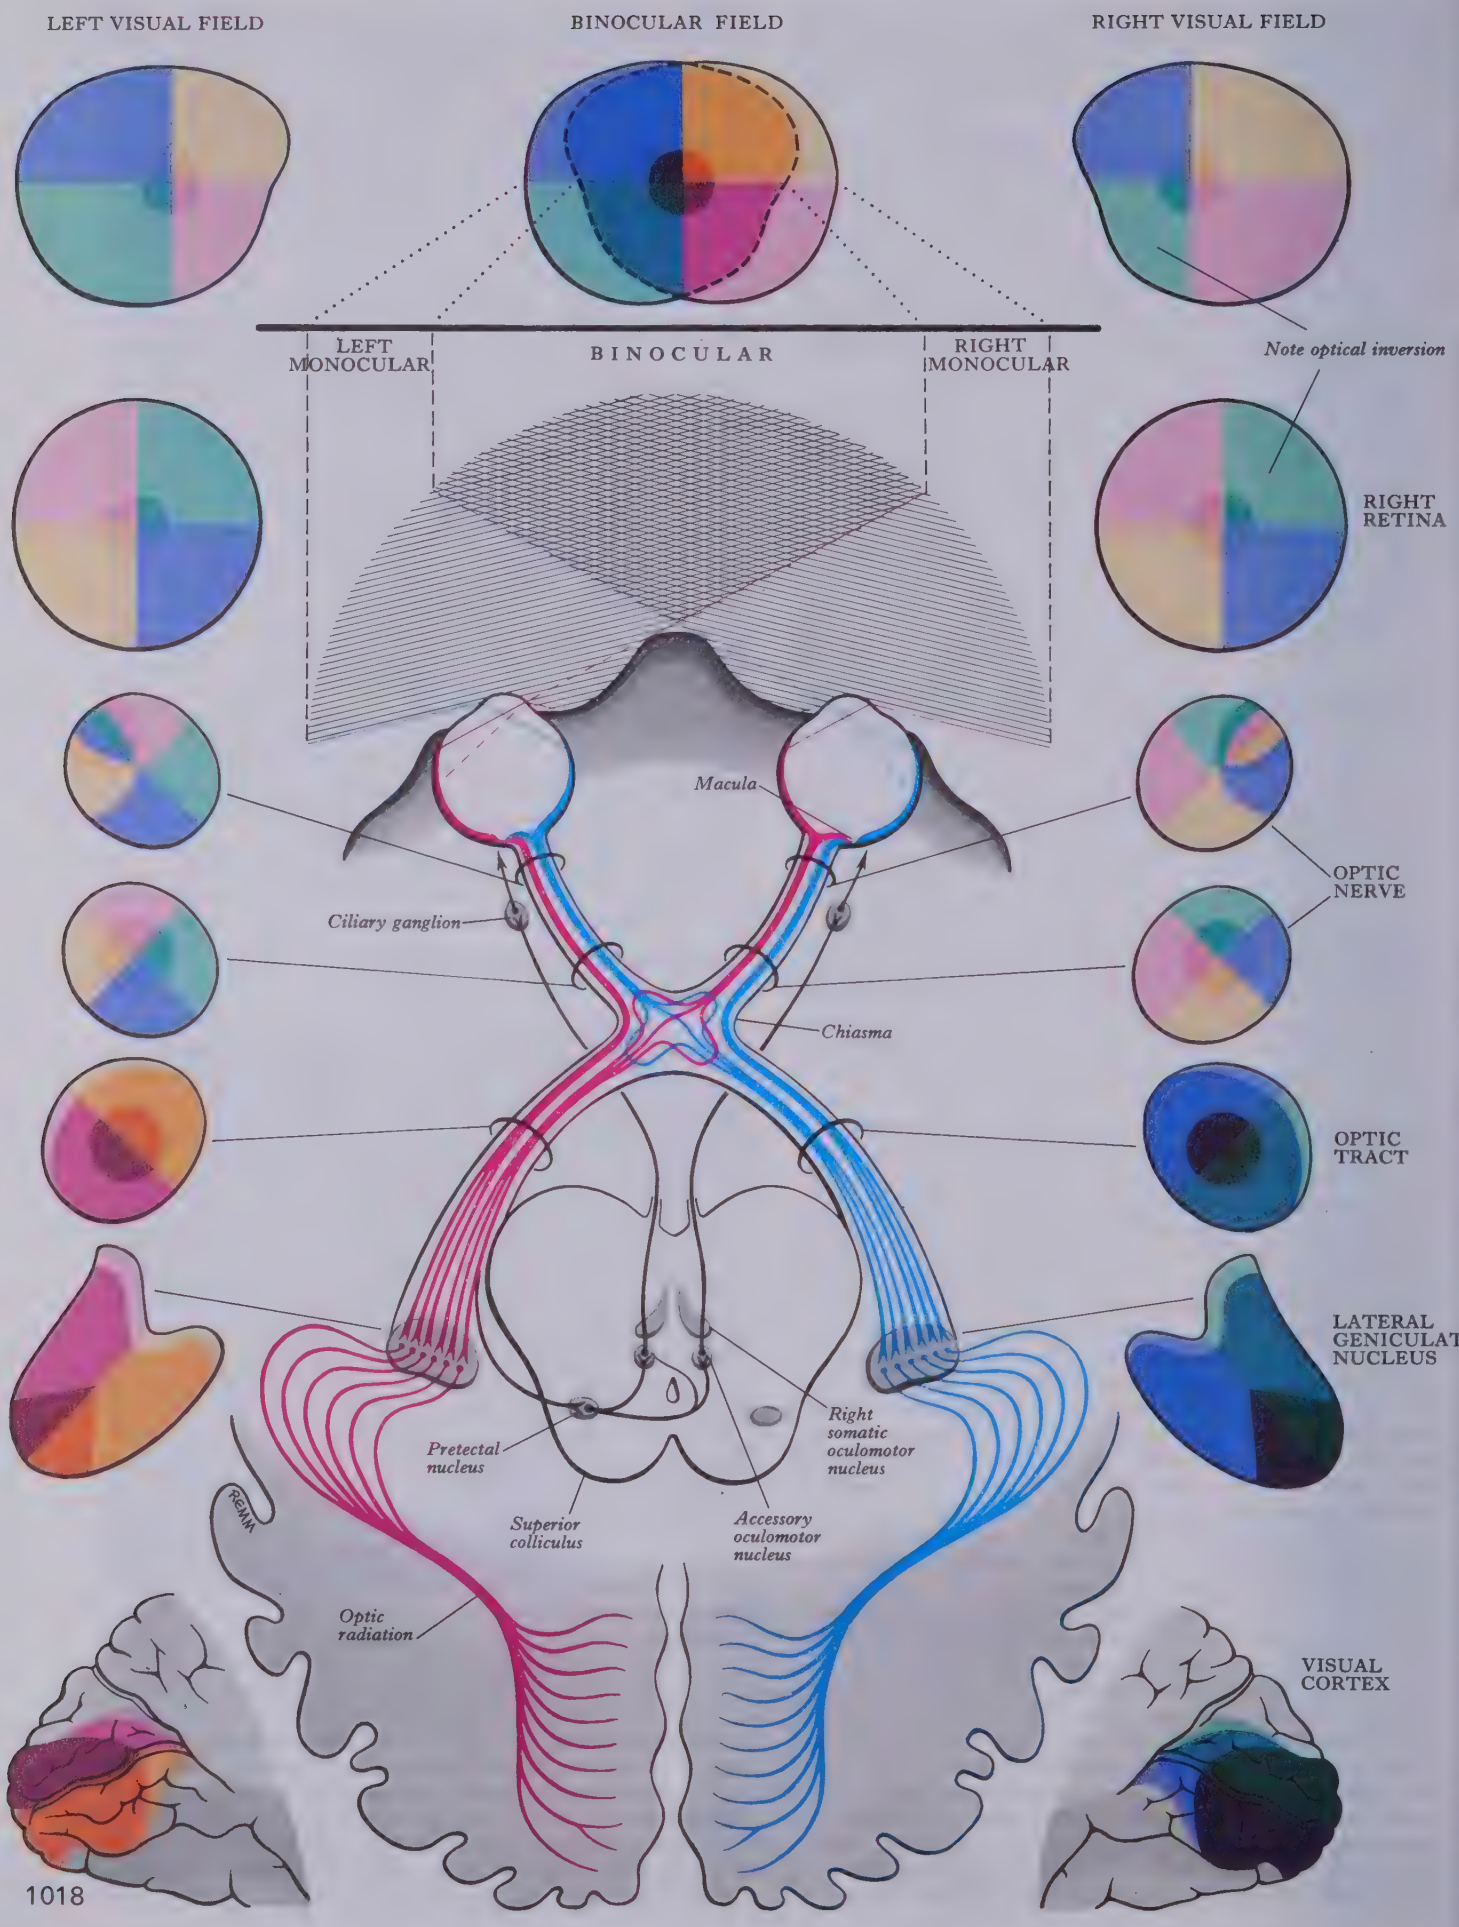
The dorsal (main) lateral geniculate nucleus has a well-known laminar structure, with six (and perhaps seven) layers of neurons discernible in some part of the nucleus in primates, such as rhesus macaques (subject to much experiment) and man. It must be noted at once, because of proposals to equate this pattern with function such as trichromatic vision (Le Gros Clark 1940, 1949), that the number and arrangement of laminae varies among mammals, being three in cats (also much experimented upon). Lamination also shows regional variation in the nucleus in most species, including man. Phylogenetically, an original division into *two* laminae has been suggested, serving separate terminations of ipsi- and contralateral retinal fibres (Polyak 1957); but all six

A

7.138 A. The lateral geniculate body, shown in coronal section in the human brain to display its general position and orientation: it is the cap-shaped mass of grey and white matter near the centre of the field. Note its relationship to the inferior horn of the lateral ventricle, the structures visible on the sectioned surface of the midbrain tegmentum and the dorsal thalamus. Even at this low magnification the lamination of the lateral geniculate body is visible. The four diagrams show the right lateral geniculate nucleus in section: B. a mature human nucleus in coronal section near its central region and (C) near its posterior pole. Note the reduction in the number of discernible laminae in the latter. The lamination is also visible (D) in an approximately horizontal section at the time of birth. In some primates, e.g. *Tarsius* (E), the magnocellular layers (1 and 2) are curved externally around the parvocellular layers (3–6); the higher primate arrangement is almost the reverse of this when examined in the coronal plane. See text for further details and consult Le Gros Clark (1932), Cooper (1945), Chacko (1955). Dissection and photography as in 7.137.

layers appear simultaneously in human embryos (Cooper 1945). With the development of two classes of neurons, large and small, such primary layers may have split; interlaminar strata of larger cells occur between the three recognized laminae in the feline nucleus (Thuma 1928).

Considering the human lateral geniculate body, particularly as regards its intrinsic and external connections and functional interpretation, it is necessary to emphasize that such details are almost entirely extrapolated from experimental results, observed chiefly in cats and monkeys and linked with a comparative structural study in mammals, including many primates. Commonly used experimental animals, especially monkeys, show such similarity of organization in the lateral geniculate body that data established thus may usually be extrapolated to mankind with some degree of confidence.



The appearance and orientation of the laminae are shown in figure 7.138A–E. Orientation is often confusingly presented in textbooks as stated by Cooper (1945) and Chacko (1955), their relation to other structures being obscured by the omission of reference data. Often depicted in coronal sections (7.138A), they are also shown in sagittal section; in both the lamination is apparent, since the laminae fit like a series of caps set one upon another. The lamination is fully displayed in coronal sections central in the nuclear mass but becomes slanted towards its caudal pole. Rostrally, i.e. near the entry of the optic tract, the layers are blended into a common mass and at the caudal extremity are reduced to four, in a region considered to be monopolized by macular terminations. As illustration 7.138B shows, the laminae are curved, with a ventral concavity as a kind of 'hilum', where some retinal efferents enter from the optic tract. This hilum is more prominent in monkeys than in man. Dorsally, the nucleus is rounded, projecting towards the thalamus; from this dome most fibres of the optic radiation, the *geniculostriate projection*, emerge from the nucleus. Medially and laterally the laminae blend, at the edge of the cap-shaped mass. The lateral border is sharp; blending layers reverse their curvature here, becoming ventrally convex, upturned like the peak of a cap. Concave laminal contours are also reversed in the caudal (macular) part. Hence laminar profiles in the coronal plane are laterally sinuous. (Some of the confusion concerning lateral geniculate lamination is due to reversal of their order in some lower primates, large-celled laminae 1 and 2 being '*external*' and *dorsal* to the curvature of the entire structure. In *Tarsius* this is extreme (7.138E), lamination being an *inverted replica* of the human condition. In lemuroids transitional states occur. Much controversy has been entailed thus by the terms inversion and eversion, which need not detain us here.

The most careful estimates (Kupfer et al 1967) suggest a population of about one million neurons in a human lateral genicuate body, with corresponding numbers of fibres in the optic nerve and tract. Estimates in macaque monkeys reach 1·8 million (Le Gros Clark 1941) and 1·7 million (Rakic 1977) but only 1·2 million in the optic nerve (Bruesch & Arey 1942). Compare Chow et al (1950). This 1:1 ratio does not imply that each human optic nerve fibre connects with one geniculate cell. This relationship may obtain for the macula, but details are still uncertain. It is long established (Minkowski 1913, Le Gros Clark 1941, Glees 1941) that each fibre from a retinal ganglion cell ends by dividing into five or six terminals connecting with the same number of geniculate neurons in *one* lamina. (Geniculate cells may also connect with terminals from more than one retinal fibre.) Laminae are usually numbered 1–6, from the concave or hilar aspect. Fibres from the *contralateral* optic nerve end in layers 1, 4 and 6, *ipsilateral* in layers 2, 3 and 5. Early recognition of transneuronal degeneration (p. 871) in the lateral geniculate body (Minkowski 1913), coupled with adequate terminal degeneration technique (Glees 1946), led to detailed plotting of this bilateral retinal representation in each lateral geniculate body. Even with the Marchi technique alone (Brouwer & Zeeman 1926) it was shown in monkeys, by studying results of retinal lesions, that fibres from the retinal quadrants are located correspondingly in the optic nerves (p. 1095 and 7.139), the macular fibres being central. An orderly but somewhat different arrangement was also demonstrated in the optic chiasma and tract (7.139) but, in the tract, fibres from corresponding quadrants in *both* retinae occupy the *same* location, a pattern carried into the lateral geniculate body, where macular fibres terminate centrally and caudally in the nucleus, peripheral fibres rostrally, upper retinal quadrants laterally and the lower ones medially (7.139). Transneuronal techniques permitted more precise plotting (Le Gros Clark & Penman 1934) and, since cortical projection fibres of affected geniculate neurons also degenerate, it became clear that similarly precise point-to-point connection continues through the optic radiation to the striate cortex (p. 1058). This precise topical organization in the visual pathway has been repeatedly confirmed in cats and monkeys (Polyak 1957, Meikle & Sprague 1964, Saavedra et al 1969). (Doubts as to factors causing transneuronal degeneration in the lateral geniculate nucleus have been expressed. There is evidence that it is not due solely to deafferentation by e.g. optic tract interruption. Consult Garey et al (1976) for discussion.) As detailed elsewhere (p. 1058), ablation of small parts of the striate cortex leads to highly localized groups of degenerating geniculate cells in *six layers* on the same side. These effects form a *columnar representation* of *corresponding points* in *two retinae*, each in *three* of the six laminae. Results of transneuronal degeneration in the nucleus, following the destruction of retinal ganglion cells or of their axons, have been confirmed by equivalent but less dramatic effects of prolonged visual deprivation in kittens (Wiesel & Hubel 1963, Guillery 1973) and infant monkeys (Von Noorden 1973, Headon & Powell 1973). These experiments (suturing of eyelids) have been performed unilaterally and bilaterally; in the latter (Headon & Powell 1978) an unexplained finding is that the shrinkage of geniculate neurons observed in such experiments was greater in nuclear regions receiving fibres from monocular retinal fields when *both* eyes were subjected to prolonged closure. Autoradiographic tracing of labelled amino acids (subject to orthograde axoplasmic flow and even transneuronal transport) has confirmed these earlier results (see Graybiel 1975, Hubel et al 1976, Rakic 1976), with regard to both laminar terminations and the anatomical orientation of neurons in the nucleus and visual cortex.

Lateral Geniculate Interactions

So far the post-retinal visual pathway has been considered as a series of parallel conductors with no interaction between them, whether from one retina or both. Indeed, it has long been assumed that, apart from the inevitable convergence of far more numerous rods and cones upon the more limited population of retinal ganglion cells (p. 1195) and complex intraretinal interactions (p. 1201 et seq.), the visual pathway consists of functionally isolated conductors with a simple relay in the lateral geniculate body. This has been customary textbook teaching; the assembly of fibres from both retinae in the geniculate body was vaguely dubbed subcortical 'fusion', a naive assumption without data beyond those recounted above. Retinal neuronal organization is well known to be complex; clear evidence, anatomical and physiological (p. 1196), indicates interaction between its neurons. The pattern of impulses in the optic nerve is not the simple imprint of a mosaic of receptor responses, like signals in a cable between a television camera and monitor, even if the effects of corticofugal connections are ignored (p. 1203). Integrative activities in the cat's lateral geniculate body have also been demonstrated (Hubel & Wiesel 1961) between corticofugal fibres and the centripetal sensory projection, as in other sensory paths. While unit recording demonstrates both lateral inhibition and units responsive to specific modes of stimulation, *no clear evidence* indicates that *individual* geniculate cells receive impulses from *both* retinae (Glees 1961).

Increasingly elaborate cytological detail of dendritic fields and synaptic features has been recorded in cats and monkeys, impossible even to survey briefly here; reference to the reports of Peters & Palay (1966), Campos-Ortega et al (1968), Lieberman (1973, 1974) and Lieberman & Webster (1974) will provide an introduction to synaptic organization of the dorsal lateral geniculate nucleus. Lieberman has identified a variety of synapses, pre- and postsynaptic, inhibitory and excitatory, dendrodendritic, and triplet synapses (triads) of glomeruli (vide infra). These and other researches carried out in rodents, cats and monkeys show some species differences but basic resemblances predominate. To

correlate these findings into a model of geniculate activity is not yet possible but the view of this as a simple relay mechanism is completely demolished. Three main elements are involved: (1) *afferents* from the retinae, with some *corticofugal fibres* and perhaps ubiquitous *reticular axons*; (2) the *efferent geniculostriate projection*, (3) an *intrinsic neuronal population*, largely of Golgi type II cells, not all of whose axons are confined to single laminae (and hence some may possibly mediate connections between bilateral retinal afferents). Most accounts say little of the precise arrangement of cells (Golgi type I) whose axons stream through intervening laminae to form the geniculostriate radiation; attention has been largely concentrated, in light and electron microscope studies, on dendritic arrangements and the distribution and attributes of the synapses, and their profusion in the resulting neuropil suggests a highly complex, interneuronal mediation between the afferents and efferents (Szentágothai 1963, Lieberman 1974). A special feature is the occurrence of *glomeruli*, conglomerations of synapses between dendritic and axonal terminals, the latter in part from optic nerve fibres (Peters & Palay 1966, Campos-Ortega et al 1968, Lieberman 1974). Similar to synaptic glomeruli in the cerebellum (p. 971) and in other thalamic 'relay' nuclei (p. 1000), they probably serve similar integrative functions. Glomeruli are complexes of a main and peripheral axons, a main and peripheral dendrites and various other neuronal and glial elements (p. 888). Some axons may be involved in several glomeruli; others, structurally distinguishable, occur in the glomerular periphery, making synaptic contacts both with peripherally placed dendrites *and* with the central axon. The latter type of synapse, like other *axoaxonal* connections, is probably inhibitory (Eccles 1964, Shepherd 1974). Dendrodendritic and axodendritic are, however, the predominant types of synapse (Lieberman 1974). Such observations indicate a structural substrate for inhibitory and excitatory receptive field effects identified by unit recording in the lateral geniculate nucleus (Hubel & Wiesel 1961). Similar glomeruli have been identified in monkeys (Colonnier & Guillery 1964). Brauer & Winkelmann (1976) have surveyed the functions of interneuronal participation in mammalian glomeruli. *Synaptic* glomeruli are not to be confused with groups of nerve cells, also called glomeruli, described much earlier (Taboada 1927); these also exist in all laminae of the simian geniculate nucleus, the numbers increasing from 12–15 in lamina 1 to 60–100 in lamina 6. Peters & Palay (1966) suggested that somata of neurons whose neurites are involved in a *synaptic glomerulus* may be clustered together as a *cellular glomerulus*, a tentative view which equates the latter with the groups noted above. Electron microscopic evidence suggests that synaptic glomeruli may be more complex in outer laminae of the lateral geniculate nucleus.

Findings so far noted largely concern *intra*laminar integration; *inter*laminar interaction is of special interest respecting integration of signals from both eyes. Since each retinal ganglion cell axon terminates, as far as is known, merely in one lamina, any interaction between fibres derived, as is presumed, from ganglion cells near the same locus in one retina but ending separately in three geniculate laminae requires interlaminar connections. Even were these unsupported by anatomical evidence, the results of unit recording at geniculate level indicate their existence. Similar reasoning might apply to the interaction between impulses from corresponding loci in *both* retinae (but vide infra). Again, as far as is known, each lamina projects separately to the striate cortex and not, as some diagrams vaguely depict, by a fictitious form of neuron with a soma in each lamina and a conjoined axon projecting to the cortex! Physiological evidence suggests that impulses from the *two* retinae are integrated *only* at cortical level (Hubel & Wiesel 1969). However, it has been claimed that unit recording demonstrates binocular interaction at lateral geniculate level; and electron microscopy suggests that in the neuropil between the laminae are synapses between intrinsic lateral geniculate neurons (Guillery & Colonnier 1970, but vide infra). Neurons in laminae, probably secondary interneurons, have also been claimed to mediate interlaminar connections (Guillery 1966, 1971); these *could* channel the effects from both retinae towards single geniculostriate fibres. It is on such problems that most synaptological research on geniculate neurons is currently focused. Peculiarities of the interneurons have attracted special attention (Lieberman & Webster 1974); many, perhaps almost all are amacrine in rodents and some, at least, are anaxonal in monkeys (LeVay 1971). They are integrative, as is clear from their complex presynaptic contacts with retinal and cortical connections in glomeruli. In their most recent summary of activity in visual pathways, Hubel & Wiesel (1977) gauge the evidence strongly *against* the existence of lateral geniculate neurons responding to biretinal impulses and they reject 'fusion' at this level.

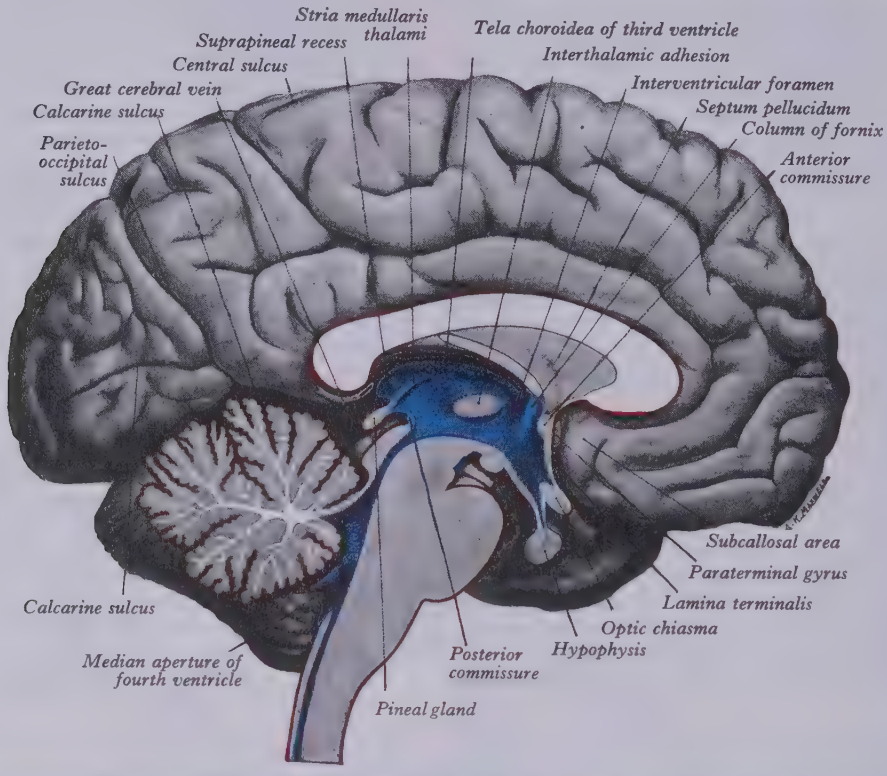
7.139 A diagram of the visual pathway to show the spatial arrangement of nerve cells and their fibres in relation to the quadrants of the retinae and visual fields. The proportions at various levels are not exactly to scale and in particular the macula is exaggerated in size in the visual fields and retinae. In each quadrant of the visual field, and the parts of the visual pathway subserving it, two shades of the respective colour are used, the paler for the peripheral fields and a darker shade for the macular part of the quadrant. From the optic tract onwards these two shades are both made more saturated to denote intermixture of neurons from both retinae, the palest shade being reserved for parts of the visual pathway concerned with uniocular vision. The path of the light reflex has also been indicated.

The Third Ventricle

The third ventricle (7.125, 140, 191A,B), a derivative of the primitive forebrain vesicle, is a median cleft lying mainly between the two (dorsal) thalami and hypothalami but extending beyond them to the epithalamus and subthalamus and communicating caudally with the fourth ventricle by the cerebral aqueduct and rostrally with the lateral ventricles through the interventricular foramina. A roof, a floor, anterior and posterior boundaries and two lateral walls are ascribed to it.

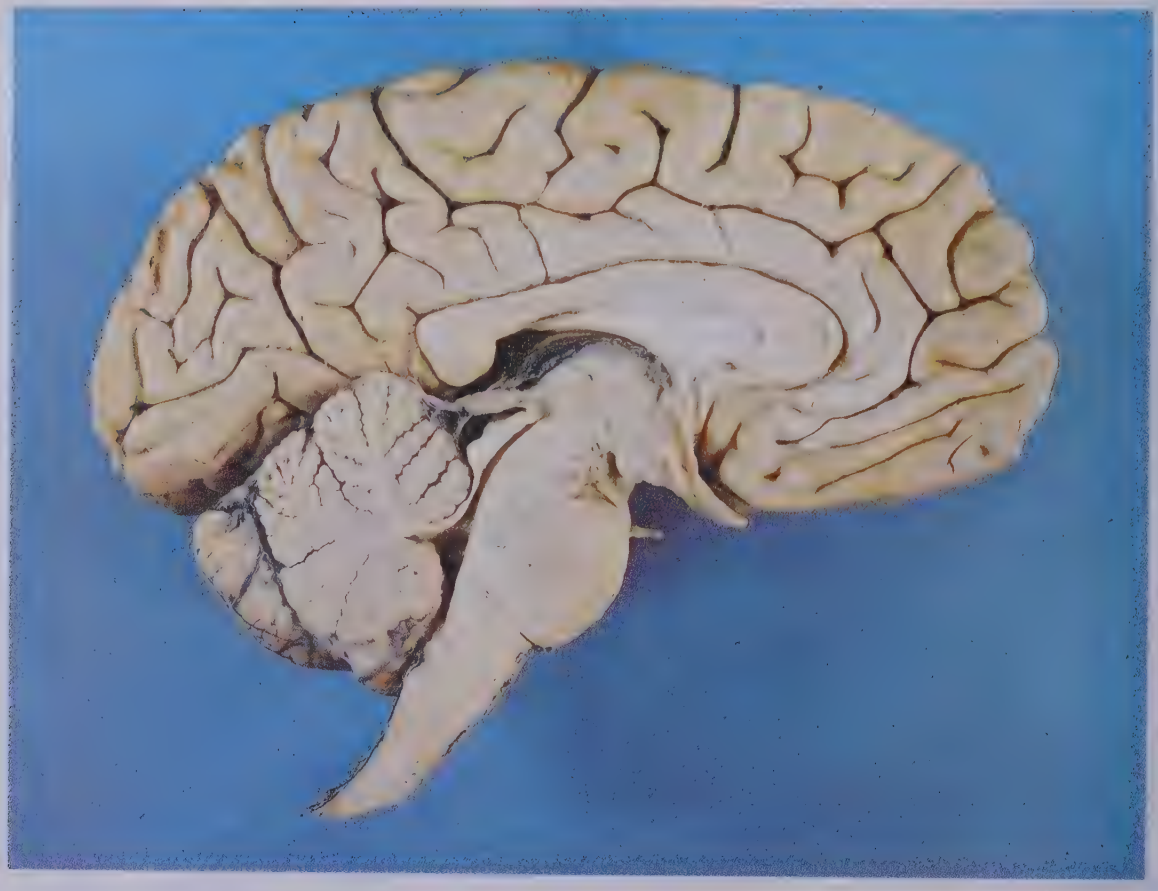
The *roof* is a layer of ependyma stretched between the upper edges of the lateral walls and is continuous here with the general ependymal ventricular lining. The roof is covered by and adherent to a reduplicated fold of the pia mater, the *tela choroidea*, from the surface of which a pair of parasagittal vascular fringes, *choroid plexuses*, project vertically downwards, invaginating the ependymal roof into the cavity (7.198).

The *floor* (7.133, 140) descends ventrally and is formed mainly by hypothalamic structures; rostrocaudally these are: the optic chiasma, infundibulum and tuber cinereum and the mamillary bodies, caudal to which the floor is formed by the posterior perforated substance and tegmentum of the cerebral peduncles. The ventricle is prolonged into the infundibulum as the *infundibular recess*. The neurohypophysis is continuous with the apex of the infundibulum.



The *rostral boundary* (7.133, 140) is ventrally the *lamina terminalis*, the rostral end of the neural tube. It is a thin layer stretching from the dorsum of the optic chiasma to the rostrum of the corpus callosum. Above this the boundary is formed by the fornical columns, diverging as they descend into the lateral walls of the third ventricle and by the anterior commissure (p. 1034), which crosses the midline rostral to the columns. At the junction of the floor and the rostral wall, just above the optic chiasma, the ventricle has a small angular *optic recess*. At the junction of the roof with the rostrolateral limits of the ventricle are the *interventricular foramina*, by which the third and lateral ventricles communicate. They represent sites of original diverticular outgrowths from the telencephalon to form the cerebral hemispheres, being *relatively* large and circular in a 10 mm human embryo. In the adult, however, they are crescentic slits, between the curving columns of the fornix (anteriorly) and convex anterior thalamic tubercules (posteriorly).

The *posterior boundary* (7.140) consists of the pineal gland, posterior commissure and cerebral aqueduct. A *pineal recess* projects into the pineal stalk, above which is a *suprapineal recess*, a diverticulum of the epithelial ventricular roof.



Each *lateral wall* has an upper part, which is the medial surface of the rostral two-thirds of the (dorsal) thalamus, and a lower formed by the hypothalamus continuous with the grey matter of the floor and part of the subthalamus, the upper and lower areas being separated by the curved *hypothalamic sulcus*, extending from the interventricular foramen to the cerebral aqueduct; the sulcus varies from deep to scarcely perceptible. As noted (p. 997),

the hypothalamic sulcus divides the diencephalon; above (dorsal to) the sulcus is the *pars dorsalis diencephali* (dorsal thalamus and epithalamus) and below (ventral) is the *pars ventralis diencephali* (hypothalamus and subthalamus). Each lateral wall is limited dorsally by a ridge covering the stria medullaris thalami (7.125).

The columns of the fornix curve ventrally rostral to the interventricular foramina to run in the lateral walls, where at first they are prominent, rapidly sinking into them. The lateral walls are joined across the cavity by the *interthalamic adhesion*, a band of grey matter (p. 998). An extensive account of the phylogeny and

development of the third ventricle has been contributed by Kier (1977). The specialized ependyma forming *circumventricular organs* is described on pp. 189, 894, 1005.

The interpeduncular fossa (7.81, 132, 146A,B), a trapezoid area, is limited anteriorly by the optic chiasma, posteriorly by the anterosuperior surface of the pons, anterolaterally by the converging optic tracts and posterolaterally by the diverging cerebral peduncles. The structures in it have been described, being the posterior perforated substance, mamillary bodies, tuber cinereum (pp. 1007, 1014), infundibulum and hypophysis cerebri (p. 1009).

THE TELENCEPHALON OR 'ENDBRAIN'

Expansion of the telencephalon and development of the cerebral hemispheres are described in pp. 192-194. In earlier vertebrates each hemisphere is predominantly concerned with olfactory signals, entering it rostrally at the *olfactory lobe*. This lobe is elongated as an *olfactory bulb* connected to the hemisphere by an *olfactory tract*. Basally in each hemisphere masses of grey matter, *basal nuclei*, form early motor centres. The wall of the hemisphere is the *pallium*, where olfactory and other information are presumably integrated. During evolution visual, auditory and other paths have extended through the thalamus to the cerebral pallium, an instance of encephalization. Each hemisphere is thus enlarged by an additional *neopallium*, the largely olfactory pallium being confined to a *piriform lobe*, sited inferolaterally. The hemisphere's medial wall becomes specialized as the *hippocampal formation*, long regarded as primarily olfactory, a view now untenable (see p. 1035). In higher mammals the neopallium is greatly enlarged and the piriform lobe relatively reduced; neopallial motor paths develop from it but the basal nuclei remain essential parts of motor control. This mammalian neopallial expansion is largely due to the growth of *association areas* concerned with interaction between afferent and efferent connections. The hippocampal formation is often termed *archipallium* or *primal* cortex and the piriform lobe *paleopallium* or *ancient* cortex; some, however, group both as *archipallium*.

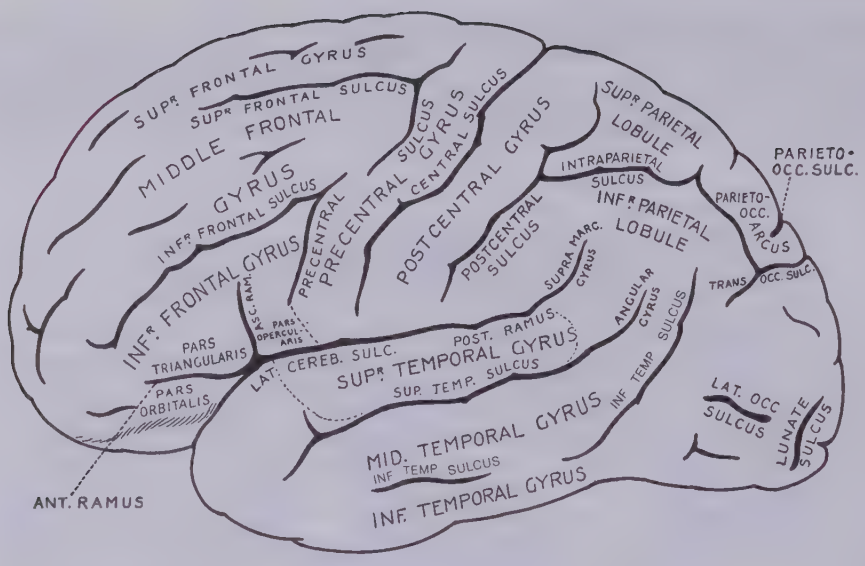
The telencephalon includes: (1) the cerebral hemispheres, their commissures and their cavities; (2) the anterior part of the third ventricle, including the preoptic regions in the telencephalon impar (p. 1007). Each cerebral hemisphere has an external stratum of neurons, the *cortex*, an internal mass of neuronal processes (*centrum semiovale*), deeply situated *basal nuclei* and a *lateral ventricle*. The cerebral hemispheres are the largest part of the brain and, viewed from above, have an ovoid shape, broader behind, the greatest transverse diameter being between the parietal tuberosities. They are incompletely separated by a deep median cleft, the *longitudinal cerebral fissure*, each hemisphere containing a *lateral ventricle*.

The longitudinal cerebral fissure contains a crescentic fold of the dura mater, the *falx cerebri*, and anterior cerebral vessels; in front and behind, the fissure completely separates the hemispheres; centrally it descends to a large commissure, the *corpus callosum*, connecting the hemispheres.

Surfaces of the Cerebrum

Each cerebral hemisphere presents superolateral, medial and inferior surfaces or aspects.

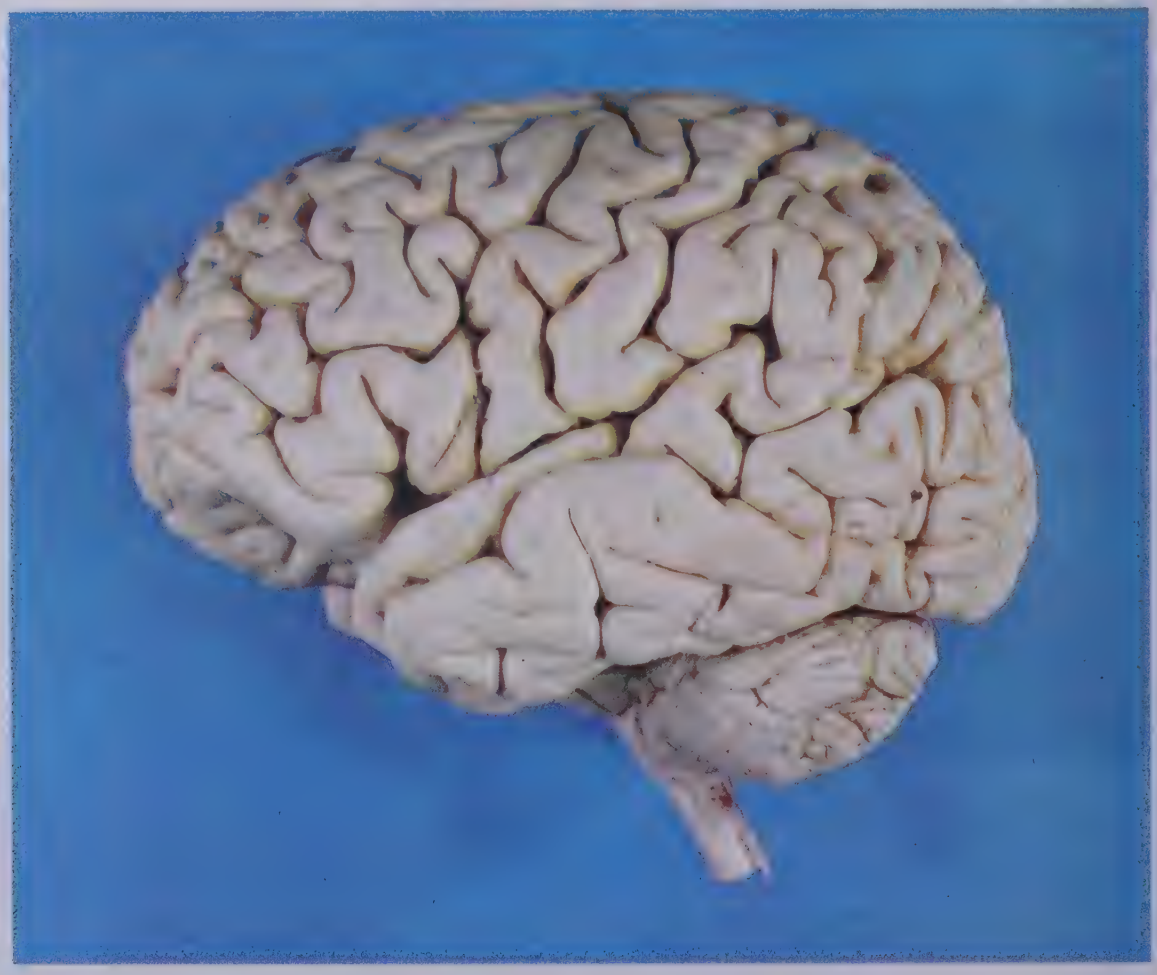
The *superolateral surface* is adapted to the concavity of its half of the cranial vault. The *medial surface*, flat and vertical, is separated from its fellow by the longitudinal fissure and falx cerebri. The *inferior* (*basal*) *surface* is irregular and divided into orbital and tentorial regions; the orbital part of the frontal lobe is concave and lies above the orbital and nasal roofs. The tentorial region is the concavoconvex inferior surface of the temporal and occipital lobes, anteriorly adapted to its half of the middle cranial fossa; posteriorly it is above the tentorium cerebelli which is interposed between it and the superior cerebellar surface.



The surfaces are separated by the following borders: (1) *superomedial*, between the superolateral and medial surfaces; (2) *inferolateral*, between the superolateral and basal surfaces (its anterior part separates the superolateral from the orbital surface in the frontal lobe, as the *superciliary* border); (3) *medial occipital*, between the tentorial region of the inferior surface and the medial; (4) *medial orbital*, separating the orbital region of the inferior surface from the medial. The anterior and posterior hemispheric extremities are the *frontal* and *occipital poles* respectively; the temporal pole is the anterior extremity of the temporal lobe. About 5 cm anterior to the occipital pole on the inferolateral border is the *preoccipital incisure*.

A paramedian line, from a point a little superolateral to the inion to one just superolateral to the nasion, marks the superomedial margin. The superciliary border is at the level of the eyebrows as far as the zygomatic process of the frontal bone, ascending thence to the pterion. The temporal pole corresponds to a line, convex forwards, on the surface of the head, from the pterion to the midpoint of the upper border of the zygomatic arch; it then continues back above the arch to cross the ear a little above the external acoustic meatus; it corresponds to the inferolateral margin, which then curves down to the posterior end of the superomedial margin (**6**.151).

Hemispheric surfaces are moulded into a number of *gyri* or *convolutions*, separated by *sulci* or *fissures*. This familiar appearance is gradually achieved. Until the end of the third fetal month, the surfaces are smooth, as in the brains of reptiles and birds. Thereafter localized depressions appear, deepen and extend over the surfaces as sulci (see p. 192). Each sulcus is an infolding of the cortex, increasing the cortical grey matter about three times. Some sulci develop along the zones separating areas differing in details of structure and functions (Le Gros Clark 1945) and may be termed *limiting sulci*. The central is a limiting sulcus, being between two areas differing in thickness enough to be visible to the eye (7.146A). Some sulci develop in the long axis of a rapidly growing area and are *axial sulci*; the posterior part of the calcarine sulcus is merely a fold in the centre of the striate area. In other sites a sulcus may be between two structurally different areas; but its lip, not its floor, may divide two areas and then a third area may be in the walls of the sulcus without appearing on the surface; such a sulcus is *operculated*, exemplified in the human brain by the lunate sulcus, separating striate from peristriate areas on the surface and containing the submerged parastriate area, which intervenes between them. These varieties include all sulci on the surface, except the lateral sulcus and parieto-occipital sulci; the former results from the slower expansion of the insular cortex with consequent submersion by adjoining areas, which eventually come into contact to delimit the lateral sulcus. The parieto-occipital sulcus is associated with the development of the corpus callosum. The posterior end of this commissure conveys not only fibres from the occipital lobes but also a large number from the temporal lobes. Hence, several smaller axial and limiting sulci are crowded together and some are buried in the walls of the parieto-occipital sulcus. These are really *secondary sulci*, depending on factors other than exuberant growth in the adjoining areas.



Some sulci are deep enough to produce elevations in the ventricular walls; the anterior part of the calcarine sulcus, which thus produces the calcar avis of the posterior cornu, and the collateral fissure, producing the collateral eminence in the inferior cornu, are therefore termed *complete fissures*; but no special morphological or functional significance is attached to the fact that some sulci are complete and others incomplete.

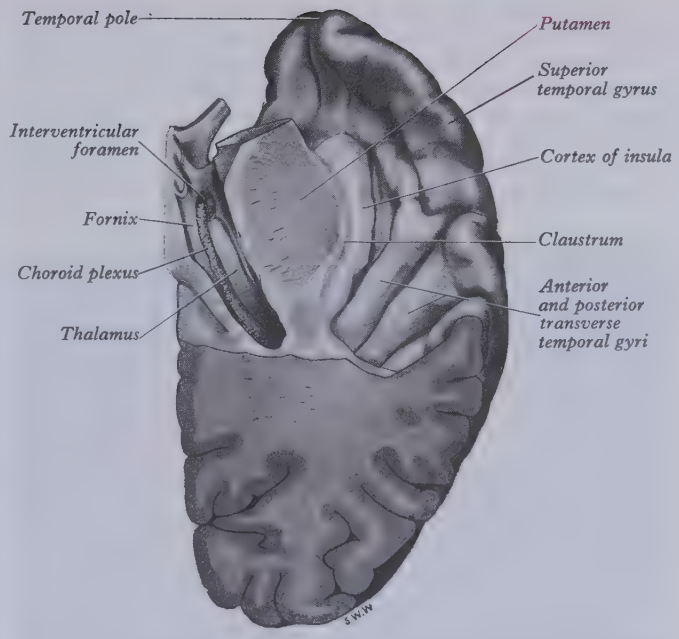
Gyri and their intervening sulci are approximately constant in their general overall arrangement but vary in their dimensions and minor details (or even their occurrence in the smaller cases), not only in different individuals but in the hemispheres of one brain. The gyral pattern is an inevitable result of the greater

7.141A Lateral aspect of the superolateral surface of the left cerebral hemisphere.

increase in volume of the pallium or mantle of neurons in the cortex compared with the much smaller increase in the subjacent white matter. The area of the human cortex is about 2200 cm^2, a third of this being visible on the surface while the rest is obscured in the sulci and fissures. By this mode of evolution a large increase in the cortical area entails a lesser change in cranial capacity; but it is misleading to explain the arrangement in this teleological manner. Similarly, a presumed association of high intelligence with great complexity of convolutional pattern is fallacious; the most intricate arrays of sulci and gyri occur in the cerebra of the

7.141B A left lateral view of the brain to show the pattern of gyri and sulci on the superolateral aspect of the cerebral hemisphere. Compare with 7.141A, which was drawn from a different specimen, for labelling of the many structures visible. Note also the contrasting cortical patterns of the cerebrum and cerebellum. Preparation by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

elephant and whale (Hammelbo 1972), both of which also have larger brains than man, though not so in relation to total size. No close relation between gyral complexity and brain size with cerebral abilities has been established in mankind; abundant examples of highly able individuals with relatively small brains and the reverse of this are attested. Attempts to draw deductions from endocranial casts of fossil forms, as an indication of development of certain gyri and hence abilities (e.g. capacity for speech), have likewise proved misleading and are largely abandoned except by anthropologists.

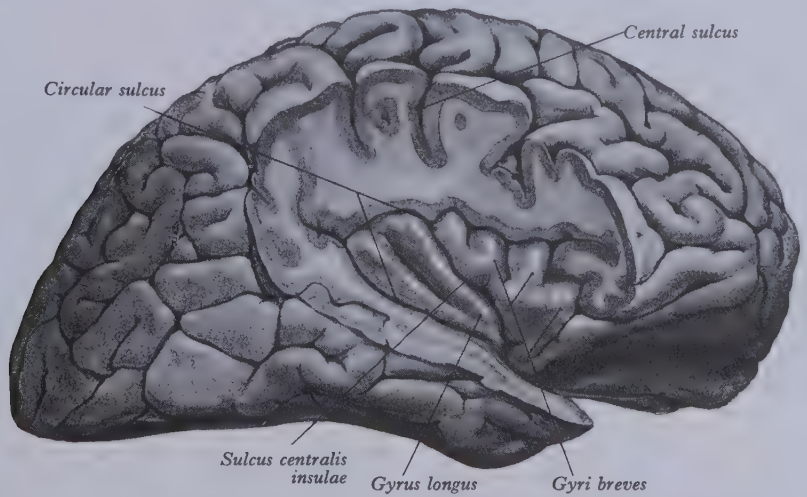


It is convenient to separate the cerebral hemisphere into a number of lobes but this division is purely descriptive; nor do lobes precisely correspond in surface extent to the cranial bones from which they take their names.

THE SUPEROLATERAL CEREBRAL SURFACE

Two sulci, viz. the *lateral* and *central*, are the outstanding features of this surface and the main factors used in limiting its surface divisions (7.141A,B).

The lateral sulcus (7.141, 146), a deep cleft on the inferior and lateral surfaces, has a short stem dividing into three rami. The *stem* commences inferiorly at the anterior perforated substance, extending laterally between the frontal lobe's orbital surface and the anterior pole of the temporal lobe. It is adapted to the posterior border of the sphenoid's lesser wing and contains the sphenoparietal venous sinus. Reaching the lateral surface it divides into anterior horizontal, anterior ascending and posterior rami. The *anterior ramus* runs forwards for 2·5 cm or less into the inferior frontal gyrus while the *ascending ramus* ascends for an equal distance into the same gyrus; the *posterior ramus*, the longest, runs posteriorly and slightly up across the lateral surface for about 7 cm, turning up to end in the parietal lobe. Its floor is the limen insulae and insula; it conducts the middle cerebral vessels from the inferior to the superolateral surface. It is represented by a line sloping back and slightly up for about 7 cm from the pterion, then curving up to the parietal eminence.

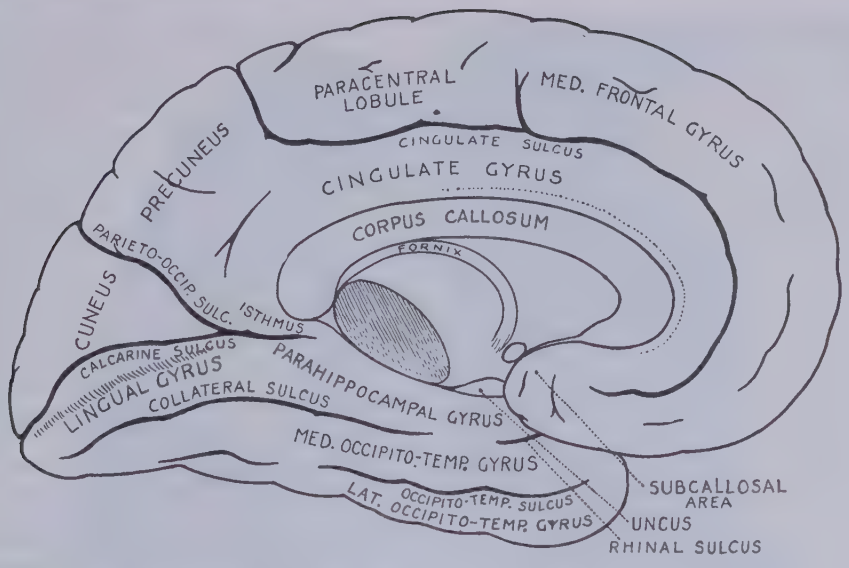


The central sulcus (7.141A,B) starts in or near the superomedial border a little behind the mid-point between the frontal and occipital poles (i.e midway between the nasion and inion). It runs sinuously down and forwards for about 8–10 cm to end a little above the posterior ramus of the lateral sulcus, from which it is always separated by an arched gyrus. Its general direction makes an angle of about 70° with the median plane (7.141A,B). It demarcates the primary motor and somatosensory areas of the cortex (pp. 195, 1047). When the sulcus is opened up, its opposed walls are seen to be marked by small gyri which alternate like gears in mesh, hence termed *interlocking gyri*. This provides an additional cortex without the corresponding increase in the surface area. About the middle of the sulcus its walls are usually connected by a transverse gyrus; this is due to the mode of development of the central sulcus. When it appears in the sixth month, it is in the superior and inferior parts, at first separated by a transverse gyrus connecting the precentral to the postcentral gyrus. The two occasionally remain separate but usually coalesce, the transverse gyrus being buried as a *deep transitional gyrus*.

7.142 Horizontal section showing the superior surface of the right temporal lobe.

The frontal lobe, the rostral region of the hemisphere, is limited behind by the central sulcus, above by the superomedial border and below by the superciliary border and stem of the lateral sulcus. Its superolateral surface is traversed by three sulci and four gyri. The *precentral sulcus* is parallel to the central, separated from it by a precentral gyrus and usually divided into upper and lower parts, which may be confluent. The *superior frontal sulcus* curves forwards from about midway in the upper precentral sulcus; the *inferior frontal sulcus* is parallel but at a lower level. The area of frontal lobe anterior to the precentral sulcus is thus divided into the superior, middle and inferior frontal gyri; an incomplete sulcus often divides the middle gyrus (7.141A,B).

The *precentral gyrus*, with the central sulcus posterior and precentral sulcus anterior to it, extends from the superomedial border, where it is continuous with the paracentral lobule on the medial surface, down to the posterior ramus of the lateral sulcus.



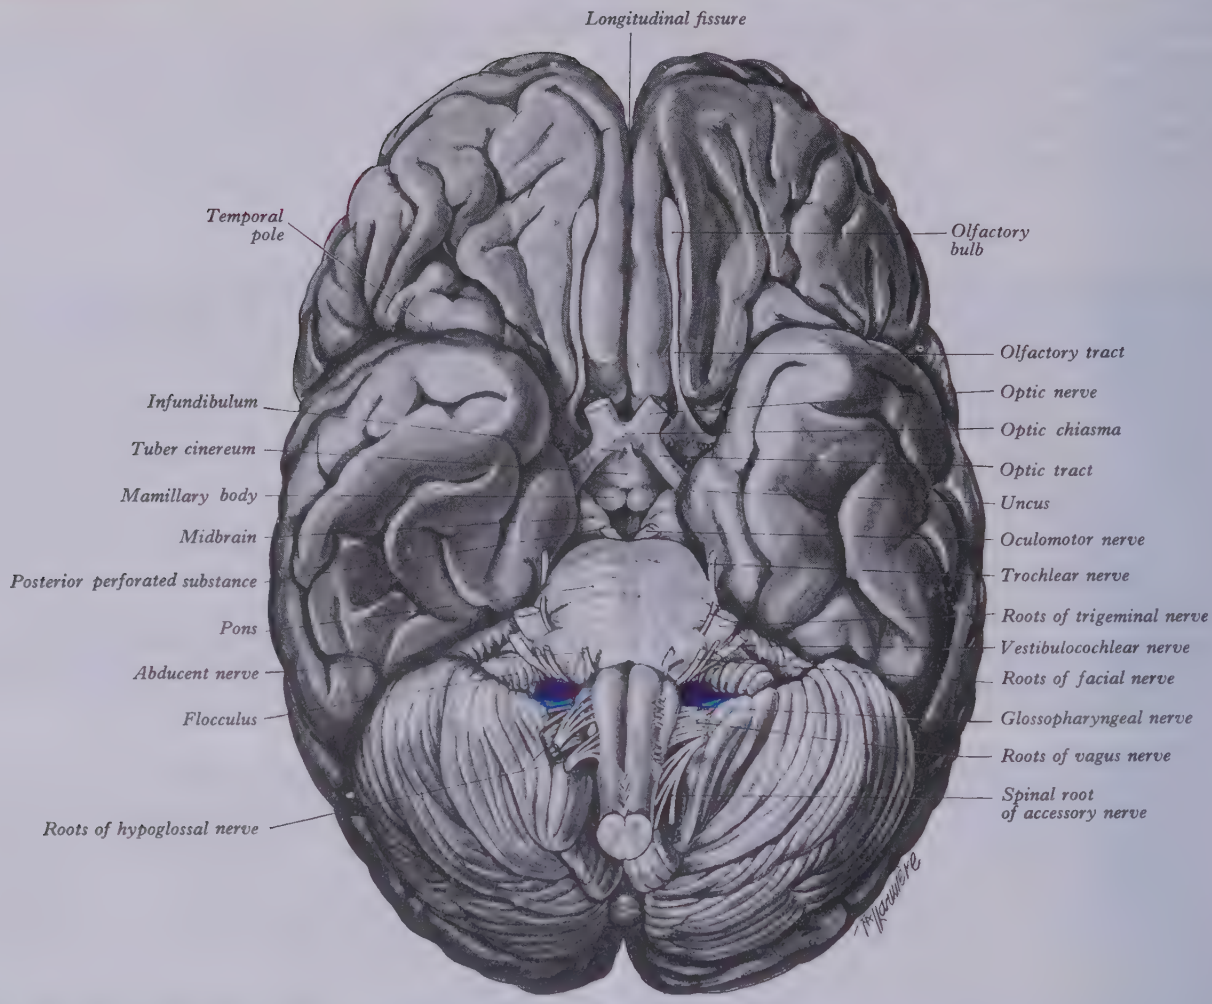
7.143 The right insula, exposed by the removal of its opercula.

Its cortex is the origin of many of the fibres of large corticonuclear and corticospinal tracts, in addition to a multitude of other connections.

The *superior frontal gyrus*, above the superior frontal sulcus, is continuous over the superomedial margin with the medial frontal gyrus. It may be incompletely divided (7.141A,B). The *middle frontal gyrus* is between the superior and inferior frontal sulci. The *inferior frontal gyrus* is below the inferior frontal sulcus and is invaded by the anterior and ascending rami of the lateral sulcus. The areas around these rami on the left are the *speech area of Broca* (areas 44 and 45), associated with the motor aspects of speech (p. 1055). The region below the anterior ramus is the *pars orbitalis*, curving round the superciliary margin to the orbital surface. The area between the ascending and anterior rami is the *pars triangularis* and that posterior to the ascending ramus is the *pars opercularis* (*posterior*), continuous posteriorly with the inferior end of the precentral gyrus.

7.144 A series of dissections of the left cerebral hemisphere at progressively deeper levels to demonstrate the insula and subjacent structures: A. the intact brain; note the position of the posterior ramus of the lateral cerebral sulcus on which the dissections are centred; B. the cortical gyri of the insula exposed by removal of the frontal, temporal and parietal opercula; C. the removal of the insular cortex, extreme capsule, claustrum and external capsule has exposed the lateral aspect of the lentiform nucleus (the putamen); D. removal of the lentiform nucleus displays fibres of the internal capsule coursing across its medial aspect; E. removal of part of the temporal lobe shows the internal capsular fibres converging on the crus cerebri of the midbrain; F. removal of the optic tract, and superficial dissection of the pons and upper medulla, emphasizing the continuity of the corona radiata, internal capsule, crus cerebri, longitudinal pontine fibres and the medullary pyramid. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

7.145A The medial surface of the left cerebral hemisphere, after sagittal section of the brain and removal of the brain stem.



The temporal lobe is inferior to the lateral sulcus and limited behind by an arbitrary line from the pre-occipital incisure (p. 1021) to the parieto-occipital sulcus, meeting the supero-medial margin about 5 cm from the occipital pole. Its lateral surface is divided into three parallel gyri by two sulci.

The *superior temporal sulcus* begins near the temporal pole and slopes slightly up and backwards parallel to the posterior ramus of the lateral sulcus. Its end curves up into the parietal lobe. The *inferior temporal sulcus* is subjacent and parallel to the superior and often broken into two or three short sulci; its posterior end also ascends into the parietal lobe, posterior and parallel to the upturned end of the superior sulcus.

The lateral surface is thus divided into three parallel *superior*, *middle* and *inferior temporal gyri*. Along its superior margin the superior temporal gyrus is continuous with gyri in the floor of the posterior ramus of the lateral sulcus; these vary in number, extending obliquely anterolaterally from the *circular sulcus* around the insula as *transverse temporal gyri* (7.142), usually two

7.145B The medial surface of the left cerebral hemisphere after sagittal section of the brain, followed by removal of the brain stem and septum pellucidum. (For identification of the principal gyri and sulci of the cerebral cortex, compare with 7.145A.) The dissection has been deepened in the region of the dorsal thalamus and hypothalamus to demonstrate the column, body, crus and fimbria of the fornix and the mamillothalamic fasciculus (compare with 7.148, 149). The head of the caudate nucleus is visible bulging into the floor of the anterior horn of the lateral ventricle. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

7.146A Basal aspect of the brain. The anterior perforated substance (unlabelled) is between the diverging lateral and medial roots of the olfactory tract and anterolateral to the optic tract.

(anterior and posterior), but sometimes single on one or both sides (Campain & Minckler 1976). The anterior transverse temporal gyrus and adjoining part of the superior temporal gyrus are auditory in function (p. 1055) and considered to be Brodman's area 42; the anterior gyrus is approximately area 41.

The parietal lobe extends from the central sulcus in front to a lobe joining the pre-occipital incisure to the superomedial margin where it is crossed by the parieto-occiptal sulcus. Inferior is the posterior ramus of the lateral sulcus and an imaginary posterior prolongation from its straight part. Parts of its boundaries are thus arbitrary. Its lateral aspect is subdivided into three areas by *postcentral* and *intraparietal sulci*.

The *postcentral sulcus* (7.141A,B), often divided into upper and lower parts, is posterior and parallel to the central sulcus. Inferiorly it ends above the posterior ramus of the lateral sulcus some distance in front of its upturned end, dividing the parietal lobe into the postcentral gyrus and a large posterior area, subdivided by the *intraparietal sulcus*, which usually starts in the postcentral sulcus near its midpoint or at the upper end of its lower part. It extends postero-inferiorly across the parietal lobe, dividing it into superior and inferior parietal lobules. Posteriorly, as its *occipital ramus*, it extends into the occipital lobe, joining the *transverse occipital sulcus* at right angles. The *postcentral gyrus* is between the central and postcentral sulci. Its cortex receives somatic sensory impulses (p. 1002) and has numerous other connections (vide infra).

The *superior parietal lobule*, between the superomedial margin and the intraparietal sulcus, is continuous anteriorly with the postcentral gyrus round the upper end of the postcentral sulcus; posteriorly it often joins the *arcus parieto-occipitalis*, surrounding the lateral part of the parieto-occipital sulcus (7.141A,B).

The *inferior parietal lobule*, below the intraparietal sulcus and behind the lower part of the postcentral sulcus, is divided into three: the *anterior part* is the *supramarginal gyrus* arching over the upturned end of the lateral sulcus and is continuous anteriorly with the lower part of the postcentral gyrus and postero-inferiorly with the superior temporal gyrus; it may be limited behind by a small *sulcus intermedius primus* descending from the intraparietal sulcus. The *middle part*, the *angular gyrus* (believed to be concerned with the visual element in stereognosis, p. 1017) arches over the end of the superior temporal sulcus and is continuous postero-inferiorly with the middle temporal gyrus; sometimes a small *sulcus intermedius secundus* appear at its posterior end. (Anterior and middle parts of the inferior parietal lobule are subjacent to the parietal tuberosity, p. 381.) The *posterior part* arches over the upturned end of the inferior temporal sulcus on to the occipital lobe, forming an *arcus temporo-occipitalis*.

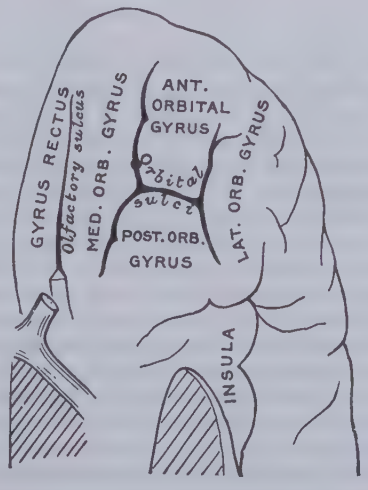
The occipital lobe is behind the arbitrary line joining the pre-occipital incisure to the parieto-occipital sulcus. The *transverse occipital sulcus* descends from the superomedial margin behind the parieto-occipital sulcus and is joined about its midpoint by the intraparietal sulcus. Its superior part is behind the *arcus parieto-occipitalis*, an arched gyrus surrounding the end of the parieto-occipital sulcus. The lateral occipital sulcus, short and horizontal on the lateral aspect of the occipital lobe, divides it into *superior* and *inferior occipital gyri* (7.141A,B). The *lunate sulcus*, when present, is just in front of the occipital pole, placed vertically and sometimes joined to the calcarine sulcus, but the two are more often separate; its lips, which are opercular, separate *striate* from *peristriate areas* but the *parastriate area* is buried in the sulcus

between the other two striate areas. The lunate sulcus is posterior to the *gyrus descendens*, which is behind the superior and inferior occipital gyri. Curved superior and inferior polar sulci often appear near the ends of the lunate sulcus. The *superior polar sulcus* arches up on to the medial occipital surface near the upper limit of the lunate sulcus; the *inferior polar sulcus* arches down and forwards on to the inferior cerebral surface from the lunate's lower limit. These polar sulci enclose semilunar extensions of the striate area (p. 1058), indicating the expansion of the visual cortex associated with the large cortical macular area (Smith 1930).

The insula (7.142-144B), deep in the floor of the lateral sulcus, is almost surrounded by a *circular sulcus* and is overlapped by growth of the adjacent cortical areas and is thus only visible when the lateral sulcus is artificially widely opened; these overlapping areas are therefore termed the *opercula of the insula*, separated by ascending and posterior rami of the lateral sulcus. The *frontal* operculum or *lid* is between the anterior and ascending rami, forming the pars triangularis of the inferior frontal gyrus; it is small when the rami arise by a common stem. The *frontoparietal operculum*, between ascending and posterior rami of the lateral sulcus, is the pars posterior of the inferior frontal gyrus and lower ends of the precentral and postcentral gyri, also the lower end of the anterior part of the inferior parietal lobule. The *temporal operculum*, below the posterior ramus of the lateral sulcus, is formed by superior temporal and transverse temporal gyri. Anteriorly the inferior region of the insula adjoins the pars orbitalis of the inferior frontal gyrus.

When the opercula are removed, the insula appears as a pyramidal area, its apex inferior and near the anterior perforated substance (7.143, 144B), where the circular sulcus is deficient and the medial part of the apex is termed the *limen insulae* (*gyrus ambiens*). The *insular surface* is divided into a larger *anterior* and a smaller *posterior* part by the *sulcus centralis insulae*, slanting posterosuperiorly from the apex. The anterior part is divided by shallow sulci into three or four *short gyri*, the posterior being one *long gyrus*, often divided at its upper end. The cortex of the insula is continuous with that of its opercula in the circular sulcus. The insula is approximately co-extensive with the subjacent claustrum and putamen (7.144B,C,D).

The angio-architecture of the primate insula has been studied by Vlahovitch et al (1973). Despite the development of the opercula in man and their exiguous size in, e.g. the baboon or chimpanzee, these observations indicated great similarity of vascular pattern in all primates examined.



7.146B The base of the brain. For labelling compare with 7.81,146A. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

THE MEDIAL CEREBRAL SURFACE

The medial surface (7.145A,B) is clearly visible only when the cerebral hemispheres are separated by division of all the commissures and the structures around the third ventricle (7.18). The most conspicuous feature is the great commissure, the *corpus callosum*, a broad arched band in the floor of the central region of the longitudinal fissure (7.140A,B). Its curved anterior part is the *genu*, continuous below with the *rostrum* and narrowing rapidly as it passes back to the upper end of the lamina terminalis. The genu continues above into the *trunk*, the main part of the commissure, which arches up and back to a thick, rounded posterior extremity, the *splenium*. To the concave surfaces of the trunk, genu and rostrum the bilateral vertical laminae of the septum pellucidum are attached, occupying the interval between them and the fornix, a curved, flat band inferior to it. In front of the lamina terminalis, almost co-extensive with it, is a narrow triangle of grey matter, the *paraterminal gyrus* (p. 1033), separated from the rest of the cortex by a shallow *posterior parolfactory sulcus*. A little anterior to this a short, vertical sulcus may occur, the *anterior parolfactory sulcus*; the cortex between these two sulci is the *subcallosal area* (*parolfactory gyrus*) (7.140, 148, 151). The anterior sloping edge of the paraterminal gyrus is sometimes called the *prehippocampal rudiment* (p. 1035).

The anterior region of the medial surface is divided into outer and inner zones by the curved *cingulate sulcus*, starting below the rostrum and passing first forwards, then up and finally backwards, conforming to the callosal curvature. Its posterior end turns up to the superomedial margin about 4 cm behind its midpoint and is posterior to the upper end of the central sulcus (7.140, 145). The outer zone, except for its posterior extremity, is part of the frontal lobe, subdivided into anterior and posterior areas by a short sulcus ascending from the cingulate sulcus above the midpoint of the corpus callosum. The larger, anterior area is the *medial frontal gyrus*, the posterior being the *paracentral lobule*. The superior end of the central sulcus usually invades the paracentral lobule posteriorly and the precentral gyrus is

7.147 The orbital surface of the left frontal lobe.

continuous with the lobule. This area is concerned with movements of the contralateral lower limb and perineal region; clinical evidence suggests that it exercises voluntary control over defaecation and micturition (pp. 1375, 1420).

The zone under the cingulate sulcus is the *cingulate gyrus*. Starting below the rostrum this follows the callosal curve, separated by the *callosal sulcus*, and continues round the splenium to the inferior surface, continuing into the parahippocampal gyrus through the narrow *isthmus* (7.148). The cingulate sulcus is interrupted posterior to the paracentral lobule but partially continued by a variable *subparietal* (*suprasplenial*) *sulcus*.

The medial surface's posterior region is traversed by two deep sulci converging anteriorly to meet a little posterior to the splenium. These are the parieto-occipital and the calcarine sulci. The *parieto-occipital sulcus* starts on the superomedial margin about 5 cm anterior to the occipital pole, sloping down and slightly forwards to the calcarine sulcus. When opened it is clear that the parieto-occipital and calcarine sulci, though on the surface apparently continuous, are separated by the deeply sited *cuneate gyrus*. The walls of the sulcus also show two or more vertical sulci, originally exposed on the medial surface but included in the parieto-occipital sulcus by growth of the splenium (p. 194). The walls of the parieto-occipital sulcus thus resemble those of the lateral sulcus, though its contained sulci and gyri are fewer and smaller.

The *calcarine sulcus* starts near the occipital pole. Though usually restricted to the medial surface, its posterior end may reach the lateral. Directed anteriorly a little above the inferomedial margin in a slightly curved course with an upward convexity, it joins the parieto-occipital sulcus at an acute angle behind the splenium. Continuing forwards it crosses the inferomedial margin to the interior aspect of the hemisphere, forming the inferolateral boundary of the *isthmus* (which, as noted, connects the cingulate with the parahippocampal gyrus). At its junction with the parieto-occipital sulcus the calcarine sulcus is crossed by a buried *anterior cuneolingual gyrus*. Its posterior part, behind the junction with the parieto-occipital, is an axial sulcus in the long axis of the visual cortex (p. 1058); but the anterior part is a limiting sulcus separating the striate (visual) cortex from that of the isthmus. The anterior part of the calcarine is a complete sulcus, producing the *calcar avis*, an elevation in the posterior cornu of the lateral ventricle.

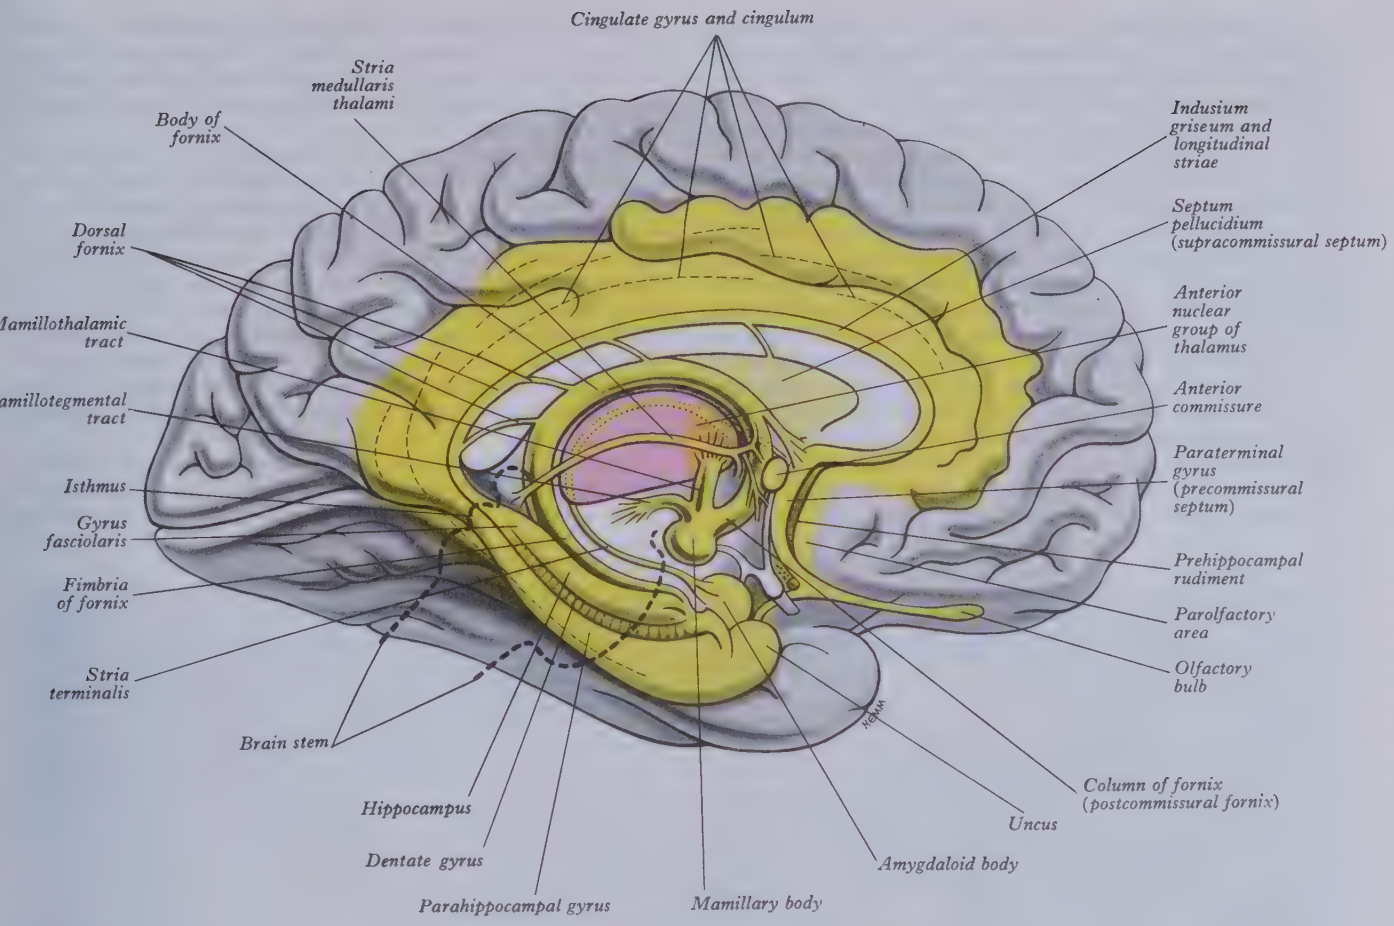
The quadrilateral area, posterior to the upturned end of the sulcus cinguli, anterior to the parieto-occipital sulcus, inferior to the superomedial margin and superior to the suprasplenial sulcus, is the *precuneus*; with the part of the paracentral lobule behind the central sulcus it forms the medial surface of the parietal lobe. The wedge of cortex bounded in front by the parieto-occipital sulcus, below by the calcarine sulcus and above by the superomedial margin, is the *cuneus* (its surface usually indented by one or two irregular sulci) and is the medial surface of the occipital lobe.

THE INFERIOR CEREBRAL SURFACE

This surface is divided by the stem of the lateral fissure into smaller and larger parts, respectively anterior and posterior to it (7.146A,B, 147). The anterior is the orbital region of the inferior surface, transversely concave and above the cribriform plate of the ethmoid, the orbital plate of the frontal and lesser wing of the sphenoid. A rostrocaudal *olfactory sulcus* traverses it near its medial margin, overlapped by the olfactory bulb and tract. The medial strip thus marked off is the *gyrus rectus*. The rest of this surface bears irregular *orbital sulci*, generally H-shaped, dividing it into *orbital gyri*, usually four: the anterior, medial, posterior and lateral orbital gyri (7.147).

The larger, posterior region of the inferior cerebral surface is partly superior to the tentorium but also to the middle cranial fossa and traversed by the anteroposterior collateral and occipitotemporal sulci (7.145). The *collateral sulcus* starts near the occipital pole, extending anteriorly and parallel to the calcarine sulcus, separated by the *lingual gyrus*. Anteriorly it may continue into the *rhinal sulcus* but they are usually separate. The *rhinal sulcus* runs forwards in the line of the collateral, separating the temporal pole from a somewhat hook-shaped *uncus* posteromedial to it. This sulcus is the lateral limit of the *piriform lobe* (7.151).

The *occipitotemporal sulcus* is parallel to the collateral sulcus and lateral to it. It usually does not reach the occipital pole and is frequently divided.



The *lingual gyrus*, between the calcarine and collateral sulci, passes into the *parahippocampal gyrus*, which commences at the *isthmus* where it is continuous with the cingulate gyrus and passes forwards medial to the collateral and rhinal sulci. Anteriorly the parahippocampal gyrus continues into the uncus, its medial edge lying lateral to the midbrain. The *uncus*, the anterior end of the parahippocampal gyrus, is the posterolateral boundary of the anterior perforated substance. The medial part of the uncus extends laterally above its lateral part and will be described later (7.151); its inferior surface is exposed only when its lateral, more superficial part has been removed (7.152). The uncus is part of the *piriform lobe* of the olfactory system (vide infra), phylogenetically one of the oldest parts of the pallium. (For details of the uncal region and complex terminology, consult illustrations 7.148 and 7.151.)

The *medial occipitotemporal gyrus* extends from the occipital to the temporal poles, limited medially by the collateral and rhinal sulci and laterally by the occipitotemporal. Lateral in this area is the *lateral occipitotemporal gyrus*, which is continuous round the inferolateral margin with the inferior temporal gyrus.

THE LIMBIC LOBE AND OLFACTORY PATHWAYS

During development the superolateral aspects of the diencephalon gradually merge with central areas of the inferomedial surfaces of the hemispheres (p. 192). *Bordering* the whole area of fusion on each side, a series of structures develops in the hemisphere's wall as the **limbic lobe**, a term introduced in 1878 by Broca on a comparative anatomical basis. Many structures of the limbic lobe (literally the *bordering* lobe) are phylogenetically old, with an arched form, topographically interposed between the diencephalon and the cerebral neopallium (7.148, 149). Interest was heightened when Papez (1937) suggested a role in emotional behaviour; subsequent research, most voluminously, has emphasized its profuse connections with the olfactory system, hypothalamus, thalamus, epithalamus and areas of the neocortex. It is intimately involved in the higher integration of visceral, olfactory and somatic information and patterns of complex long and short-term homeostatic responses. These include seeking and capturing prey, courtship, mating, rearing of young, subjective and expressive elements in emotional responses, the balance between aggressive and communal behaviour and (particularly the hippocampus), the formation of memory (Maclean 1958, 1969, Livingston 1970). For reviews, see Isaacson (1974), Isaacson & Pribram (1975), Livingston & Hornykiewicz (1978).

The terminology of these regions is complex; alternative schemes are used and common agreement in terms of a rational basis for scientific definition has not been achieved (White 1965, Brodal 1969, Bargmann & Schade 1963). However, the increasingly widespread popularity of the terms *limbic lobe* and *limbic system* indicates that many investigators currently believe that these collective names and concepts are useful, despite differences in application of the terms by some and strong opposition to their use at all by a minority (Brodal 1969). Most protagonists include a series of subcortical nuclei and their connections, the phylogenetically older areas of the cortex, archipallium and paleopallium and the adjacent neopallium—the cingulate and parahippocampal gyri and associated tracts. Difficulties arise in placing precise boundaries between these and the adjacent

7.148 Diagram of a dissection of the medial aspect of a cerebral hemisphere to demonstrate the majority of the structures included under the term limbic system in the present account; these are coloured yellow. The anterior nuclear group of the dorsal thalamus is coloured orange and included with the limbic system; the remainder of the dorsal thalamus is magenta. The approximate position of the brain stem which was removed in the course of dissection is outlined in a heavy interrupted line. This diagram should be compared with the colour photograph of a dissection prepared from the *lateral* aspect of a hemisphere (7.149).

regions, with which some are functionally connected, e.g. opinions differ concerning the inclusion of the frontal cortex and intimately related hypothalamus. There is a need for international nomenclature for as many orders of subdivision of the brain as may be needed, based on the most widely acceptable criteria available, with continuous revision as further knowledge accumulates. In this account 'limbic lobe' and 'system' are used and the structures described under these headings will be listed.

Even greater terminological difficulty attaches to the term **rhinencephalon** (Bargmann & Schade 1963). The name was once used for all brain structures associated with olfaction and it was long assumed that most limbic structures were primarily olfactory paths and centres of integration. But studies in comparative, developmental, physiological, anatomical and behavioural fields have changed the emphasis. Since 'rhinencephalon' has many meanings for different workers, it will not be used here.

The limbic system includes:

(1) Olfactory nerves, bulb and tract (with the nervus terminalis and the transient accessory olfactory bulb and vomeronasal nerve).

(2) The anterior olfactory nucleus.

(3) Medial, intermediate and lateral olfactory striae, with medial and lateral olfactory gyri.

(4) The olfactory trigone, anterior perforated substance and olfactory tubercle and diagonal band of Broca.

(5) The piriform lobe, including: (*a*) the lateral olfactory gyrus continuing into the gyrus ambiens, together forming the prepiriform cortex; (*b*) lateral olfactory stria continuing into the gyrus semilunaris (periamygdaloid area); (*c*) the uncus hippocampi, including the uncinate gyrus, tail of the dentate gyrus (band of Giacomini) and intralimbic gyrus; (*d*) the entorhinal area (area 28), cranial part of the parahippocampal gyrus.

(6) The amygdaloid complex of nuclei.

(7) Septal areas, including the septum pellucidum and septum verum (a nuclear complex, much of which is deeply placed but in part superficially corresponding to the paraterminal gyrus).

8) The hippocampal formation, including: (*a*) the prehippocampal rudiment, indusium griseum and longitudinal striae; (*b*) the gyrus fasciolaris, Ammon's horn, dentate gyrus, subiculum and related regions.

(9) The fornix and its various ramifications and divisions.

(10) The stria terminalis.

(11) The stria medullaris thalami (stria habenularis).

(12) Cingulate and parahippocampal gyri. The hypothalamus, the medial part of the thalamus, prefrontal cortex and anterior commissure, all intimately related to the foregoing structures, are described elsewhere. The hypothalamus is regarded by some as the *essential centre* of the limbic system (Isaacson 1974).

THE OLFACTORY BULB

The olfactory bulb (7.146A), a flat, oval, reddish-grey mass, is superior to the medial edge of the frontal's orbital plate near the lateral margin of the ethmoid's cribriform plate, inferior to the anterior end of the olfactory sulcus on the orbital surface of the frontal lobe.

Olfactory nerve fibres, central processes of olfactory cells in the nasal mucosa (p. 1094), converge to the inferior aspect of the cribriform plate, collecting into about 20 bundles, which traverse the plate's foramina to enter the inferior surface of the bulb.

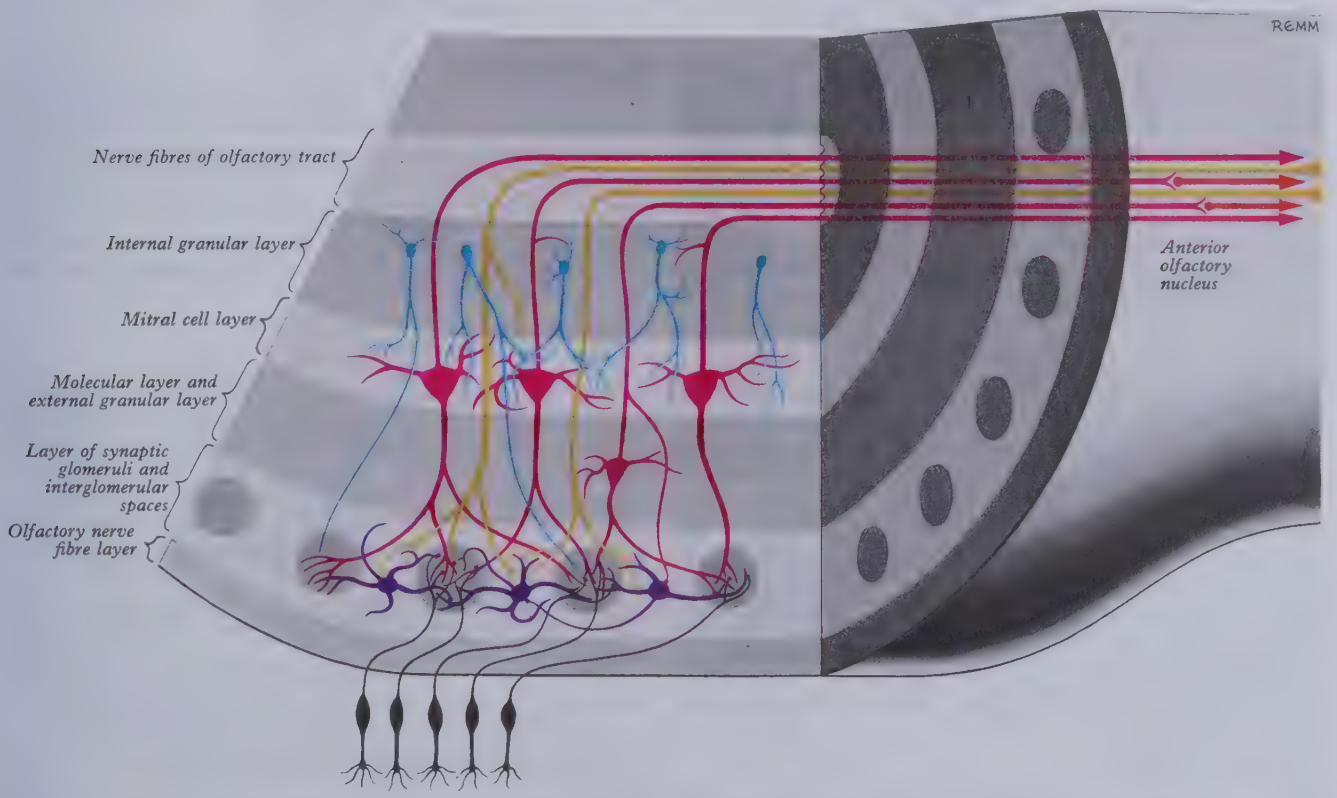
The olfactory bulb and tract develop (p. 192) as a hollow diverticulum from the floor of the primitive cerebral hemisphere. The basal part of this elongates to form the olfactory tract and in human embryos the cavity of the olfactory bulb ('olfactory ventricle') and of the elongating tract are gradually obliterated by fusion or their walls. The site of the original cavity is sometimes marked by vestigial groups of modified ependymal cells. Therefore the olfactory bulb has a *radial organization* with a number of superimposed layers. This laminar pattern is well defined in many mammals other than man and in the human fetus, but becomes less distinct as the brain matures. Detailed histology of the olfactory bulb has been known since the turn of the century (Cajal 1890, 1911, 1955, Blanes 1898, Le Gros Clark 1951, 1957, Valverde 1965); the Nissl and Golgi techniques used have been supplemented by experimental studies with degeneration techniques (e.g. Powell & Cowan 1963, Price 1968, Heimer 1968), physiological studies (e.g. Sem-Jacobsen et al 1956, Døving 1967), electron microscopy (Pinching & Powell 1971, Shepherd 1974, 1977), autoradiography and immunofluorescence (Macrides & Davis 1983).

From the surface inwards the olfactory bulb consists of: (1) an olfactory nerve fibre layer; (2) a layer of synaptic glomeruli and interglomerular spaces; (3) a molecular and external granular layer; (4) a layer of mitral cells; (5) an internal granular layer; (6) fibres of the olfactory tract.

Neurons of the olfactory bulb comprise: (1) large *mitral cells* in a layer one or two cells thick; (2) internal, middle and external *tufted cells*, similar to but smaller than mitral cells and diminishing in size throughout the molecular layer from the superficial aspect of the mitral layer to the deep aspect of the glomerular layer; (3) small round or stellate *internal granule cells*; (4) various types of small *periglomerular cell* distributed around and in the synaptic glomeruli. The periglomerular and small external tufted cells form the *external granular layer* of the earlier histologists. Histofluorescence and immunocytochemical techniques show periglomerular cells to be *dopaminergic*, classified as cell group A15 (see p. 993).

Previous accounts of the olfactory bulb, as a simple relay between olfactory nerve fibres and dendrites of mitral cells whose axons enter the olfactory tract, were, as so often happens, too

7.149 A dissection of the left cerebral hemisphere from the superolateral aspect to demonstrate various structural features of the limbic system. The corpus callosum is divided sagittally in the region of its body only; the frontal, temporal and occipital lobes have been sectioned horizontally and their superior parts removed. The left lentiform nucleus, much of the caudate nucleus and dorsal thalamus have been removed and the floor of the inferior horn of the lateral ventricle laid open. Note: (1) the horizontally sectioned head of the caudate nucleus; (2) the spiral disposition of the fornix as it curves from the mamillary body through its left column, body, crus and fimbria; (3) the curved elevation of the hippocampus projecting into the floor of the inferior horn of the ventricle and ending anteriorly as the grooved pes hippocampi; (4) the anterior commissure entering the left hemisphere immediately anterior to the column of the fornix and passing laterally, to diverge into small anterior and large posterior components; between the latter the deep aspect of the anterior perforated substance is visible; (5) within the curve of the fornix the medial aspect of the *right* thalamus crossed superiorly by the stria medullaris thalami; (6) coursing above the corpus callosum a longitudinal white stria is visible and above this arches the right gyrus cinguli. Compare with 7.148. Dissection by A M Seal, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.



simple. The bulb is structurally complicated (see references quoted for details). The following features must be noted: (1) There is great *convergence* of olfactory fibres to dendrites of mitral and tufted cells occupying much of the synaptic glomeruli (vide infra). (2) A number of cells, mitral, tufted and others contribute axons to the tract which proceed to other centres. (3) Several types of interneuron provide for the complex interaction between the main conductors and complicated feedback routes. (4) Transmission in the bulb is modulated by centrifugal axons from the contralateral olfactory bulb, anterior olfactory nucleus and other centres (vide infra). Some of these features are summarized in illustration 7.150. It is convenient to consider first the main path through the bulb, followed by the complications introduced by local interneurons and centrifugal pathways.

In addition to *basal* dendrites, establishing synaptic connections with granule cell processes, the large mitral cells and the more prominent external tufted cells both have large *apical* dendrites passing superficially to the glomerular layer, where they branch to form dense arborizations in several synaptic glomeruli. Incoming olfactory nerve fibres converge on the glomeruli, forming numerous axodendritic synapses with apical dendrites of mitral and tufted cells, axons of the latter passing through the inner granular layer and giving off collateral branches before continuing to form the main constituents of the olfactory tract.

Synaptic glomeruli of the olfactory bulb are large, spherical territories, often exceeding 100 μm in diameter, containing thousands of neurites from various sources, with a wide variety of synaptic connections between them. In addition to the large dendrites of mitral and internal tufted cells just described, a glomerulus also receives dendrites from types of *periglomerular cell* (including external granule cells, external tufted cells and superficial short-axon cells of different authors, see Pinching & Powell 1971). About 100 neurons contribute dendrites to each glomerulus and (in rabbits) each receives terminals of about 25 000 olfactory nerve axons. Axonal terminals of several periglomerular cells also penetrate the glomerulus. Detailed analyses of synaptic contacts between these elements and possible modes of operation, are still in progress (Price & Powell 1970, Pinching & Powell 1971, Shepherd 1974, 1977, 1978). The following synaptic contacts have been described. Terminals of olfactory axons do not receive axoaxonic (presynaptic) contacts from other sources, but establish axodendritic contacts with mitral and tufted cell dendrites and also dendrites of periglomerular cells. Periglomerular cell dendrites form reciprocal dendrodendritic contacts with mitral and tufted cell dendrites; one or both of the elements in such a double dendrodendritic contact often also receive an axodendritic synapse from an olfactory terminal. Dendrites of periglomerular cells receive several axodendritic synapses from axons of other periglomerular cells.

Interglomerular spaces are partly occupied by cell somata of different types of periglomerular cell and their processes; some have dendrites ramifying in spaces and in glomeruli, as described above. Other interneurons, designated short-axon cells, have wholly extraglomerular dendritic trees. Interglomerular spaces are also penetrated by mitral cell dendrites, many axonal ramifications and terminals of periglomerular cells and terminations of centrifugal axons from the olfactory tract. Again, reciprocal dendrodendritic contacts occur between periglomerular dendrites and those of the mitral and tufted cells, with axodendritic contacts between either the extrinsic or the intrinsic axons and periglomerular cells. Details of these contacts will not be pursued here (see Pinching & Powell 1971, Shepherd 1974, 1978).

The internal granular layer, deep to the layer of mitral cells, contains large numbers of microneurons, *amacrine granule cells* (Rall et al 1966, Price & Powell 1970, Shepherd 1974, 1977, 1978) with no true axons. Their dendrites branch repeatedly; some branch locally, others pass into the molecular layer where, once

7.150 A scheme of the olfactory bulb based upon neurocytological and experimental studies in a number of mammalian types. The radial organization of the bulb into 'layers', with their principal neuron types, and an approximate indication of their main connectivity patterns is shown. The 'layers' of the bulb which receive the names indicated are, of course, merely a convenient descriptive frame of reference; they should not obscure the functionally essential interconnections which cross the boundaries between these zones. Red = mitral and tufted neurons and their processes; blue = internal granule neurons; purple = dopaminergic periglomerular neurons; black = olfactory receptor neurons and their processes. Note that the olfactory tract consists of (1) centripetal axons of mitral and tufted cells, some of which synapse with neurons in the anterior olfactory nucleus and (2) centrifugal axons (yellow) which terminate in the different zones indicated. Refer to text for a more detailed description of both the organization of the bulb and the destinations of olfactory tract fibres.

7.151 A diagram of structures on the inferior aspect of the human brain in the area immediately surrounding the optic nerves, chiasma, optic tracts and interpeduncular fossa. Many of these structures are intimately related to the olfactory and limbic systems; they are coloured blue. The right temporal pole has been displaced laterally to expose underlying structures. In addition to the features which have been labelled fully, the abbreviations used have the following significance: OT = olfactory tubercle; APS = anterior perforated substance; DBB = diagonal band of Broca. The uncus hippocampi is divided into three areas: IG = the intralimbic gyrus; BG = the band of Giacomini; UG = the uncinate gyrus. The lateral olfactory stria continues into the gyrus semilunaris (GS); this is bordered laterally by the gyrus ambiens (GA); whilst further laterally is the entorhinal area (EA) which is the rostral extension of the parahippocampal gyrus. Note the curved extensions of the prehippocampal rudiments, medial olfactory striae and diagonal bands of Broca on to the medial aspect of the hemisphere. The triangular midline zone between the converging diagonal bands and superior to the optic chiasma is the lamina terminalis. The occasional intermediate olfactory stria which merges with the olfactory tubercle is illustrated but unlabelled. After Kuhlenbeck; redrawn and modified from Nauta & Haymaker 1969, with permission of the authors and publishers.

again, reciprocal dendrodendritic synapses are made with the dendrites of mitral and tufted cells. Granule cell dendrites also receive axodendritic synapses from the recurrent collaterals of mitral and tufted cell axons and from many terminals of centrifugal axons in the olfactory tract.

In short, neurons of the olfactory bulb and their processes present some of the most complex synaptic patterns yet described. Granule and periglomerular cells are considered inhibitory interneurons. By their geometric organization and array of contacts they provide a substrate for interaction between the principal conduction channels through the bulb, mediating feed-forward, lateral and feed-back inhibitory processes and inhibitory effects by centrifugal axons entering the bulb from the opposite olfactory tract.

Chemoarchitecture

This is more complex than, e.g. the cerebellar cortex. Olfactory nerve fibres contain the dipeptide carnosine and a specific olfactory marker protein (mol wt 20 000) but their role in neuromediation is conjectural. The mitral neurons and deep tufted neurons and their projection axons have glutamate or aspartate as their neuromediator. Intermediate and external tufted neurons, however, have dopamine or substance P and in some instances contain both. The periglomerular cells and the granule cells may be treated together, the majority contain GABA, the minority dopamine; quite frequently enkephalin co-exists with either in periglomerular cells. In granule cells GABA alone is the outstanding neuromediator; in a small number enkephalin alone has been demonstrated; here they do not co-exist.

The *centrifugal supply* to the olfactory bulb has fibres from different sources containing different neuromediators (see p. 891):

Enkephalin from the anterior olfactory nucleus and precommissural hippocampus.

VIP from the anterior olfactory nucleus, piriform cortex and amygdala.

LHRH from the anterior olfactory nucleus, precommissural hippocampus, medial septal and diagonal band nuclei.

SST from the piriform cortex and diagonal band nucleus.

Substance P from mesencephalic raphe nuclei.

Cholinergic fibres from the ventral nucleus of the diagonal band.

Serotonergic fibres from mesencephalic raphe nuclei.

Noradrenergic fibres from the nucleus coeruleus.

In many non-primate mammals and submammalian forms, a diverticulum with a specialized epithelium, the *vomeronasal organ* (of Jacobson), is sited on each side of the nasal septum. Neural fascicles from this epithelium run with ventral groups of olfactory nerve fibres and then converge to form the *vomeronasal nerve*

ending in an *accessory olfactory bulb* on the dorsomedial aspect of the main bulb. Although an accessory bulb and vomeronasal nerve occur on one or both sides in some human embryos, both structures degenerate (McCotter 1915, Hume 1940, Crosby & Humphrey 1941).

THE OLFACTORY TRACT

The olfactory tract (7.146A,B, 151), a narrow white band issuing from the posterior pole of the olfactory bulb, continues on the inferior (orbital) surface of the frontal lobe, along the olfactory sulcus. Triangular in transverse section, its narrow apex recessed into the olfactory sulcus, it consists of centripetal axons of mitral and tufted cells and some centrifugal axons from the opposite bulb and anterior olfactory nucleus which have crossed in the anterior commissure and from neurons in or near the anterior perforated substance and various brain-stem levels (vide supra). The precise contribution of these and other possible centrifugal sources is still under investigation (Cragg 1962, Powell & Cowan 1963, Powell et al 1965, Price 1968, Heimer 1968).

The Anterior Olfactory Nucleus

Posteriorly in the olfactory bulb its characteristic cell layers disappear, but the granule cell layer is represented in the olfactory tract by scattered medium-sized multipolar neurons, the *anterior olfactory nucleus*; these continue into the olfactory striae and trigone (vide infra) to the grey matter of the prepiriform cortex, the anterior perforated substance and precommissural septal areas. Many centripetal axons from mitral and tufted cells relay in, or give collaterals to, the anterior olfactory nucleus, whose axons continue with the remaining direct fibres from the bulb into the olfactory striae.

THE OLFACTORY STRIAE AND TRIGONE

As the olfactory tract approaches the anterior perforated substance it flattens and splays out into the *olfactory trigone* (olfactory pyramid), from whose caudal angles fibres of the tract continue as diverging *medial* and *lateral olfactory striae* bordering the anterior perforated substance (7.151). In some brains a small *intermediate stria* passes from the centre of the trigone to sink into the anterior perforated substance.

The lateral olfactory stria follows the anterolateral margin of the anterior perforated substance as a visible bundle continuing into the limen insulae (p. 1036), where it bends posteromedially to merge with an elevated region, the *gyrus semilunaris*, at the rostral margin of the uncus hippocampi (7.151); the gyrus incorporates some of the *corticomedial* subdivision of the *amygdaloid complex* (vide infra). A tenuous grey layer covering the lateral olfactory stria is the *lateral olfactory gyrus*, merging laterally with the *gyrus ambiens*, part of the limen insulae. The lateral olfactory gyrus and gyrus ambiens form the *prepiriform region* of the cortex, passing caudally into the *entorhinal area* of the parahippocampal gyrus.

The prepiriform and periamygdaloid regions and the entorhinal area (area 28) together comprise **the piriform lobe**, bounded laterally by the *rhinal sulcus* and relatively prominent in macrosmatic mammals and during fetal development. The relative positions of these structures will be clarified by reference to figure 7.151.

The medial olfactory stria, covered thinly by grey matter, the *medial olfactory gyrus*, passes medially along the rostral boundary of the anterior perforated substance towards the medial continuation of the diagonal band of Broca (vide infra). Together they curve up on the medial aspect of the hemisphere, anterior to the attachment of the lamina terminalis (7.151). The diagonal band enters the paraterminal gyrus, the medial stria becoming indistinct as it approaches the boundary zone which includes the paraterminal gyrus, parolfactory gyrus and, between them, the prehippocampal rudiment (7.148).

THE ANTERIOR PERFORATED SUBSTANCE

An important landmark on the cerebral base, this is caudal to the olfactory trigone and diverging olfactory stria, in the angle between the optic chiasma and tract medially and the uncus caudally (7.151). It is continuous medially above the optic tract with the grey matter of the tuber cinereum and, more anteriorly, with the paraterminal gyrus. Laterally, it reaches the limen insulae to continue into the prepiriform cortex; more caudally it merges with the periamygdaloid area (gyrus semilunaris). Superiorly, it is continuous with the grey matter of the corpus striatum and claustrum through aggregations of grey and white matter forming the *substantia innominata*. Part of the latter, with fascicles of the ansa lenticularis and anterior commissure, separate the anterior perforated substance from the globus pallidus. The aggregates of grey matter in the substantia innominata are grouped as the *basal forebrain nucleus* (of Meynert); over 90% of its neurons are strongly cholinergic and these together with similarly reactive large neurons in the medullary laminae of the globus pallidus are classified as cholinergic group Ch4.

The anterior perforated substance is related to the end of the internal carotid artery and origins of the anterior and middle cerebral arteries, from which central arteries pierce the surface to supply deeper structures (p. 747). Caudal to the olfactory trigone the anterior perforated substance displays a small *olfactory tubercule*, variable in prominence, into the base of which the occasional intermediate olfactory stria sinks. The tubercle is large in macrosmatic animals but greatly reduced and sometimes indistinguishable in mankind. The intermediate stria, though sometimes absent, is occasionally two or three fine striae radiating into the perforated substance. The caudal zone of the substance, where it adjoins the optic tract, is the smooth surface of the *diagonal band of Broca*. Caudolaterally the band is continuous with the periamygdaloid area; rostromedially it continues above the optic chiasma into the paraterminal gyrus (precommissural septum).

GENERAL ORGANIZATION OF THE LIMBIC GREY MATTER

Variations in cytoarchitectonic pattern and the numerous and divergent views on connections of the various limbic regions cannot be detailed, but the following salient points may be noted.

The six laminae which, though varying in different regions, are held to characterize the neocortex (p. 1041) do not appear as such in archipallial and paleopallial regions of the limbic system. In some sites a laminar pattern is absent or scarcely distinguishable, in other areas an obvious but different lamination exists, varying from a primitive three-layered to a transitional six-layered variety where the limbic cortex merges with the neopallial regions. Medial and lateral olfactory gyri, the prepiriform cortex and indusium griseum have isolated patches or a film of grey matter and associated fibres, with no laminar pattern, and rostral and caudal zones of the anterior perforated substance, diagonal band of Broca, paraterminal gyrus and periamygdaloid cortex are poorly differentiated without laminar pattern; specific cell aggregations do occur in some of them, including the *nucleus of the lateral olfactory tract* in the periamygdaloid region and the *nucleus of the diagonal band of Broca*. The centre of the anterior perforated substance is more differentiated, with three layers: outer plexiform, intermediate pyramidal and deep polymorphic; this also has characteristic cup-shaped groups of granule cells in the pyramidal layer (sometimes extending into the plexiform layer). These *islands of Calleja* vary considerably, the medial, being largest, is near another prominent group of larger pleomorphic cells, the *nucleus accumbens septi*. The structure of the hippocampal formation is discussed below, but it is notable that the dentate gyrus and Ammon's horn both consist of a primitive trilaminar cortex showing a gradual transition through the subicular region to a modified six-layered variety in the entorhinal area of the parahippocampal gyrus.

TERMINATION OF THE OLFACTORY TRACT

Terminal areas of olfactory fibres have been widely studied in mammals, including monkeys, and, despite minor differences, substantial agreement reigns; what obtains in the human brain is less certain. As we have seen, olfactory fibres are axons of mitral and tufted cells in the olfactory bulb, some synapsing in the

anterior olfactory nucleus, axons from this continuing with direct fibres of the tract. Through the *lateral olfactory stria* tract fibres reach and synapse with neurons in the lateral part of the anterior perforated substance, the lateral olfactory gyrus, prepiriform cortex and corticomedial group of amygdaloid nuclei (vide infra), regions often grouped as the **primary olfactory cortex**. In contrast to all other sensory pathways, fibres reach these cortical areas without synapsing in the thalamic nuclei. The entorhinal area (area 28) of the parahippocampal gyrus, in the caudal part of the piriform lobe, receives few or no direct fibres but profuse connections from the primary cortex, hence it is sometimes named the **secondary olfactory cortex**. Primary and secondary olfactory cortices are probably the principal areas for the subjective appreciation of olfactory stimuli.

The variable *intermediate olfactory stria* ends in the anterior perforated substance but the destination of the *medial stria* is less certain: some of its fibres also end in the anterior perforated substance; others may reach the paraterminal gyrus and adjacent regions; some of its fibres decussate in the anterior commissure and end in the contralateral anterior olfactory nucleus and olfactory bulb.

The primary olfactory cortex also projects to the basolateral part of the amygdaloid complex, septal areas, nucleus medialis dorsalis of the thalamus and many hypothalamic nuclei.

THE AMYGDALA

The amygdala (amygdaloid body, amygdaloid nuclear complex) is a series of neuronal masses dorsomedial in the temporal pole. It forms the ventral, superior and medial walls of the tip of the inferior cornu of the lateral ventricle. Its relations are complicated. It is partly continuous above with the inferomedial margin of the claustrum; fibres of the external capsule and substriatal grey matter incompletely separate it from the putamen and globus pallidus; it is close to the optic tract. It is partly deep to the gyrus semilunaris, gyrus ambiens and uncinate gyrus (7.151). Transitional zones connect it with the anterior perforated substance, prepiriform cortex and parahippocampal gyrus. Caudally, it is near the ventral part of the hippocampus and it fuses with the apex of the tail of the caudate nucleus; the stria terminalis issues from its caudal aspect. (For a comprehensive review of the amygdala consult Eleftheriou 1972.)

Divisions of the Amygdala

The amygdaloid complex is divided into two main groups, the *corticomedial* and *basilateral* nuclei, with junctional zones where these adjoin or partly fuse with adjacent areas. Details of the subdivisions, connections and homologies are only briefly summarized here (Crosby & Humphrey 1941, Crosby et al 1962, Eleftheriou 1972, Isaacson 1974).

The corticomedial amygdaloid complex has *central*, *medial* and *cortical amygdaloid nuclei*, *the nucleus of the lateral olfactory stria* and a transitional ill-differentiated *anterior amygdaloid area*. The cortical nucleus is a rudimentary cortex, with irregular groups of pyramidal and granule cells, occupying the surface of the gyrus semilunaris. The corticomedial complex is continuous through the transitional zones with the anterior perforated substance, the diagonal band of Broca, substantia innominata, putamen, caudate nucleus and surrounding cortical areas of the uncus and parahippocampal gyrus. It is small in the human brain.

The basilateral amygdaloid complex, large and well differentiated in the human brain, has *lateral*, *basal* and *accessory basal amygdaloid nuclei* and is partly continuous with the claustrum and, through a transitional zone, with the cortex of the parahippocampal gyrus.

Connections of the Amygdaloid Complex

These are incompletely established in the human brain; most of the available information is derived from degeneration and electrophysiological studies in mammals, including monkeys (Le Gros Clark & Meyer 1947, Allison 1954, Powell et al 1965, Gloor 1960, Wendt & Albe-Fessard 1962, Eleftheriou 1972).

Afferent connections reach the corticomedial complex via the lateral olfactory stria from the olfactory bulb and anterior olfactory nucleus, with the basilateral complex receiving many afferents from the cortex of the piriform lobe (p. 1033). Other afferents converge from the hypothalamic nuclei, specific and non-specific thalamic nuclei, brain-stem reticular formation and probably areas of the neocortex (vide infra).

The best known **outflow** is via the stria terminalis to the septal areas, preoptic and adjacent regions of the hypothalamus, some continuing into the stria medullaris thalami to reach the habenular nucleus. Other *amygdalofugal fibres* follow a more central direct route (p. 1009) to many hypothalamic nuclei, the cortex of the piriform lobe, nucleus medialis dorsalis of the thalamus and the reticular formation of the midbrain tegmentum. Reciprocal connections probably exist between the complex and the orbitofrontal, cingulate and temporal regions of the neocortex; *interamygdaloid fibres* run through the anterior commissure (vide infra).

THE STRIA TERMINALIS

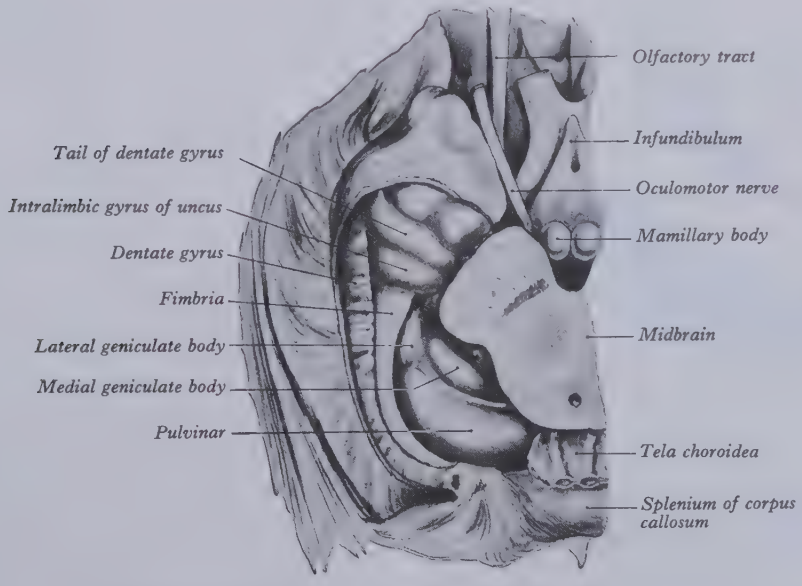
This small, discrete bundle of fine myelinated nerve fibres is visible to the unaided eye in much of its course. Fibres pass in both directions in it to various destinations. The stria issues posteriorly from the amygdaloid complex, running caudally in the roof of the inferior cornu of the lateral ventricle, medial to the tail of the caudate nucleus, then following its curve to pass ventrally in the floor of the body of the ventricle, in a groove between the caudate nucleus and the thalamus, close to the thalamostriate vein. It passes inferior to the interventricular foramen to the anterior commissure, where it diverges into *supracommissural*, *commissural* and *subcommissural* components. As it nears the anterior thalamic pole, scattered groups of small neurons occur between the bundles, the *bed nucleus of the stria terminalis*, in which some of its fibres relay. Many fibres in supra- and subcommissural components are amygdalofugal, passing to the septal areas (vide infra), preoptic and anterior hypothalamic nuclei, while others descend to the anterior perforated substance and adjacent regions of the piriform lobe. Some subcommissural fibres recurve to join the column of the fornix and others pass caudally with the stria medullaris to the habenular nucleus. Reciprocal connections probably exist between some of these regions and the amygdaloid nuclei, by returning fibres in the stria. The *interamygdaloid* fibres have an intricate course; leaving one complex they traverse most of the highly curved stria terminalis to the anterior commissure, cross and curve in the reverse direction through the contralateral stria to its amygdaloid complex.

THE ANTERIOR COMMISSURE

This is a compact bundle of myelinated nerve fibres crossing anterior to the columns of the fornix and embedded in the lamina terminalis, where it is part of the anterior third ventricular wall, 1·5–2·0 cm above the optic chiasma (7.140, 145, 176). In sagittal section it is oval, its long diameter (about 1·5 mm) vertical. Its fibres twist and entwine like the strands of a rope and laterally it separates into two bundles: the smaller *anterior bundle* curves forwards on each side to the anterior perforated substance and olfactory tract; the *posterior bundle* curves posterolaterally on each side for some distance in a deep groove on the antero-inferior aspect of the lentiform nucleus, beyond which it fans out into the anterior part of the temporal lobe, including the parahippocampal gyrus. Commissural fibres have been described in mammals, including primates, as interconnecting the following structures with their fellows: (1) the olfactory bulb and anterior olfactory nucleus, (2) the anterior perforated substance, olfactory tubercle and diagonal band of Broca, (3) the prepiriform cortex, (4) the entorhinal area and adjacent parts of the parahippocampal gyrus, (5) part of the amygdaloid complex, especially the nucleus of the lateral olfactory stria, (6) the bed nucleus of the stria terminalis and nucleus accumbens septi, (7) the middle and inferior temporal gyri in their anterior regions, (8) possibly other neocortical areas, including the frontal lobe.

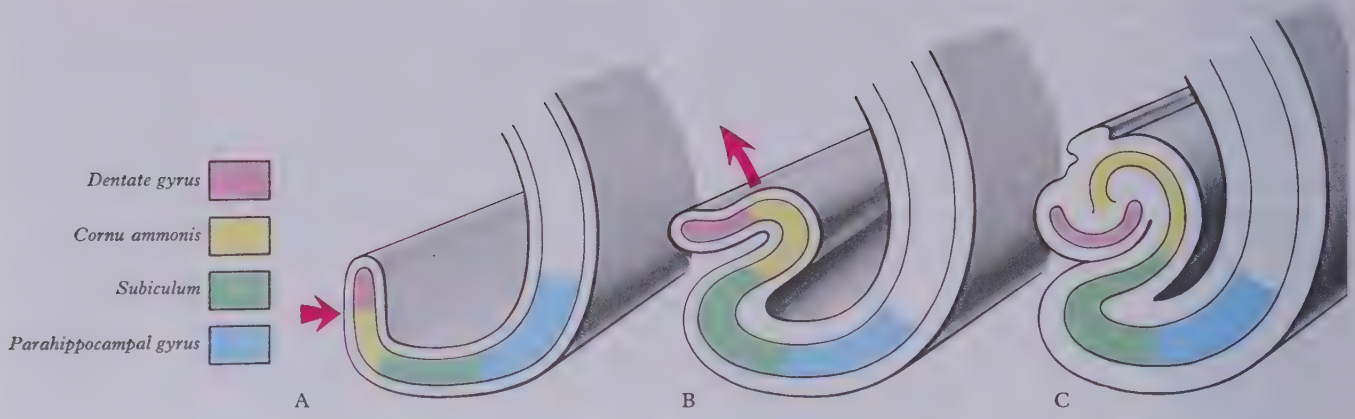
The inter-temporal neocortical connections are the largest component of the anterior commissure in primates, including mankind. However, many detailed connections in the human commissure remain unknown. Some fibres may not be commissural but decussating pathways between dissimilar structures.

THE SEPTAL AREAS



In subprimate mammals, *the septal areas* are the thick medial walls of the cerebral hemispheres anterior and superior to the lamina terminalis and anterior commissure, consisting of nuclear masses with relatively coarse bundles of fibres, divisible into *pre-* and *supracommissural* parts. In higher primates, particularly in the human brain, septal areas are modified by expansion of the neocortex and corpus callosum. The human supracommissural septum corresponds largely to the bilateral laminae of fibres, sparse grey matter and neuroglia, forming the septum pellucidum. The precommissural septum (*septum verum* of some) consists of well-defined dorsal, ventral, medial and caudal *groups of nuclei*, each divisible into a series of smaller groups, not detailed here. The precise limits of the human septum verum and the terminology applied to its surface topography and nuclear groups are sources of confusion and disagreement. (For detailed reviews consult Stephan & Andy 1962, Andy & Stephan 1968, Nauta & Haymaker 1969.) Most agree that the precommissural septum corresponds partly to the paraterminal gyrus (p. 1027), a narrow vertical strip between the anterior surface of the lamina terminalis and the posterior parolfactory sulcus. Its anterior slope passing into the sulcus is sometimes called the *prehippocampal rudiment*. Inferiorly, the gyrus and rudiment are continuous with the diagonal band of Broca and the medial olfactory stria (7.151); superiorly they narrow, spreading round the rostrum and genu of the corpus callosum to the indusium griseum (p. 1036). But some hold that only the prehippocampal rudiment is continuous with the indusium griseum; the detailed connections of the medial olfactory stria are uncertain in the human brain. Some of the septal nuclei are in the paraterminal gyrus, others are interspersed with fibres of the precommissural fornix (p. 1039). Scattered cell groups interconnect the precommissural septum with the septum pellucidum, substantia innominata and anterior perforated substance.

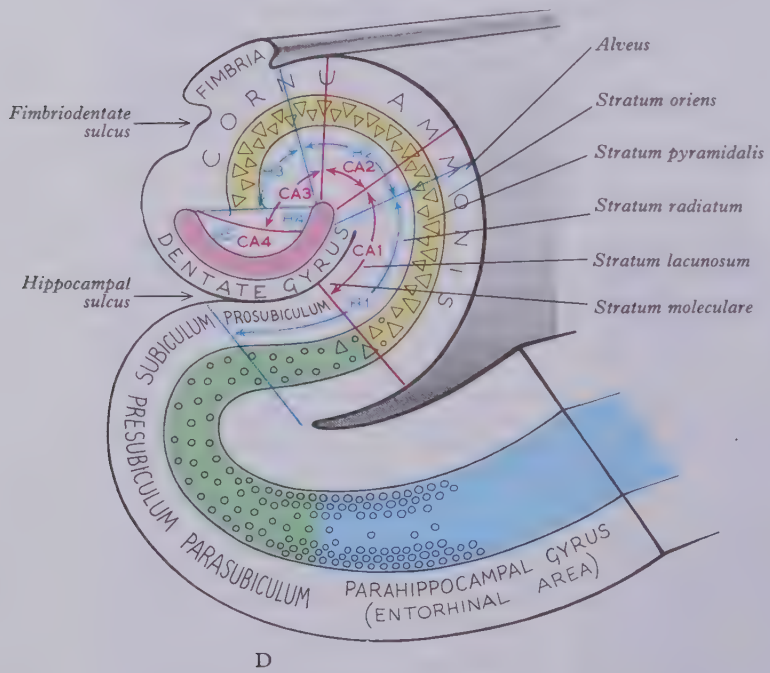
The main afferent connections to the septal nuclei are from: (1) the amygdaloid complex via the diagonal band and stria terminalis; (2) the anterior perforated substance by fibres probably running with the medial olfactory stria; (3) the hippocampus via the fornix; (4) the midbrain reticular formation and hypothalamic nuclei by ascending fibres in the medial forebrain bundle. (For the monoaminergic status of some of these see pp. 992-994.)



The main outflows from the septal nuclei are: (1) fibres returning to the hippocampal formation via the fornix; (2) descending fibres in the medial forebrain bundle distributed to many hypothalamic nuclei and the midbrain reticular formation; (3) fibres via the stria medullaris thalami to the habenular nuclei. Interconnections are probably established between septal areas and the vestigial indusium griseum and cingulate gyrus, but details remain uncertain. The septal areas are thus focal zones for the interconnection of principal limbic and hypothalamic structures. For long thought to be reduced, atrophic and perhaps functionless in primates, the septal nuclei have been shown to *increase* in prominence throughout primates, reaching their highest degree of development in the human brain (Andy & Stephan 1968).

Hippocampal Formation

The hippocampal formation develops in the medial pallial fringe of the hemisphere, adjacent to the convex border of the choroidal fissure (p. 1081), where it assumes a highly arched form extending from the anterior aspect of the interventricular foramen and lamina terminalis to the ventral extremity of the inferior cornu of the lateral ventricle. (The adjacent 'ends' of the arch are connected by other limbic structures, vide infra.) Modifications in its superior part, accompanying expansion of the neopallium and corpus callosum, have been discussed (p. 193). Essentially, it is a curved band of ancient cortex (*archipallium*), limited on its concave aspect by the choroidal fissure and merging on its convex aspect with the surrounding *neopallium*. Traced radially from the choroidal fissure towards the neopallium, three main zones are distinguished in the archipallium: *the dentate gyrus*, *cornu ammonis* and *subiculum*. The dentate gyrus and cornu ammonis have contrasting features but are regarded as the most primitive *trilaminar* cortex; the subiculum shows a graded variation from four, through five, to a modified six-layered cortex where it merges with the surrounding neocortex. Growth changes occur infolding these archipallial zones towards the adjacent lateral ventricle. These zones and their changes in position are shown in a simplified manner in figure 7.153A–C. The form of infolding is similar throughout Mammalia; but its *degree* and *areas* of hemispheric wall, in which well-differentiated hippocampal formation persists, vary in different groups. These variations reflect differences in the relative expansion of the neopallium,



7.152 Basal aspect of part of the brain dissected to display the uncus, dentate gyrus, fimbria, etc.

7.153A–C The hippocampus and related structures seen in coronal section: A, B and C are a series of diagrams to assist understanding of the assumption of the definitive positions of the dentate gyrus, cornu ammonis, subiculum and parahippocampal gyrus in the floor of the inferior horn of the lateral ventricle in the human brain. Note that these are *not* tracings from a series of embryonic sections and that they have been somewhat simplified in the interests of clarity. Note also that the amount of curvature and infolding which occurs varies along the length of the hippocampus and in different specimens. It is important to appreciate that, following folding, the original *external* surfaces of the dentate gyrus and part of the subiculum are in contact and that the degree of tissue fusion which occurs along the line of the hippocampal sulcus is quite variable.

corpus callosum and temporal lobe in different groups. In the human brain the part of the hippocampal arch related to the medial wall and roof of the *body* of the lateral ventricle is greatly reduced, due to the relatively enormous size of the corpus callosum, the fully developed hippocampal formation being confined to the floor and medial wall of the inferior cornu. Anteroinferiorly, the ends of the archipallial arch are continuous with the septal area, including the paraterminal gyrus, the anterior perforated substance and part of the piriform lobe (p. 1029). Topographical limits of structures included in the term *hippocampal formation* vary in different accounts. Here, it is considered to include: (1) the indusium griseum, longitudinal striae and their extensions; (2) the gyrus fasciolaris; (3) the dentate gyrus, cornu ammonis and subiculum; (4) parts of the uncus. The term *hippocampus* is often restricted to the macroscopic swelling in the floor of the inferior cornu, consisting of the dentate gyrus, cornu ammonis and closely related structures.

7.153D An analysis of the major topographical zones and the complex terminology applied to the hippocampus and related structures seen in a coronal section of the floor of the inferior horn of the lateral ventricle in a mature human brain. Colour code for tissue zones as in A–C. The approximate limits of the various subdivisions of the subiculum are labelled. CA 1–4 are the cornu ammonis fields of Lorente de Nó (1934) and H 1–5 are the hippocampal fields of Rose (1927).

THE INDUSIUM GRISEUM

The indusium griseum, the *supracallosal gyrus*, is a poorly differentiated film of grey matter covering the superior aspect of the corpus callosum. Laterally, on each side, it enters the callosal sulcus to continue into the cortex of the cingulate gyrus. Anteriorly, it sweeps around the genu and rostrum to merge with the superior end of each paraterminal gyrus, which is continuous below with the diagonal band of Broca and, through this, with the anterior perforated substance and periamygdaloid area. Posteriorly, the indusium griseum diverges on the splenium to merge with the *gyrus fasciolaris* (*splenial gyrus*), a delicate strip of grey matter curving down, forwards and laterally to the posterior extremity of the *dentate gyrus*. Embedded in the indusium, ridging its free surface, are two narrow bundles of fibres on each side, *the medial* and *lateral longitudinal striae* (7.174). The medial striae are near the midline, the lateral in the callosal sulci. The striae are regarded as the reduced white matter of a vestigial indusium. Anteriorly, they pass towards the paraterminal 'gyri'; posteriorly they continue through the gyrus fasciolaris to the fornical fimbriae (p. 1039). Connections of the striae are uncertain but in their supracallosal course they probably contribute fibres piercing the corpus callosum to form part of the *dorsal fornix* (p. 1039).

THE HIPPOCAMPUS

The hippocampus consists of complexly folded layers of the dentate gyrus and cornu ammonis, the latter being continuous through the subicular region with the parahippocampal cortex. The name stems from its supposed resemblance, in coronal section, to the profile of a sea-horse. The hippocampus is above the subiculum and medial parahippocampal gyrus, forming a curved elevation about 5 cm long along the floor of the inferior cornu of the lateral ventricle. Its anterior end is expanded and here its margin may have two or three shallow grooves giving a paw-like appearance, the *pes hippocampi*. The ventricular aspect is coronally convex and covered by ependyma, beneath which fibres of the *alveus* converge medially on a longitudinal bundle of fibres, the *fimbria of the fornix*. The general order of these cell layers and fasciculi in coronal section are best appreciated in a simplified diagram (7.153D). Note that passing *medially* from the collateral sulcus, the neocortex of the *parahippocampal gyrus* merges with the transitional cortex of the *subiculum*, which curves superomedially to the inferior surface of the *dentate gyrus*, continuing laterally to the laminae of the *cornu ammonis*; this

continues the curvature, first superiorly then medially above the dentate gyrus, and ends pointing towards the centre of the superior surface of the dentate gyrus. The degree of curvature varies somewhat along the length of the hippocampus and in different specimens.

The *dentate gyrus* (7.152,153D) is a crenated strip of cortex related inferiorly to the subiculum, laterally to the cornu ammonis, superiorly to the recurved cornu ammonis, the alveus and, more medially, the fimbria of the fornix (7.154). The form of the fimbria is quite variable, but medially it is separated from the crenated medial margin of the dentate gyrus by the *fimbriodentate sulcus*. The *hippocampal sulcus*, of variable depth, is between the dentate gyrus and the subicular extension of the parahippocampal gyrus. Posteriorly the dentate gyrus is continuous with the gyrus fasciolaris and thus with the indusium griseum. Anteriorly, it is continued into the notch of the uncus, turning medially across its inferior surface, as the *tail of the dentate gyrus* (band of Giacomini), vanishing on the medial aspect of the uncus. The tail separates the inferior surface of the uncus into an anterior *uncinate gyrus* and posterior *intralimbic gyrus* (7.151,152).

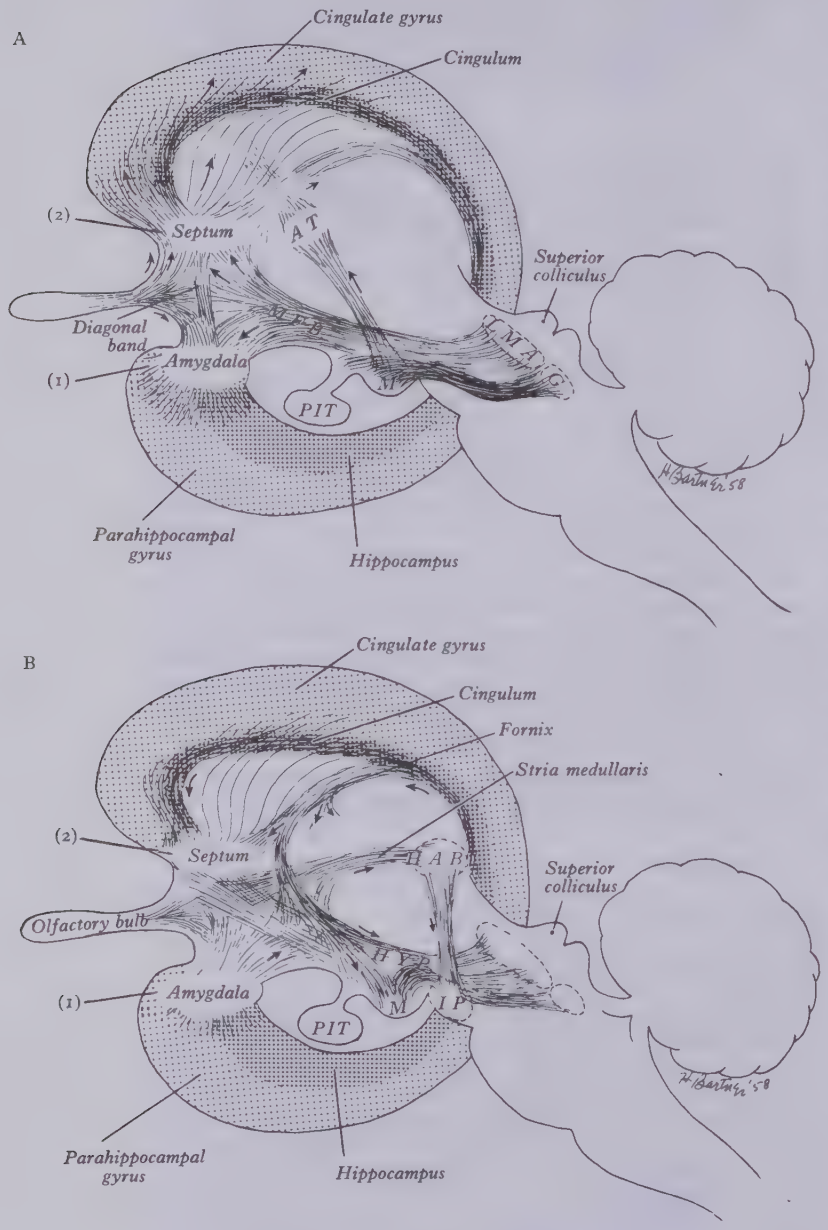
THE STRUCTURE OF THE HIPPOCAMPUS

Since the early researches of Cajal (1890, 1911) and Lorente de Nó (1934) a huge literature has accumulated on hippocampal structure and connections. Only the salient points can be mentioned here; for details, monographs and papers must be consulted (Kappers et al 1936, Crosby et al 1962, Brodal 1969). Earlier reviews of complex terminologies for various laminae and subdivisions are to be found in the writings of Lorente de Nó (1934), Rose (1927), and Gastaut & Lammers (1960). Examples of investigations into connectivity patterns are found in papers by Blackstad (1956, 1958), Raisman et al (1965, 1966) and White (1959, 1965), using ultrastructural techniques (Blackstad 1967, Blackstad & Kjaerheim 1967, Blackstad & Flood 1963, Hamlyn 1962) and neurophysiological recording methods (Andersen et al 1964a, b, 1966). More recent comprehensive collections of essays devoted to many aspects of the structure, development, neurophysiology and behavioural aspects, the product of many leading authorities and containing extensive bibliographies are brought together in two volumes entitled *The Hippocampus* and edited by Isaacson & Pribram (1975).

Some aspects of the terminology used and some of the main structural features are shown in outline in figure 7.154.

7.154 Some of the main features of the neuronal organization and connectivity patterns of the dentate gyrus, cornu ammonis, subiculum and parahippocampal gyrus. The cell somata, dendrites and axons of the pyramidal neurons of the cornu ammonis are yellow; their axons form the efferent hippocampal fibres of the alveus and fimbria. Afferent fibres to the cornu ammonis from the fimbria are purple, those following the alvear path are green, whilst those following the perforant path are blue. Basket neurons are in black. The neurons of the dentate gyrus and their axons which form the mossy fibres of the hippocampus are in magenta. See text for further details.

It should be noted that because of the form of cortical folding which occurs during development, the original *external* surfaces of the dentate gyrus and subiculum (the *stratum moleculare*) are closely applied to each other in the depths of the sulcus hippocampi (or along the obliterated line of the sulcus). Throughout much of its extent, the subicular region merges laterally with the modified six-layered cortex of the *entorhinal* area of the parahippocampal gyrus. (Some authorities prefer to include the subiculum with the parahippocampal gyrus, rather than with the hippocampal formation.) As noted, in its curved course from the entorhinal area to Ammon's horn, the subiculum gradually changes its structure from a modified six-layered to a four-layered cortex, with differences in the patterns of connection. It is hence often divided into zones: *parasubiculum*, *presubiculum*, *subiculum* and *prosubiculum*. The prosubiculum merges into the cornu ammonis which, by the same criteria, is a primitive trilaminar cortex with *molecular*, *pyramidal* and *polymorphic* layers from the original external surface to the ventricular. But, by other methods and criteria, more sublayers are often described in Ammon's horn (vide infra). Though the general cytoarchitectonic design is similar throughout Ammon's horn, there are regional differences in structure and connections. Therefore investigators have proposed varying methods and criteria dividing this region into a series of radial fields (7.153D), including the **cornu-ammonal fields** CA1–CA4 of Lorente de Nó and the **hippocampal fields** H1–H5 of Rose. These do not correspond; the former are limited to Ammon's horn while the H1 field of Rose includes part of the subiculum, prosubiculum and part of Ammon's horn.



The cornu ammonis, following Cajal, is usually considered to have the following strata, starting from its ventricular aspect: (1) the *ependyma*, (2) *alveus*, (3) *stratum oriens*, (4) *stratum pyramidalis*, (5) *stratum radiatum*, (6) *stratum lacunosum*, (7) *stratum moleculare*. Many group the last two as the *stratum lacunosum-moleculare*.

The *alveus* is a subependymal stratum of fibres entering and leaving the hippocampus. *Efferent* fibres are predominantly the axons of large neurons in the stratum pyramidalis but with a smaller number from cells in the stratum oriens and dentate gyrus, whose axons together form the large efferent component of the *fimbria of the fornix* (vide infra). Before joining the fimbria efferent axons have fine collateral branches which re-enter the hippocampus. *Afferent* fibres from other regions, including commissural fibres from the opposite hippocampal formation, approach the cell layers of the hippocampus via the alveus.

The *stratum oriens* is interlaced by axons and collaterals of fibres entering and leaving the hippocampus; it is penetrated by some basal dendrites of the large pyramidal neurons of the adjacent layer, containing cell somata and dendrites of small, irregularly shaped neurons, some termed *basket cells*, and shown to be inhibitory interneurons, receiving axosomatic and axodendritic synapses from some afferent collaterals to the hippocampus and also from efferent fibres. Axons of these interneurons penetrate the radiate and molecular layers, synapsing by axodendritic contacts with the pyramidal cells; but the most distinctive terminals are those of the basket cells which form numerous, crowded, axosomatic synapses on the somata of pyramidal neurons.

The *stratum pyramidalis* is a well-defined *double* layer of large and small pyramidal neurons. Their bases face the stratum oriens

and alveus, their apices are directed to the stratum radiatum. The axon of a pyramidal cell issues from its base or a basal dendrite, passing into the alveus, where it has collateral branches, then continuing into the fimbria. Some of these collaterals end on cells in the stratum oriens, but many (*Schaffer collaterals*) are recurrent to the stratum moleculare, terminating on apical dendrites of adjacent pyramidal cells. The dendritic tree of a pyramidal cell has two parts, basal and apical; *basal dendrites* radiate into the nearby pyramidal layer but the majority pass into the stratum oriens and overlying alveus and are beset with dendritic spines.

7.155 Schematic drawings of one concept of the 'limbic lobe' (after MacLean) in which emphasis is placed upon the medial forebrain bundle (MFB) as a major line of communication between the limbic cortex, the hypothalamus and the midbrain. Note the relationship between the fornix and the cingulum. The limbic cortex, which is considered as a hierarchical system of concentric strips, is indicated by heavy and light stipple. The neocortex is not included. A. The ascending pathways to the limbic structures, with emphasis on the divergence of fibres from the medial forebrain bundle to the amygdala (1) and to the septal area (2). Note also the input from the olfactory bulb and tract. B. Descending pathways from the limbic system. AT = anterior group of thalamic nuclei; G = tegmental reticular nuclei; HAB = habenular nucleus; HYP = hypothalamus; IP = interpeduncular nucleus; LMA = limbic midbrain area (of Nauta); M = mamillary body; PIT = hypophysis cerebri. From MacLean 1958 by courtesy of the author and publishers.

The *apical dendrites* pass deeply and with associated axons and a few pyramidal cells make up the *stratum radiatum*. Reaching the *stratum lacunosum-moleculare*, apical dendrites branch profusely and these terminal branchlets, with their stem dendrite, are also covered with dendritic spines. Thus, these deepest layers contain the terminal dendrites of pyramidal cells, terminal axons of afferents to the hippocampus, the recurrent collaterals mentioned above and the somata, dendrites and axonal arborizations of scattered, deeply placed interneurons. The connections of the hippocampus are treated later but it is noted here that the zones of pyramidal dendritic trees receive distinct axonal terminals. Thus, fibres from corresponding regions of the opposite hippocampus end on basal dendrites, while those from non-corresponding regions end on apical dendrites in the strata lacunosum and moleculare. Afferents from the entorhinal cortex synapse with the most terminal branches of apical dendrites in the molecular layer, synaptic endings of Schaffer collaterals being in the stratum lacunosum. Mossy fibres from cells of the dentate gyrus form large synaptic terminals enclosing prominent dendritic spines of apical dendrites in the stratum radiatum; but, as noted above, basket cell terminals form a dense array of axosomatic synapses. These zonal variations in axonal terminals have been tentatively correlated with variations in unit recordings from microelectrodes at varying depth in the cornu ammonis (Anderson et al 1964, 1966). Many afferents and pyramidal cells are excitatory; some interneurons, particularly basket cells, are inhibitory.

The dentate gyrus is considered a trilaminar cortical structure. Extending deeply from the hippocampal sulcus it consists of: (1) a superficial *molecular layer*, (2) an intermediate *granular layer*, (3) a deep *polymorphic layer*. Briefly, cell types in the laminae have spine-studded dendritic trees radiating locally or traversing the superficial layer. They receive synaptic terminals from some hippocampal extrinsic sources, also from neighbouring neurons. Some cells are Golgi type II neurons with local axons, others have longer axons which, after collateral branching, join efferent fibres in the fimbria. Most distinctive, however, are the so-called *mossy fibres*, arising from many cells in the granular layer and passing through the polymorphic layer with collateral branches to its neurons. They then proceed along a curved course lying superficial in the stratum radiatum of the cornu ammonis and making a series of '*giant*' synapses with spines on the initial segments of pyramidal apical dendrites.

THE CONNECTIONS OF THE HIPPOCAMPUS

Afferent pathways to the hippocampus arise in: (1) parts of the cingulate gyrus, (2) septal nuclei, (3) the entorhinal cortex, (4) indusium griseum, (5) contralateral hippocampal formation, (6) possibly the prepiriform cortex, (7) brain-stem reticular cell aggregates, which provide a dual monoaminergic input (pp. 992–994).

Cingulate fibres reach the hippocampus via the cingulum (p. 1072) and are distributed both directly to the cornu ammonis and indirectly after relays in the subicular region. Afferents from septal nuclei retrace a curved path in the fornix back to the hippocampus. Commissural fibres link both hippocampal formations via the fimbria, crus and commissure of the fornix (vide infra), then recurve through the same structures contralaterally. Some fibres from the indusium griseum run posteriorly in the longitudinal striae, passing through the gyrus fasciolaris to the hippocampus via the fimbria.

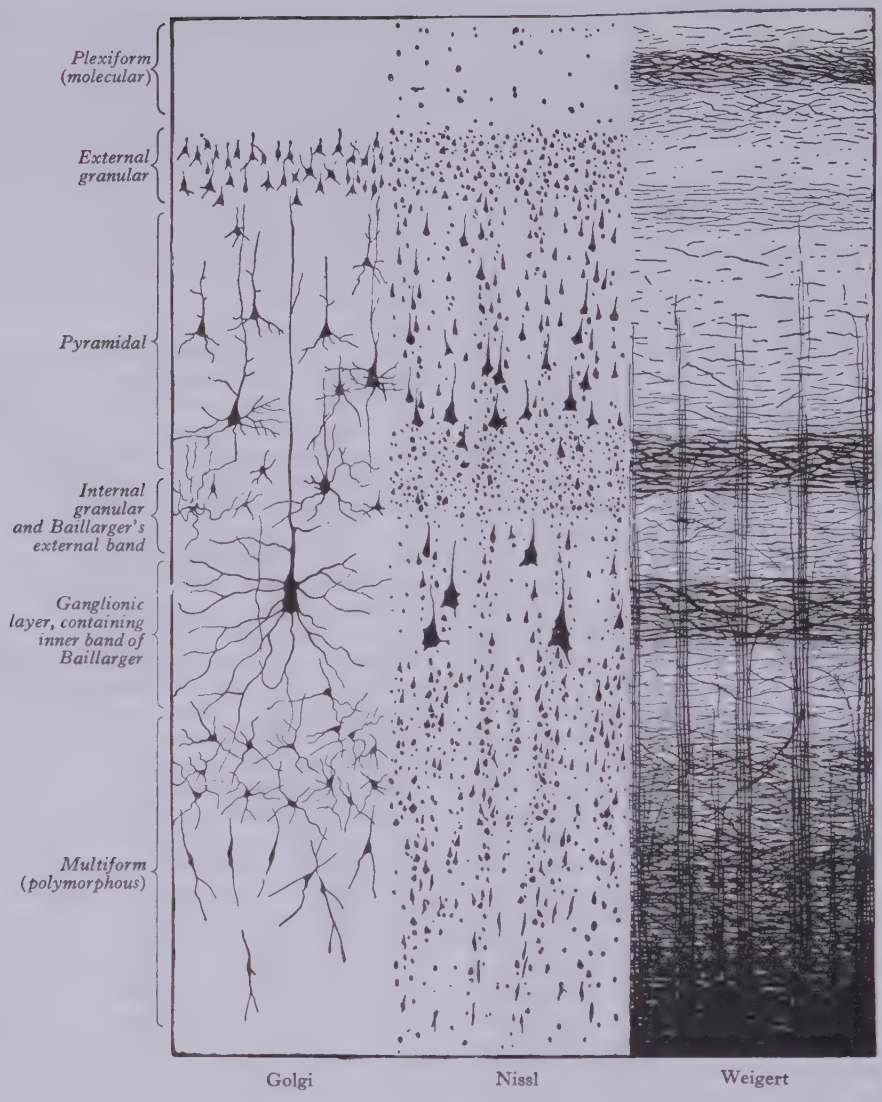
Most abundant afferent connections of the dentate gyrus and cornu ammonis are from the entorhinal cortex and subicular regions, long held to have distinct routes. Fibres from the *medial* entorhinal area and parasubiculum follow an *alvear path* through the prosubiculum to the alveus and stratum oriens of the cornu ammonis. In contrast, afferents from the *lateral* entorhinal area follow a *perforant path* through the subiculum, crossing the alvear path to the stratum lacunosum-moleculare of the cornu ammonis and adjacent parts of the dentate gyrus. These routes and those from the fimbria are shown in Figure 7.154; the perforant path predominates and is more certain; some doubt the significance, or even the existence, of an alvear path, at least in some mammals.

THE FORNIX (7.148)

In addition to the afferent hippocampal fibres and commissural fibres described above, the fornix is the sole **efferent system from the hippocampus**, these efferents being mainly continuations of axons of pyramidal cells in the cornu ammonis; but a few come from neurons in the stratum oriens and dentate gyrus. These axons traverse the alveus and converge on the medial border of the ventricular surface of the hippocampus to form the *fimbria*, a flat band of fibres superior to the dentate gyrus and forming the inferior boundary of the choroidal fissure. Its position varies; it may project above the dentate gyrus with a free medial edge, *the taenia fornicis*, and a lateral border merging into the alveus; alternatively, its free border may be twisted over towards the lateral side, uncovering the dentate gyrus (7.152). Anteriorly, it continues into the hook of the uncus (7.145); traced posteriorly on the floor of the inferior cornu, it ascends towards the splenium, most fibres passing forwards *below* the splenium to curve forwards above the thalamus, as the *crus of the fornix*. The two crura are applied to the inferior surface of the corpus callosum and are interconnected by transverse fibres passing between the hippocampal formations of both sides as the *commissure of the fornix* (hippocampal commissure), a thin triangular sheet which, together with converging crura, is sometimes termed the *psalterium* or *lyra* (both varieties of harp!). Between the commissure and corpus callosum a horizontal cleft (so-called *ventricle of the fornix*) sometimes occurs. Anteriorly, the crura meet to form the *body of the fornix*, really a symmetrical bilateral structure above the tela choroidea and ependymal roof of the third ventricle (7.198) and attached to the inferior surface of the corpus callosum and, anteriorly, inferior borders of the laminae of the septum pellucidum. Laterally, the fornical body overlies the medial upper surface of the thalamus; the choroidal fissure is below its free lateral edge. Through this fissure the choroid plexus in the lateral margin of the tela choroidea enters the lateral ventricle (7.198). Above the interventricular foramina the body of the fornix diverges into right and left fascicles curving down towards the anterior commissure anterior to the foramina; approaching the commissure each divides around it into a *precommissural fornix* and a *postcommissural fornix* (column of the fornix). Each column continues to curve inferoposteriorly to sink into the corresponding lateral wall of the third ventricle to the mamillary body. In addition to these bundles, fibres leave the fimbria *near the splenium* to run forwards with the *supracallosal* medial and lateral longitudinal striae, joined by others from the indusium griseum. Some strial fibres descend between the callosal fascicles, joined by others passing into the corpus callosum from the fimbria. These fascicles, intersecting the callosal bundles, are the *dorsal fornix*. Some of the dorsal fornical fibres relay in the scattered grey matter in the septum pellucidum, while others course directly through the septum; direct and indirect fibres largely rejoin the main subcallosal body of the fornix.

Thus, by different fornical fascicles, *hippocampal efferents* pass to: (1) the gyrus fasciolaris, indusium griseum, cingulate gyrus and septum pellucidum via the *dorsal fornix*, (2) the precommissural septum, preoptic and anterior hypothalamic nuclei via the *precommissural fornix*, (3) the anterior thalamic and many hypothalamic nuclei (p. 1010) via direct fibres from the descending *postcommissural column of the fornix*, before proceeding to their main termination in the medial mamillary nucleus, (4) to the habenular nuclei and midbrain reticular formation via other fibres curving caudally from the column of the fornix to join the stria medullaris thalami.

Figures 7.155A,B roughly summarize some main inflow and outflow pathways associated with the limbic system (MacLean 1958, 1969), retained for its historical significance.



Much research has been directed towards the biological roles of the various complex interconnected structures grouped under the term limbic system. Despite this their significance can be described only in the most general terms. Even a brief review is beyond the present scope. Much information and bibliographies exist in the writings of Eleftheriou (1972), Isaacson (1974), Isaacson & Pribram (1975), Livingston & Hornykiewicz (1978). It is also instructive to inspect the data and speculations which stemmed from them of the extensive review of neuromediator distribution by Nieuwenhuys (1985). 25 of the commoner established or putative neuromediators were chosen and the neural sites (e.g. nuclei, certain gyri, 'central grey' tracts, fasciculi) in which they could be located with confidence were listed. Many (but not all) the sites with seven or more neuromediator profiles were noted (19 was the largest figure, present in the midbrain, periaqueductal grey and the nucleus solitarius) and then plotted graphically on a standardized diagram of the brain. The structures so demarcated are termed the *core of the central nervous system* and added tentatively: *the (paracrine?) core*, distinguishing this from the *median paracore* (raphes nuclei) and *bilateral paracores*, a series of grey aggregates usually allocated to the reticular system. In large measure the structures included largely correspond to those described under 'the limbic system' in this volume together with the reticular 'cores' of the brain stem and spinal cord. The principal addition consists of large areas of the neostriatum which it is stressed, however, have profuse amygdalostriate projections, that is the neostriatum can be divided into 'limbic' and 'non-limbic' (somatasensorimotor) parts. (The writer is forced to wonder whether 18 neuromediators per structure are more 'paracrine' beneath a limbic arch than when in mesocortex, neocortex or dorsal thalamus?) Nieuwenhuys' review is a splendid source of limbic and paralimbic data but most especially of provocative thought.

THE CEREBRAL CORTEX

Introduction

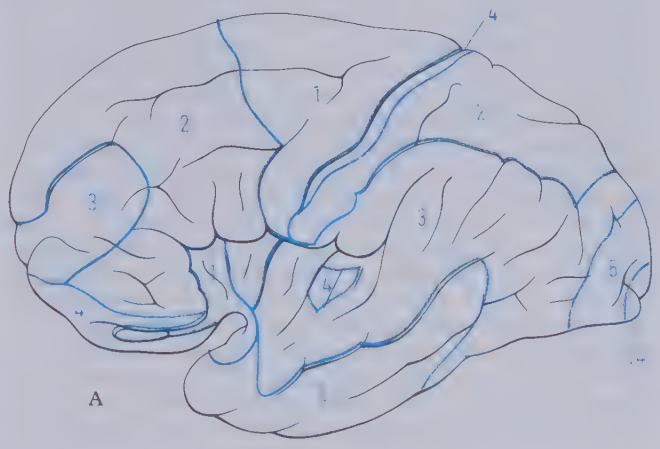
The cerebral cortex has been studied over several centuries. It was examined by the first microscopists; as early as 1776 the occipital cortical stria named after him was seen by Gennari and was the first recorded structural detail. Improved microscopes in the 1830s and later made investigation of cortical organization more effective; it has continued uninterruptedly, producing a spate of papers and becoming an unmanageable deluge in this century. No more than the most outstanding contributions can even be mentioned here; our emphasis must be on work in recent decades but it is useful to note the basic discoveries from which the current intricate knowledge has expanded, if only to maintain a perspective amid the flood of detailed description and speculation which makes current activity interesting and yet confusing in its constant sallies and revisions. The accent of endeavour has, naturally, varied with the availability of technique; but major aims remain the elucidation of the *modus operandi* in the cerebral cortex and the localization of different activities in it.

Earlier observations, inevitably microscopic, were stimulated by the technique of Nissl, Golgi, Cajal and Weigert (7.156), amongst others. Even earlier, with inferior methods, Baillarger (1840) and Meynert (1867–8) had ascribed a *laminar pattern* to the cortex, with emphasis on its fibre structure, or *myeloarchitecture*. Later workers using the newer techniques mentioned (Lewis 1878, Campbell 1905, Cajal 1909–11, Brodmann 1909, Vogt & Vogt 1926, von Economo & Koskinas 1929, Lorente de Nó 1949) confirmed this (with notable variations and disagreements, now largely forgotten). The *cortical laminae* described, existed at successive depths and essentially *parallel to* the pial surface. A six-layered schema prevailed (Brodmann), though based only on Nissl-stained material in which all the details of dendrites and axons studied by other workers were invisible; moreover, the data were accumulated from a comparative series which, though

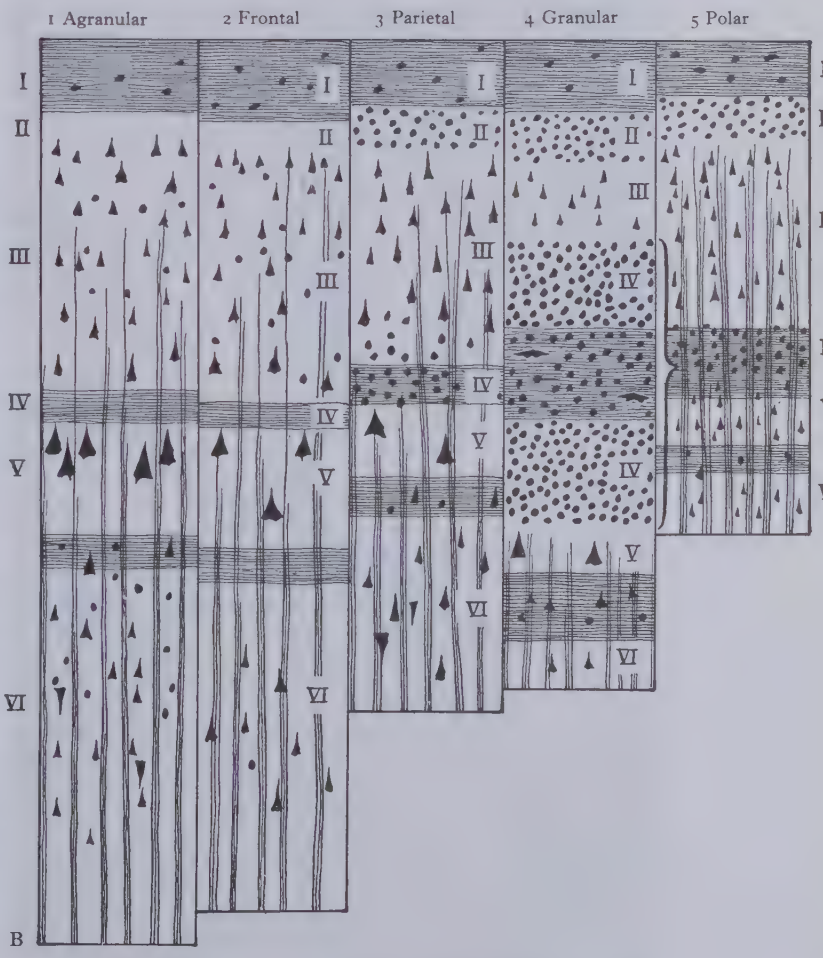
7.156 Representations of the layers of the human cerebral cortex, as stained by the techniques of Golgi, Nissl and Weigert.

7.157 The superolateral (A) and medial (B) surfaces of the human cerebral hemisphere demonstrating the cytoarchitectonic areas identified and designated numerically by K Brodmann (1909). See text for further details and references. Compare with 7.158A.

including simian brains, did *not* include the human cortex. These studies, in which sexalaminarity became almost dogma, led to the recognition of great variations in different cortical regions or 'areas', no less than 52 being distinguished. These results, embodied in the familiar 'Brodmann maps', are still widely current and were transferred arbitrarily to man by others, gaining much credence among physiologists, perhaps mostly as a useful numerical guide to the cortex (7.157A,B), as they still are.



Techniques such as Nissl's reveal only the structural variation and distribution of neuronal somata: a *cytoarchitectural* mode of study required additional *myeloarchitectural* methods to display the neighbouring myelinated axons. Only with *both* methods, also coupled with somatic and neurite staining by techniques such as Golgi's, to which must be added the more recent availability of electron microscopy and refined degeneration, histochemical and neurite tracing techniques, could finer details of cortical organization be discerned. Unfortunately, the Nissl-based cytoarchitectonic mapping of the cerebral cortex initially attracted more attention and its continued use, with myelin staining added, has led to an almost excessive parcelling of the cortex into different areas, few of which can be accorded clear physiological significance. One useful outcome was the diversion of interest among younger workers to physiological studies. Rapid advance in this field of cortical investigation gradually led to much discordance between the results of stimulation and architectonic mapping (except in broad details), prompting several notable reviews (e.g. Lashley & Clark 1946, Scholl 1956). These have not entirely deterred the 'architectonicians' and it must be stated that only in the *broader* aspects of their schemata is there some degree of accord between structurally defined areas and the results of experimentation.

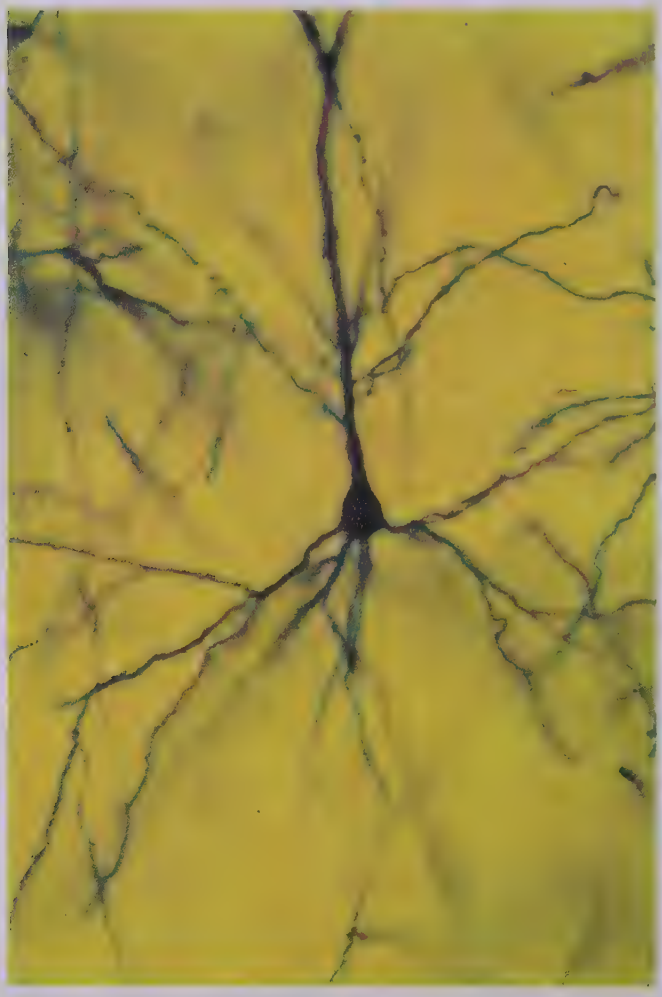


The definition of five or six major classes of cortical organization (cf. Campbell 1905, von Economo & Koskinas 1925, 7.158) has proved to have some functional validity, but excessive architectonic geography is reminiscent, except in the admittedly serious structural basis, of the multi-faculty maps of phrenology. Division of the cortex into such a relatively small multiplicity of 'organs' seems basically improbable. As critics have stressed, the variations in a single area in different individuals of one species, the effects of cortical development and folding and other factors, particularly the patterns of subcortical connection, may all contribute to the variable structural appearances in the cortex, variations which themselves are not uniform. The need for quantitative approaches to the problem has also been emphasized but this remains partly an exhortation, though their ultimate necessity is recognized.

That lamination characterizes the cerebral cortex is obvious but dogmatic views on the numbers of layers in this neuronal continuum, or regarding variations in and the equivalence of the customarily numbered six layers in different areas may, if pushed to excess, obstruct rather than enlighten. Nevertheless, the Brodmann schema is still almost universally employed, perhaps as a mere convenience, and will perforce be described below. Of course, an orderly arrangement of neuronal and glial units in the cortex, to some degree stratified, is undeniable and perhaps to be expected. Localization of function to a considerable degree (inasmuch as some areas receive or project large and easily identifiable subcortical connections) also remains undeniable; the polemics which this concept provoked in the late nineteenth century are largely forgotten (Clarke & O'Malley 1968). But the original extents of 'motor' and 'sensory' areas, as defined (and artificially *con*fined) by architectonic studies, have been much modified and augmented by physiological and anatomical experimentation.

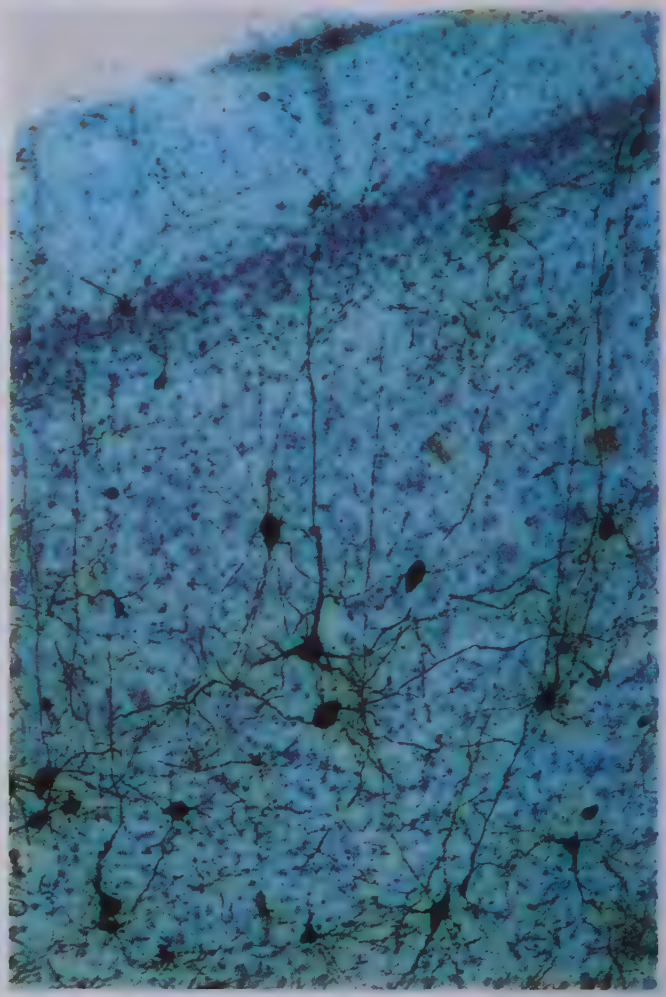
Studies of the cortex by Golgi and silver-staining methods, though once somewhat obscured by work with the Nissl technique, have received a renewed stimulus with the development of micro-recording from individual cortical neurons. Prior to this, elaborate structural studies of their neurites, available for half a century, could not be equated with the results of functional experimentation but, as mentioned elsewhere (pp. 872, 873), during recent years the intimate arrangement of neurons and their electrical activities have shown a growing correlation in elaborating concepts of modes of action in small volumes of nervous tissue at many sites in the central nervous system, including the cerebral cortex.

While the classic *cytoarchitectonic* doctrine is now perhaps little more than a useful geographical definition of the cortical areas (though sometimes a source of confusion in the 'translation' of areas from species to species), cyto*architectural* details, as revealed by the methods of Golgi and Cajal, are beginning to fit observed behaviour of 'units' in the living cortex. Classic neurite studies of the cerebral cortex, chiefly in lower mammals such as rodents (e.g. Lorente de Nó 1934), have led to the recognition of many types of neuron. The familiar pyramidal and stellate



7.158 The distribution of the five major types of cerebral cortex, as projected on to the superolateral surface of the hemisphere, according to von Economo & Koskinas (1925). The numbering of cortical areas (A) corresponds to the cytoarchitectonic types (B). See text for further details and references. Compare with 7.157A,B.

(granule) cells of Nissl-stained material were chiefly sorted by their relative size into unsatisfactory categories (subjectively assessed as large, medium, or small, and so on) without real measurement. Comparatively unilluminating data of this kind are represented in 7.158B, to be compared with 7.159A, B, which illustrates the more usable information provided by techniques revealing the interconnections between cortical neurons. By such criteria a larger range of neuronal specialization can be based; and since it is interneuronal *connections* which must be correlated with living activities this approach is inevitably more appropriate than plain cytoarchitectonics. The results of both methods do not generally conflict; but one is overwhelmingly more informative. Even though light microscopy proved unequal to full visualization of synapses in the cerebral cortex, the general patterns of interconnection of cortical neurons were, in major details, well clarified many years before electron microscopy appeared.



The termination of afferent axons in superficial cortical layers, nearer the surface than the somata of efferent neurons, with the existence of recurrent axon collaterals from the latter which turn back superficially to form connections through interneurons with their own dendrites and the existence of a clear '*vertical*' organization in the cortex, these and other features were all established as one main feature of basic cortical 'circuitry' before microelectrode experimentation began to require a more detailed background to its recordings. As will become apparent, 'chains' of neurons, emphasized by Lorente de Nó, arrayed in innumerable units repeated through the cortex, have fitted aptly into physiological studies of, firstly, the postcentral and striate regions (Mountcastle 1957, Hubel & Weisel 1962, Colonnier 1974, Zeki 1974, and pp. 1056, 1058), and subsequently many other, perhaps all, cortical regions (vide infra).

As elsewhere in the central nervous system, unit recording and the more precise study of transmission in excitatory and inhibitory synapses have generated a renewed demand for the finest details of interneuronal connections. Various forms of synapse and their ultrastructure are described elsewhere (p. 882); though their identification in the cerebral cortex was comparatively late (Gray 1959), a large literature on cortical synaptology has now accumulated. Axodendritic and axosomatic synapses predominate and for a period were considered the only types present, but dendrodendritic synapses have been identified in some locations. The multitudes of synapses, especially at the dendritic spines of pyramidal cells, provide an obvious structural basis for the most complicated interactions, however far we may yet be from anything more than the simplest interpretations, much less the detailed 'circuitry' of even the most elementary cortical events. Nevertheless, structure and function are rapidly progressing together in current cortical study; even if joint 'models' of cortical activity that are presently evolving evince a tendency to rather rapid change, this is surely a healthier state than the stagnating dogma which has sometimes becalmed neurological research.

In the following simple account of the cerebral cortex and its specific areas, space will not always permit adequate reflection of the intense current research; for this the reader must consult original papers and surveys, e.g. Colonnier (1966, 1968, 1974), Shepherd (1974), Rakic (1975), Szentágothai (1975), Schmitt et al (1976). Two approaches, however, are culminating in such

7.159 Preparations contrasting the Golgi and Nissl methods of staining nerve cells in the cerebral cortex. In (A) a single pyramidal cell stands out amongst many unstained elements. In (B) isolated Golgi-stained neurons are prominent amongst the remaining Nissl-stained cortical elements. Preparations provided by A R Lieberman, University College, London.

powerful influences, particularly in the last decade, that they deserve special emphasis. The overall gross *tangential lamination* mentioned is (except for details) universally accepted; much interest has been diverted to the *vertical organization* (i.e. at right angles to the pial surface). First, tissue units termed *cortical columns* were recognized (initially in certain restricted cortical areas only, pp. 1052, 1054), but a much wider, generalized concept of *cortical modules* (or *higher integrative units*) has been proposed and has stimulated much innovative research. (For reviews see: Hubel & Wiesel 1977, Phillips & Porter, 1977, Szentágothai 1978, Mountcastle 1978, Porter 1980, Phillips 1981, also vide infra). Simultaneously there has occurred an explosive increase in the scope of neurochemistry (see for review the monograph, *Chemoarchitecture of the Brain*, Nieuwenhuys 1985). As mentioned on p. 992 and elsewhere, the number of 'classic' or 'true' neurotransmitters has greatly increased and they may be short or long-acting; some classes of substance may be delivered via intercellular fluid to large numbers of neurons in relatively large volumes of tissue (paracrine effects), many other substances may be grouped as neuromodulators. All such pharmacodynamic materials should be considered in all parts of the nervous system including, of course, the cerebral cortex.

QUANTITATIVE ASPECTS OF CORTICAL STRUCTURE

Quantitative studies of the cerebral cortex were, until recently, comparatively few; a first attempt to ascribe numerical values to some of its grosser features was by von Economo & Koskinas (1925), who recorded data on variation in cortical depth, which are still amongst the most detailed for man. They also computed total surface area as 220 000 mm^2, a later estimate being 285 000 mm^2 (Scholl 1956), with a volume of 300 cm^3. (In a preliminary account using elementary cartography Walker & James 1977 estimated a much larger cortical surface area, about 800 000 mm^2. In view of these great differences, it is hoped that these investigations will be expanded and also include alternative techniques.) The total numbers of cortical nerve cells have naturally attracted much computation, and figures of 14 000 million (von Economo & Koskinas 1925), 6900 million (Shariff 1953), 5000 million (Scholl 1956) and 2600 million (Pakkenberg 1966) illustrate a downward trend, perhaps due to changing (improving?) technique. Stereological methods have been employed, e.g. Foh et al (1973) have estimated the total lengths of neuronal and glial processes in unit volumes of the visual cortex, in cats, arriving at 5000 m/mm^3 for neurites. Such data are beyond real comprehension; it is easier to grasp the magnitude of such a population by proportions in a smaller sample. For example (Hubel & Wiesel 1977), a column of cells 1 mm square and 2·5 mm deep may contain 100 000 neurons, of which some 66% are *pyramidal neurons* and the remainder *stellate interneurons* (vide infra). In one study of part of the motor cortex (precentral gyrus) each pyramidal neuron was estimated to take part in about 60 000 synapses, connecting with 600 other nerve cells (Cragg 1967, 1975). (However, also vide infra.) Such a small volume, itself containing about 3×10^9 synapses, might be multiplied, perhaps, a quarter of a million times to represent the whole cortex. The wealth of interconnections in such a huge array is clearly very great. In the striate area (Scholl 1955) where about a tenth of the cortical neurons are said to be concentrated, the dendrites of a single neuron may connect with 2000–4000 other cells and an arriving (afferent) projection fibre may ramify through a cortical volume containing 5000 cells. (Even these figures are, of course, dwarfed by cerebellar data, p. 972.)

The density of packing of neurons in different cortical areas and their laminae shows much variation, being densest in the striate area and perhaps least in the precentral gyrus. The ratio by volume of somata of neurons to all other cortical constituents (*grey/cell coefficient*) has been estimated: average ratios of 27:1 (von Economo & Koskinas 1925) and 70:1 (Haug 1956) for man have been cited. The ratio is claimed to show a phylogenetic increase up to man.

Neocortical Homogeneity

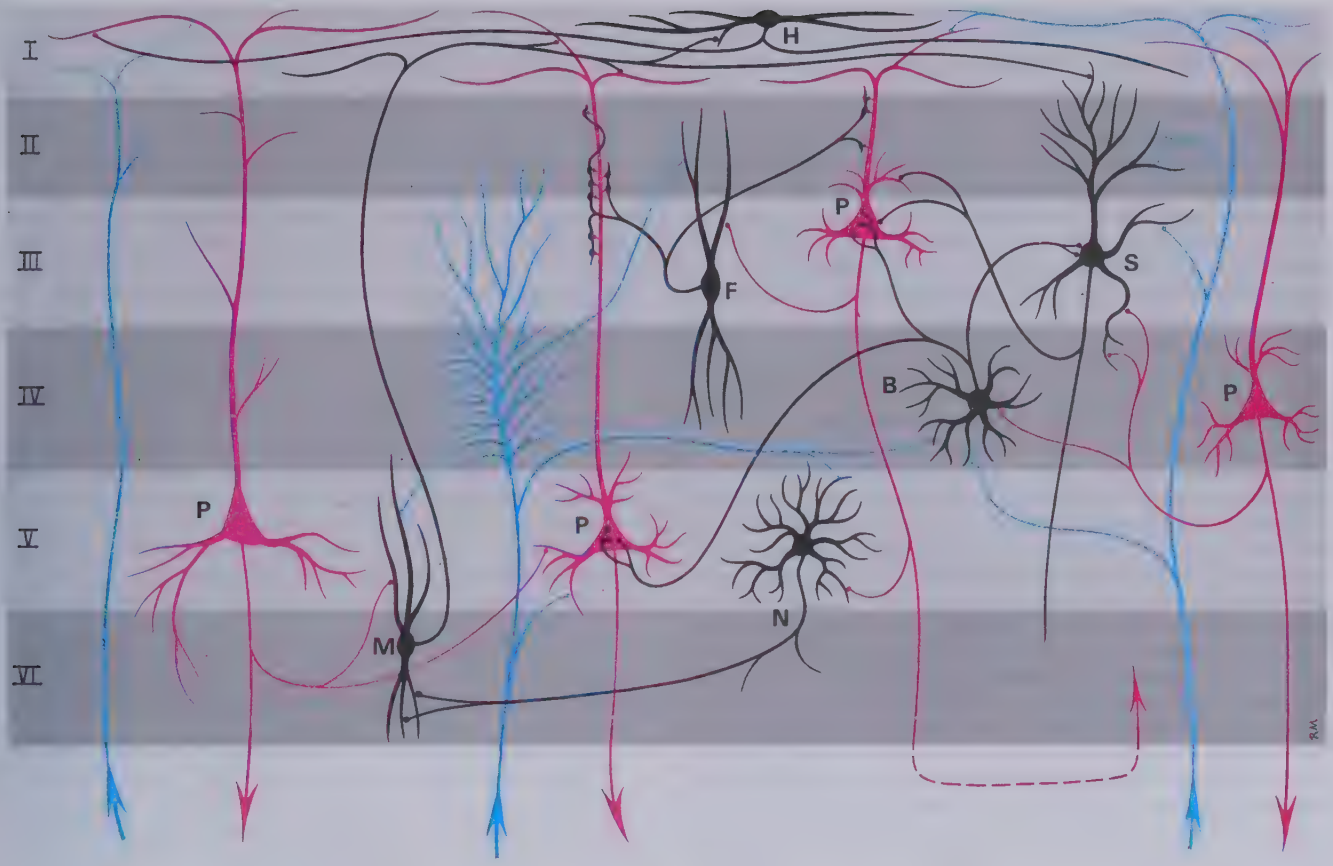
The most extensive, including comparative, quantitative studies of cortical and laminar thickness, absolute neuronal numbers in standard full-thickness cortical strips extending from the pia to white matter, and pyramidal/non-pyramidal ratios are by Rockel et al (1980) and Powell (1981). Their data (and reviewed literature) must provoke much radical reappraisal. The cortical areas, (frontal, motor, somatic sensory, parietal, visual (area 17) and temporal) were studied in the mouse, rat, cat, monkey and man; additionally area 17 only received further study in tupaia, galago, marmoset, squirrel monkey, baboon and chimpanzee. Total and differential counts were made in strips 30 μm wide and 25 μm thick cut perpendicular to the pial surface and passing to the subcortical white matter. The outstanding findings were that the *total neuronal populations* of standard strips (and therefore perpendicularly beneath a *unit area* of pial surface), with the exception of primate area 17, are so close as to be regarded as *virtually identical*, whether from different regions in the same brain, the same species or from those as remote as mouse and man. Additionally, *in all cases*, about two-thirds of the neurons are pyramidal, the remainder non-pyramidal (varieties of stellate neurons). Interestingly, the parts of area 17 concerned with primate *binocular* vision have a neuronal population that is about 2·5 times greater than other areas. Later studies (Powell & Hendrickson 1981) showed that *both* monocular and binocular parts of area 17 in the macaque monkey have the same larger population of neurons, whereas area 18 and other visual areas are like all remaining regions of the neocortex. Such findings are in full accord with the neurophysiological results and concepts of functional cortical columns and modules mentioned elsewhere. The *numerical neuronal homogeneity* (both absolute and the ratio of two principal varieties) of almost all the neocortex in a wide range of mammals, in standardized full-thickness strips or columns, despite marked variations in cortical thickness and subjectively described laminar patterns, must profoundly affect the interpretation of the classically described variations in structure ascribed to different regions (vide infra). It also stimulates speculation concerning the phylogenesis, ontogenesis, structural definition and integrative operation of *fundamental cortical units*; the establishment of absolute criteria for their universal definition presents many difficulties.

Various other quantified data regarding mammalian cortex are scattered through the literature, to be consulted for further details. In general, apart from an impression of enormous potentiality for interconnection and interaction, such figures have little immediate application. Knowledge that each afferent or efferent projection fibre may have more than 1000 neurons linked with it, more or less remotely, merely emphasizes the extremely intricate field of interaction between them. The time may be far off when events in such large neuronal assemblies can be defined in precise spatial and temporal terms, if indeed this can ever be expected in more than generalized statistical approximation; and even where accurate multimillion blueprints become available the human mind would inevitably demand combinatory concepts and technologies to aid comprehension.

For the present, limited events in minuscule volumes of cortex (e.g. columns, modules, submodules and their parts and connections) appear to offer a more promising and primarily essential field of investigation. Examples will be mentioned in connection with the particular cortical areas under consideration. Arising from such research, a profusion of evolving concepts of neuronal 'circuitry' and diagrams to illustrate these have appeared in the literature, e.g. Walter (1953), Ashby (1960), Weiner & Schade (1963), Taylor (1964), Young (1964), Arbib (1964), Minsky (1965), Shepherd (1974, 1978), Colonnier (1974), Rakic (1975), Szentágothai (1975, 1978), Hubel & Weisel (1977), Phillips & Porter (1977), Mountcastle (1978), Porter (1980), Rockel et al (1980), Powell (1981), Phillips (1981), Nieuwenhuys (1985). Naturally, these speculations undergo rapid change and modification as knowledge in the very active fields of neurocytology, synaptology, unit recording

7.160A Typical outlines of characteristic neocortical neurons as seen in sections prepared by the metallic impregnation techniques introduced by Golgi and Cajal. From left to right are shown Martinotti, neurogliaform, basket, horizontal, fusiform, stellate and pyramidal types of neuron. Many other forms and variants have been described. See text for literature.

and cerebral chemoarchitecture advances. Hence, despite their great interest, it is as yet premature to include more than passing reference to these. However, some potentially powerful general hypotheses will be mentioned below.



NEURONS OF THE CEREBRAL CORTEX

To the unaided eye the cerebral cortex forms a complete mantle or *pallium* covering the hemispheres, obviously variable in thickness (1·5–4·5 mm) when seen in section and thicker on the summits of gyri than in the depths of sulci (in which most of the cortex is hidden). Such thickness variations might well correspond to microstructural variations in the pallium; and it has been suggested that the positioning of gyri and sulci is conditioned by structural differences (Le Gros Clark 1945), but this cannot be claimed with respect to *functionally* differentiated areas, which often depart in outline from the sulcal pattern. In the freshly cut cerebral cortex some laminar details can be appreciated even without a lens (e.g. the visual stria of Gennari); elsewhere finer horizontal layers of nerve fibres, the inner and outer bands of Baillarger (p. 1046), can usually be discerned. It has even been claimed that more than a score of structurally distinct areas can be identified by simple visual inspection (Smith 1907).

The microscopic structure of the cerebral cortex, like 'grey matter' elsewhere, is an intricate blend of nerve cells and fibres, neuroglia and blood vessels. Neuroglia and vascular arrangements have been dealt with elsewhere (pp. 892, 895). The neuronal features, connections and distributions must now be considered. However, it is to be noted that variation in vascular distribution has also been utilized as a criterion in differentiating cortical areas (Pfeifer 1940) and many other finer features of its microarchitecture show corresponding variations in angioarchitecture (Duvernoy et al 1981).

Neurons of the pallium have been described and categorized in endless detail, but can be assigned to a few classes, most belonging to **two groups:** *pyramidal* cells and *stellate* (granule) cells. Both types may be assorted into variable subdivisions on the basis of size, shape and neuritic array (7.160A, B) and both occur in most cortical levels and areas, though numbers and distribution vary greatly. Other types of stellate cells commonly distinguished are: *basket*, *fusiform*, *horizontal*, *neurogliaform* and the *cells of Martinotti*; considered to be modified pyramidal neurons are the *pleomorphic cells*.

Pyramidal nerve cells, so named from their somatic shapes, vary from small elements about 10 μm across to giant pyramidal cells (of Betz) which reach 70 μm and more. They account for about 66% of the neuronal population in *all* neocortical areas (Rockel et al 1980, Powell 1981). Their apices are usually towards the cortical surface, with a thick *apical dendrite* ascending a variable distance, giving off collateral branches and often ending in a spray of terminal dendritic twigs. From the basal angles of the soma, *basal dendrites* spread laterally into the surrounding neuropil to form dendritic fields of varying shape and extent (Colonnier 1964). Statistical analysis of such branching in pyramidal and stellate cells has been attempted in the visual cortex (Scholl 1953) but such quantitative dendrological study is a neglected and difficult field. On the whole, the vertical extent of dendritic extensions of pyramidal cells is markedly greater than in the horizontal or tangential direction. The dendrites are studded, especially their smaller branches, with myriads of *dendritic spines* (p. 882), now known to be sites of axodendritic synapses (Gray 1959). Since these synapses, even by the crudest estimates, are multitudinous, a physical basis for the most elaborate cortical interneuronal reactions is immediately apparent. Axons of pyramidal cells, invariably smaller in diameter than the trunks of their main dendrites, behave variously. From larger somata, chiefly in lamina V (vide infra), *projection axons* extend centripetally to more or less distant subcortical structures, such as the basal nuclei, thalamus, hypothalamus, reticular formation and other brain-stem nuclei and the spinal grey matter. Some may return into other parts of the *ipsilateral* cortex as *long* or *short association fibres*. Others cross the midline as *commissural fibres*, their destinations being either *homotopic* or *heterotopic* points in the *contralateral hemispheric cortex*. Axons of smaller pyramidal cells usually ramify entirely in the cortex; even those which leave it commonly have a small number of collaterals which remain as intrinsic, *intracortical axons*, which may extend horizontally but more often have oblique recurrent courses to more superficial

7.160B A diagrammatic representation of the most frequent types of neocortical neuron, showing typical connections with each other and with afferent fibres (blue). Neurons limited to the cortex in their distribution are indicated in black. Efferent neurons are in magenta. The right and left afferent fibres are association or cortico-cortical connections, the central afferent is a specific sensory fibre. Neurons are shown in their characteristic lamina, but many have somata in more than one layer. They are indicated thus: P = pyramidal, M = Martinotti, F = fusiform, H = horizontal, N = neurogliaform, B = basket, S = stellate. See text for details and compare with illustration 7.164 et seq.

cortical laminae. Even this brief description shows that the larger pyramidal cells, whose somata appear in Nissl-stained sections in a *single* lamina, in fact have neurites that extend through most and often *all* cortical levels, their apical dendrites frequently entering the most superficial *plexiform lamina* (vide infra). Thus, each pyramidal neuron forms the core of one fundamental type of *columnar unit* extending right through the cortex, together with its numerous connections to other pyramidal elements, many forms of interneuron and afferent projection fibres; from its base issues its axon (which, as indicated, may be projection, long or short association, intracortical, or commissural; when its collateral branches are considered it may belong to two or more of these categories). Lateral connections are mediated by various intracortical axons and collaterals and horizontal and association neurons.

Stellate nerve cells, often called *granule cells* because of their (usually, but not invariably) small size and granular appearance in Nissl-stained material, appear in variable density in *all* cortical laminae except the most superficial (lamina I), but are usually in greatest abundance in laminae II and IV (vide infra). They account for about 33% of the neuronal population in all neocortical areas (Rockel et al 1980, Powell 1981). Like the pyramidal cells, stellate neurons would probably have been called multipolar if not first described in Nissl-stained sections. They are small, 6–10 μm in diameter, with a round soma drawn out at numerous angles by richly branching dendrites and a single short axon; they are hence Golgi type II neurons. Their dendrites carry many spines, indicating abundant synapses. Varieties of stellate cells have been distinguished, principally on the basis of their axonal disposition, length and arborization. Though confined to the cortex, their axons may travel considerable distances in it, chiefly in the vertical direction but sometimes horizontally. Vertical axons may be centripetal or centrifugal, the latter reaching lamina I. One type, the *basket cell*, is horizontally extended, with a short vertical axon soon dividing into a horizontal family of collaterals, which end in large terminal sprays, synapsing with the somata and proximal dendrites of pyramidal cells. They have a particular interest in their 'horizontality' because of the perhaps excessive attention that was, for a period, concentrated on vertical organization in the cerebral cortex (p. 1059). (Currently the *cortical module* concept is, at its simplest, a variable *four-dimensional unit*; when its submodular regions and their innumerable parameters are contemplated a term such as *multidimensional function space* becomes necessary; cf. p. 1052.) Another type of stellate cell is *fusiform*, due to the emergence of two large dendrites from opposite poles of the soma, dividing at once into elaborate groups of branches extending vertically. The axon, sometimes from a stem dendrite, extends centrifugally to lamina I. The neuron may spread through the whole depth of the cortex, probably synapsing with several pyramidal cells. *Neurogliaform stellate cells* are small, with a dense localized dendritic arborization, within which the short axon also usually ramifies (7.160A).

Horizontal cells, confined to the plexiform lamina I, are small and fusiform; their dendrites spread short distances in two opposite directions in lamina I. Their axons often stem from a dendrite, then divide into two branches which travel away from each other to greater distances in the same layer. **The cells of Martinotti** occur at most cortical levels. They are small, multipolar, with localized dendritic fields and long axons running centrifugally to the plexiform lamina, producing short horizontal collaterals en route. **Pleomorphic cells** are considered to be modified pyramidal cells with axons entering the white matter. Their somata are variously shaped, perhaps in accord with the differences in their dendritic sproutings, which spread widely into the cortex.

Other forms of neuron have been detailed in the cerebral cortex; since even the array of types mentioned here can only be tentatively linked in a co-ordinated scheme of interaction, it is merely confusing to multiply details. The most intensive studies of cortical neurons have been carried out in subprimate mammals; though appearances in the primate cortex (chiefly pursued in macaque monkeys) are similar, investigations of even 'cold' structural arrangements in the human cortex have been few (Economo & Koskinas 1929, Bailey & von Bonin 1951, Conel 1939–1959). For ultrastructural details of the human cerebral cortex consult Braak (1975), Cragg (1976) and Rees (1976). For general experimental and theoretical reviews consult Hubel & Weisel (1977), Phillips & Porter (1977), Szentágothai (1978, 1985, 1987) and Mountcastle (1978).

LAMINAR PATTERN IN THE CEREBRAL CORTEX

The cerebral cortex or pallium is often divided into an older, original part, the *allocortex*, consisting of the archicortex and paleocortex (archipallium and paleopallium), considered elsewhere (p. 1035); and a newer development, the *neocortex* (isocortex or neopallium), which may be equated with systems of sensory and motor activity which originally had little or no connection with the forebrain, but have acquired these by an evolutionary process of prosencephalization. The remarks which follow apply only to the neocortex.

As already stated (p. 1039), the customary description of a sexalaminar cortical structure, successfully promulgated by Brodmann and his followers, has by general acceptance obscured earlier disagreements and dissatisfaction with its arbitrary nature. Similar strictures apply to the excessively detailed architectonic mapping of the cortex derived from the same somewhat dogmatic views; but Brodmann's numbered layers and areas provide a reference grid of practical value and are widely used. Therefore, until more satisfactory systematics emerge, the details in so far as they are useful must be repeated here. The six laminae (7.156, 158) may be described as follows.

I. **The plexiform lamina** (molecular and zonal layer) contains sparsely scattered horizontal cells surrounded by a compacted mass of tangential fibres, derived from pyramidal cells (apical dendrites), stellate cells (vertical axons), cells of Martinotti (centrifugal vertical axons) and cortical afferent fibres, both projectional and associational.

II. **The external granular lamina** contains the somata of stellate and small pyramidal neurons, packed with varying density. Traversing it are vertical dendrites and axons from subjacent layers, intermingling with a dense neuropil of local dendrites and axons. Ascending afferents make extensive multiple synaptic contacts with the apical dendrites of large pyramidal cells (somata in lamina V) both in this and in lamina III.

III. **The pyramidal lamina** contains somata of medium-sized pyramidal neurons, the smaller ones being situated nearer to lamina II. Some stellate cells also occur, including horizontally disposed basket cells and vertically orientated fusiform cells, with dendrites and axons extending far beyond the lamina.

IV. **The internal granular lamina**, usually narrower than other laminae except lamina I, is chiefly populated by the somata of stellate neurons, with occasional small pyramidal cells. The somata are densely aggregated and the lamina is traversed by a concentration of horizontal fibres, long known as the *external band of Baillarger*. As in other laminae, this also contains large numbers of vertical neurites derived from neurons in other cortical areas, in subcortical regions and in adjoining laminae.

V. **The ganglionic lamina** contains the largest pyramidal cell somata but smaller ones also occur, the actual dimensions varying in different cortical areas. In any area, however, the largest pyramidal cells are in lamina V. Small numbers of stellate cells also occur and the lamina is permeated by a dense neuropil of dendrites and axons from its intrinsic elements and cells in other laminae. It is also traversed by the ascending and descending projection and association fibres. A considerable complement of horizontal fibres is apparent, corresponding to the *internal band of Baillarger*.

VI. **The multiform lamina** contains a range of cells, as judged by its somata and processes, the variable shape of the former reflecting variations in dendritic arrays. Most cells are small and considered to be modified pyramidal elements, despite the fusiform, triangular, ovoid and other profiles of their somata. Small, multipolar Martinotti cells are often prominent in this lamina, which is not always well demarcated from a subjacent cortical zone of fibres approaching or departing from the cortex.

The numbering and nomenclature of cortical laminae noted briefly above is in the style of Brodmann. Many synonyms are in circulation, derived from the work of investigators such as Campbell and Cajal; the Vogts also introduced another, more awkward nomenclature, based on myeloarchitectonic studies in which fibre structure is emphasized. Views as to the number of layers have varied and much subdivision has been mooted. For example, lamina VI has been divided into VIa and VIb by the distribution of triangular and fusiform cells and into no less than four sublaminae (VIa^1, VIa^2, VIb^1 and VIb^2) in material stained to show fibre structure. All except lamina II have thus been further analysed, as many as 16 laminae being recognized by the Vogts. The usefulness of such minute stratification has been much criticized; such details are only mentioned here as examples. Similar remarks are applicable to much work in cortical architectonics.

Here again the Brodmann maps have achieved most attention. Their early transference (in a form further elaborated by the Vogts but still not worked out in man) to the human cortex by Foerster has overshadowed the contribution of von Economo & Koskinas. In one respect this is fortunate, because they chose to designate areas by letters, as has Conel (1939); these, and other nomenclatures would have proved less manageable than Brodmann's simple numbers. However, newer views on the extent of major sensory and motor cortical areas have generated a need for more appropriate terminology than Brodmann's (Woolsey 1964). A suggested new series of symbols will be referred to later, for particular areas; many are already in wide use in experimental studies but since a lack of uniformity persists in this new and far from comprehensive terminology, which is only beginning to penetrate clinical neurology, the customary numerical designation of areas must be retained for the present.

REPRESENTATIVE VARIANTS OF CORTICAL STRUCTURE

Note. The following is retained for historical perspective, and because of wide usage. Nevertheless the *numerical neuronal homogeneity* of the neocortex and of its constant ratio of pyramidal/stellate neurons amply demonstrated in many mammals by Rockel et al (1980) and Powell (1981) must be constantly remembered. Individual neurons may vary greatly in size, packing density and in their profusion of efferent and afferent connections with multiple destinations and sources and these underlie the following 'varieties', with their differences in thickness and laminar pattern.

While it is here impossible, and probably unprofitable, to detail and discuss the almost endless nuances of cortical structure based on full-blown architectonics, a smaller number of variant types must be indicated. These were recognized in the classic studies of Campbell (1905) and corroborated by Economo & Koskinas (1929). *Five* fundamental types are described in the neocortex (7.158A,B). While all these are said to develop from the same *sexalaminar pattern*, two are regarded as virtually lacking certain *laminae* when differentiated and are hence *heterotypical*; these are the *granular* and *agranular* types. *Homotypical* variants, in which all six laminae persist, are called *frontal* (premotor), *parietal* (postcentral) and *polar* (visuopsychic), names linking them with specific regions in a misleading manner, as illustration 7.158A shows (e.g. the frontal type occurs in parietal and temporal lobes).

The agranular type is considered to lack, or have diminished granular laminae (II and IV) but always contains scattered stellate somata. The prominent neuronal type is pyramidal and in this form the greatest densities and largest sizes of pyramidal neurons occur. Originally identified in the precentral gyrus (area 4), it also occupies areas 6, 8 and 44 (7.157A,B) and occurs elsewhere,

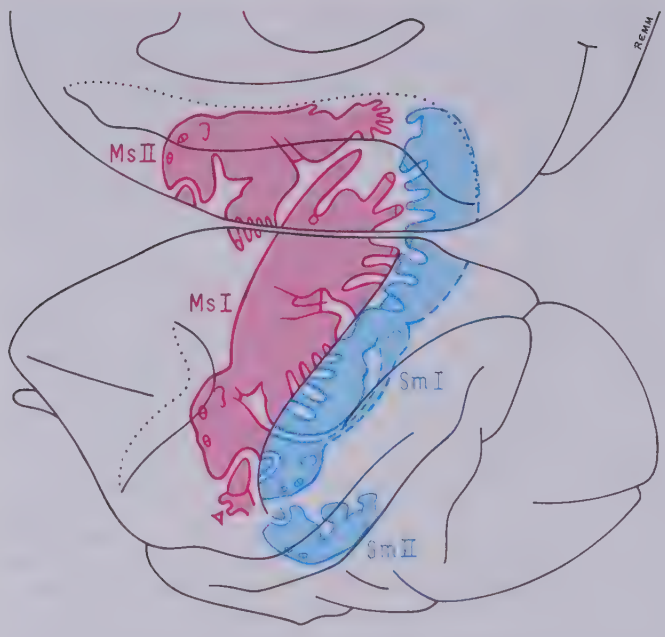
including parts of the limbic system (p. 1028). It is typified by projection of particularly large numbers of axons from its pyramidal cells; the agranular cortex is thus often equated with 'motor' areas, with the proviso that such areas also receive afferent projections. (Further, *all* neurocortical areas have many varieties of both efferent and afferent projections.)

The granular type of cortex (koniocortex) is at the opposite extreme from the main categories of cortical structure. Granular layers are maximally developed and contain densely packed stellate cells, amongst which are dispersed small pyramidal neurons. Laminae III and IV are poorly developed or unidentifiable. This type is particularly associated with afferent projections but, again, there is evidence of less numerous efferent fibres, derived from the scattered pyramidal cells in this otherwise 'granular' cortex.

Despite the relative lack of different laminae, granular and agranular cortices exhibit little qualitative distinction, being rather at opposite extremes of a gradation, in which the pyramidal and stellate neurons are reciprocally prominent. A typical granular cortex appears in the postcentral gyrus, striate area and superior temporal gyrus (acoustic area) and in small parts of the parahippocampal gyrus (p. 1029). Despite its very high density of stellate cells, especially in the striate area, it is almost the thinnest of the five main types. In the striate cortex the external band of Baillarger (lamina IV) is well defined as the *stria of Gennari* (or Vicq d'Azyr).

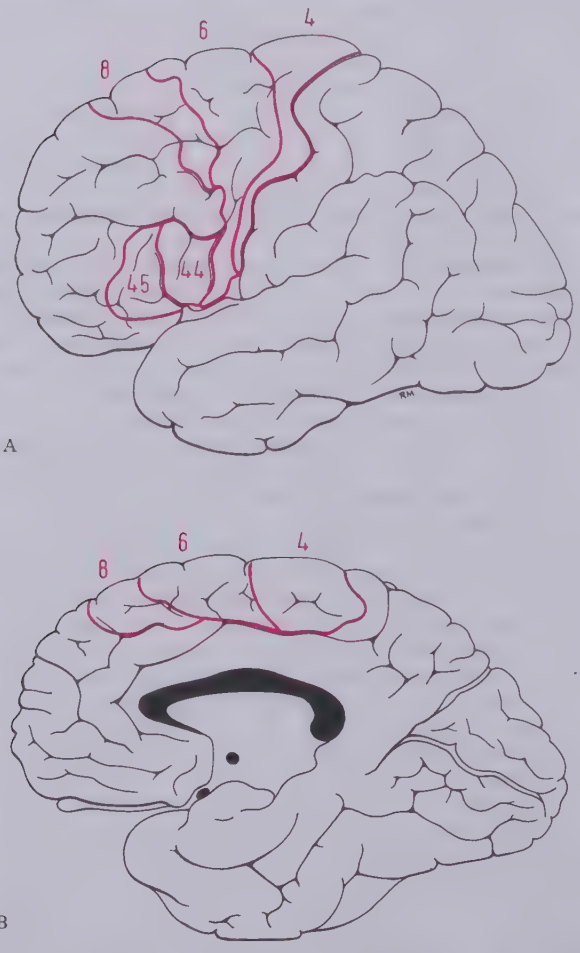
The remaining three types of cortex are intermediate forms. In the **frontal type** large numbers of small and medium-sized pyramidal neurons appear in laminae III and V, granular layers (II and IV) being less prominent. The relative prominence of these major forms of neuron vary reciprocally wherever this form of cortex exists. It is not confined to the frontal region (7.158A,B). The **parietal type** of cortex contains pyramidal cells which are mostly smaller in size than in the frontal type; granular laminae are, on the contrary, wider and contain more of the stellate cells. This kind of cortex occupies large areas in the parietal and temporal lobes (7.158A,B). The **polar type** is classically identified with small areas near the frontal and occipital poles, hence its name. It is the thinnest form of cortex (7.158B). All six laminae are represented but the pyramidal layer (III) is reduced in width and not so extensively invaded by stellate cells as in the granular type of cortex. As in the latter, the multiform layer (VI) is more highly organized than in other types.

While subdivision of these five basic types of cortical 'organization' may sometimes be useful, it must be re-emphasized again that in microscopic sections where they are customarily distinguished, whether stained to show somata or processes, the finer and more significant details of true organization are not so apparent in studies of the whole thickness of the cortex. Functional organization is naturally linked to the spatial distribution of cells but it is in their actual patterns of connection that any real enlightenment as to cortical mechanism must be sought. Golgi preparations have yielded an immense amount of information indicating the probable designs of neuronal interaction. Functional hypotheses deduced from such structural data, however intricate, require confirmation in terms of the precise nature of the synapses, both in their distribution *and* mode of action. Such details depend on electron microscopy and unit recording, techniques which deal only with much smaller volumes of cortical tissue, and also on the rapidly expanding techniques of neurohistochemistry. Nevertheless exciting results have accrued in this field in recent years and doubtless more is to come. The cytoarchitectural approach to cortical activity was a necessary prelude and the resulting definitions of forms of organization in structural terms remain the bases of orientation to which ultrastructural and other details must be referred.



THE MAIN CORTICAL AREAS

Before describing the major areas of the human cerebral cortex, customarily distinguished by functional and structural data such as the somatomotor, somatosensory, visual and auditory areas, preliminary general remarks are necessary. As already emphasized, the extreme parcelling deriving from studies by Brodmann has limited its usefulness and can be misleading if taken as much more than a reference grid. Even the simplest division of the cortex into *sensory* areas receiving afferent projections and *motor* areas projecting efferents, the remainder being regarded as 'silent' or *associational*, is no longer appropriate, being an inaccurate over-simplification. Evidence has accumulated to show that areas receiving or originating *specific named groups of* projection fibres are much more extensive than the initial classic studies indicated. Furthermore, division into 'receiving' and 'originating' areas is only relevant in relation to a particular stated tract, fasciculus or radiation, if certain *general structural features* are clearly recognized. *All neocortical areas* are *both* originating and receiving, i.e. they have substantial populations of efferent and afferent fibres. What follows is in no sense comprehensive, but a brief list to provide an ever-present background when a superadded named connection or area is under review; each receives more detailed attention elsewhere. *Efferent fibres* pass *from* all areas *to* the dorsal thalamus (cortico-thalamic), the corpus striatum (cortico-striate), the reticular formation (cortico-reticular), the pons (cortico-pontine), ipsilateral cortex (long and short association fibres), contralateral cortex (homotopic or heterotopic commissural fibres). They are lacking in distal limb areas and narrow strips in visual areas. Other efferents have more restricted origins. *Afferent fibres* pass *to* all areas *from* the dorsal thalamus (thalamo-cortical from both specific and intralaminar nuclei), some elements of the brain-stem reticular formation (reticulo-cortical) including: monoaminergic fibres radiating from the nucleus coeruleus (A6), rapheal nuclei B6–8, medial forebrain bundle and hypothalamus, cortico-cortical afferents, either ipsilateral (long and short association) or contralateral (commissural).



The named areas in the following account have, for long, been better known because of the obvious and dramatic sequelae when trauma or pathology supervenes and their greater accessibility to investigation. However, intense research effort is currently directed to elucidating the most appropriate arrays of *fundamental cortical units* which are probably repeated countless times over the qualitatively and numerically *uniform neocortex*. On this view, functional localization in the cortex is *not* an intrinsic property but is conferred on it by its mosaic of afferent and efferent channels, their sources, destinations and numbers.

With specific areas a brief historical perspective will be pursued. Thus, the postcentral gyrus is not the only area to which the somatosensory thalamic projection is directed; at least two other areas are similarly involved, as will be detailed later. Similarly, the precentral gyrus is supplemented by a second 'motor' area and it is necessary to qualify the term 'motor', because the distinction of motor and sensory areas which is still customary in most accounts of the cerebral cortex is erroneous and has been known to be so for many years. As long ago as 1933 motor responses to stimulation of 'sensory' areas were demonstrated (Dusser de Barenne 1933); and the projection of efferent ('pyramidal') fibres from this postcentral area was established shortly afterwards (Levin & Bradford 1938). Since these pioneer observations, much confirmatory evidence in various experimental animals has extended such findings to other areas. Moreover, clinical and experimental observations in mankind suggest that similar arrangements obtain. It is hence appropriate to speak of pre- and postcentral areas as *sensorimotor*. Since a mixture of afferent and efferent connections has been shown also in respect of the accoustic and visual 'sensory' areas, they also are sensorimotor.

Recognition that the corticospinal tract is derived from somata in an area far beyond the strict precentral gyrus is paralleled by

7.161 The main sensorimotor areas projected diagrammatically upon the superolateral surface of the simian cerebral hemisphere. Note the somatotopic arrangement in all four areas. Adapted from Woolsey 1964, see text for details and references.

7.162 Superolateral (A) and medial (B) surfaces of the cerebral hemispheres, showing approximate correspondence of the Brodmann areas to the main motor area (4) or MsI, the premotor area (6, 8) and motor speech area of Broca (44, 45). See text for details and compare with 7.157, 169, 170.

findings in various thalamic and geniculate projections on the cortex; these terminate in considerably wider regions than originally described. For example, as intimated, the classic somatosensory area in the postcentral gyrus is supplemented by a second, inferior to it, and even a third, on the medial hemispheric aspect which is also a motor area (vide infra). Similarly lateral and medial geniculate bodies are now known to project to regions of the cortex beyond the visual and auditory areas of older description. Not only the striate cortex (area 17, visuosensory area), but also para- and peristriate areas around it (areas 18 and 19, the 'visuopsychic' cortex) receive projection fibres. In cats the acoustic radiation terminates not only in the *first acoustic area* (41) but also in several others in the temporal cortex.

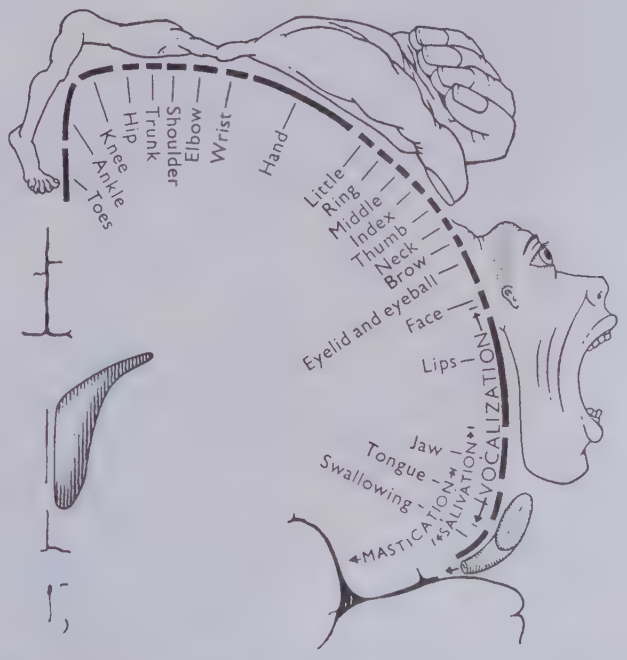
These modifications of originally simple motor and sensory areas require revised terminology. One commonly used (Woolsey 1964), though not entirely satisfactory nor yet accurately adapted to the human cortex, divides the sensorimotor area into a part in the precentral gyrus termed MsI, because it is the main or *first* predominantly *motor* area but to a lesser extent also sensory (7.161). Conversely, in the postcentral gyrus, SmI is the primary *S*ensory area, though also partly *motor*. On the medial cerebral surface is another sensorimotor area which, being largely motor, is called the *supplementary motor area*, MsII. Unfortunately, MsII is sometimes also known as the *third* somatomotor area, because there is a second sensorimotor area, SmII (7.161), inferior to SmI. It would have been easier to regard MsII as the second somatomotor area and SmII the third, as some do, but this merely shifts the numerical confusion. Some authors surmount this difficulty by disregarding the abbreviations and speaking of first, second and third motor or sensory areas. This terminology is admittedly perplexing but its shortcomings are merely incidental to the important finding that the frontoparietal sensorimotor region is a complex, each area having its own degree of somatotopic organization. *None* of these 'areas' is exclusively motor or sensory, though one or the other quality always predominates. In the following text ambiguity has been avoided by use of synonyms.

In the occipital lobe striate, parastriate and peristriate regions (areas 17, 18 and 19) are likewise termed *first*, *second* and *third visual areas*, or visual areas I, II and III. More complex terms, applied in particular to the feline cerebrum (Rose & Woolsey 1958), currently designate *four* temporal areas considered to receive auditory projection fibres *in cats*: the *first acoustic area* (AI), the auditory area of usual description, *second acoustic area* (AII) and the *anterior* and *posterior ectosylvian areas* (Ea and Ep). Accessory acoustic areas can be indicated only tentatively in the human cortex (7.173), partly because the acoustic regions are entirely superficial in feline temporal lobes, but partly folded into the lateral sulcus in mankind. All the areas named above not only receive projections *from* their particular thalamic nuclei (though this is not established for the ectosylvian acoustic areas) but also project back to the same nuclei and in some instances to other nuclei at lower levels, connections which in each modality are concerned with inhibitory and sometimes facilitatory effects in their own sensory pathway. It is this afferent–efferent nature of most, probably all, sensorimotor areas which makes the concepts of distinguishable motor and sensory cortical areas anatomically invalid and functionally misleading.

It is clear that much less of the cerebral cortex remains to be dubbed 'associational', in the vague but well-established meaning of the term; but large regions in all cerebral lobes are not accounted for by sensorimotor projections. In the human brain, much clinical evidence suggests that for long the so-called 'silent' areas are indeed concerned in further elaboration and interpretation of sensory information and in the combination of its different modalities, as has long been vaguely implied. Much less is known of the detailed connections of these areas, whether with the brain stem and diencephalon or by association or commissural fibres, although unquestionably *all* are involved. Hence, less can be said of these areas than of the sensorimotor cortical domains. Ablation experiments, coupled with the tracing of degenerating axons and the observation of disturbed behaviour, with similar deductions in human patients affected by damage, disease or surgical intervention, are beginning to provide more coherent concepts of the activities in association areas.

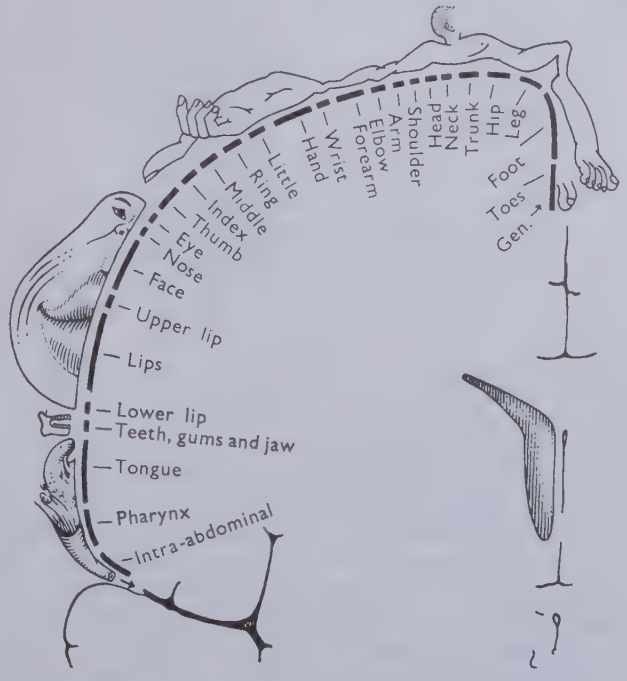
Though it might be functionally appropriate to consider first the predominantly sensory areas and then those mainly motor, widespread involvement of many parts of the cortex in even the simplest activities, and the sensorimotor nature of the areas concerned, render any such considerations of priority almost meaningless. The main areas will therefore be described on the basis of the lobes in which they are located and in an arbitrary order: frontal, parietal, occipital and temporal.

THE FRONTAL LOBE



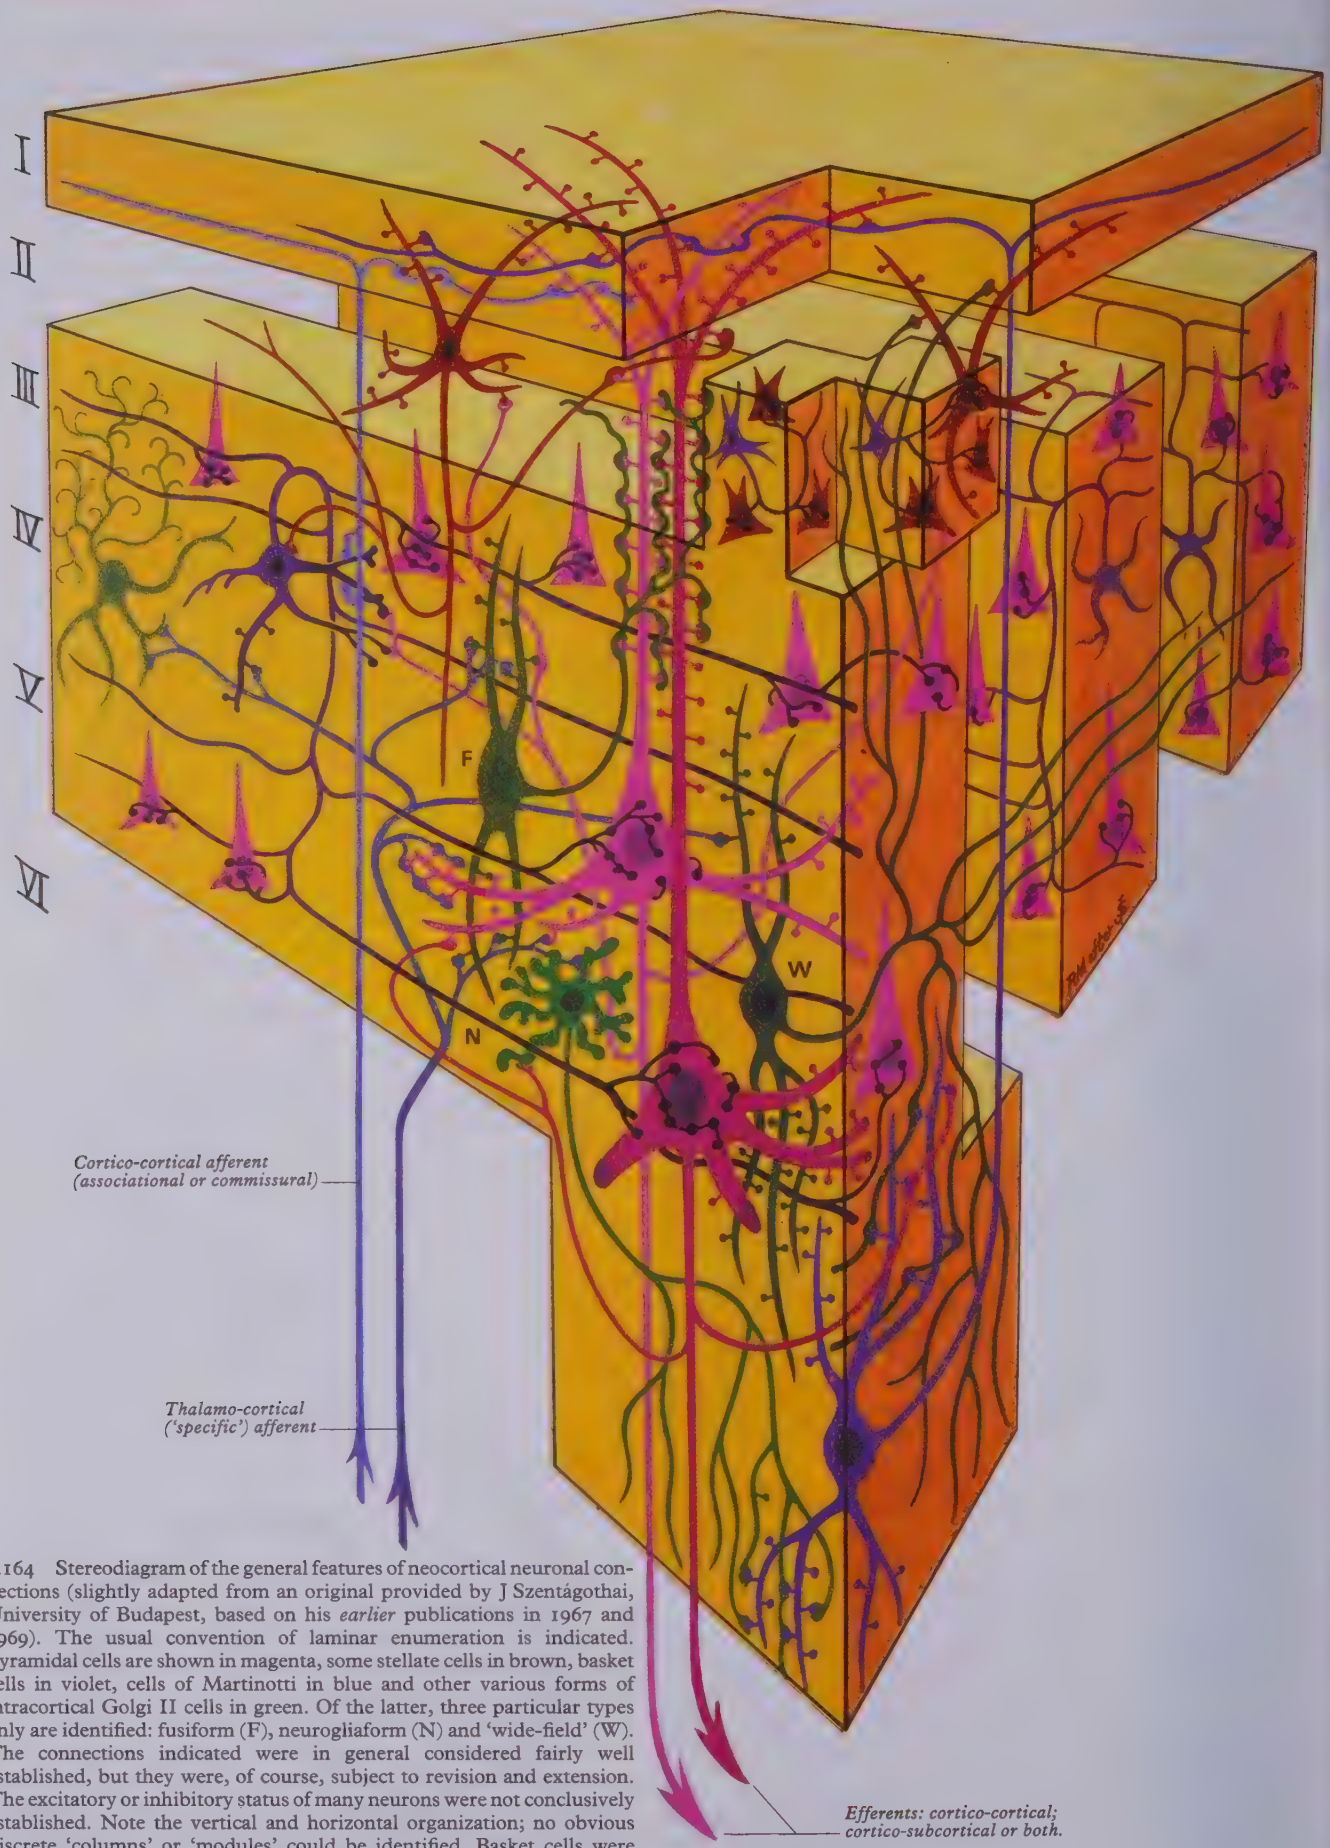
The frontal cortex may be conveniently divided into *precentral* and the unfortunately named *prefrontal* region. The former is largely sensorimotor, the latter an 'association' cortex.

The precentral area includes the whole precentral gyrus and posterior (caudal) parts of superior, middle and inferior frontal gyri (Brodmann areas 4 and 6). The whole region (7.162A,B) features an almost complete absence of granular layers. Intracortical fibres are numerous and the plexiform layer hence is densely packed. The area is sometimes divided into posterior and anterior parts, *motor* (area 4) and *premotor* (area 6), but the distinction between them differs, according to whether cytoarchitectural or physiological data are applied. As comparison of Figures 7.157A,B and 7.162A,B shows, the boundary between areas 4 and 6 descends on the precentral gyrus, whereas the entire gyrus is functionally the *motor area*. It is less confusing to disregard the Brodmann numeration, or to use it as a merely approximate indication. The premotor area occupies parts of the three frontal gyri, corresponding largely to area 6 but including parts of 8, 44 and 45 (7.162A,B). For the present, it is simpler to designate the whole precentral area as the *first* or leading **somatomotor area** (MsI), remembering that functional variations occur within it which may to some extent coincide with cytoarchitectonic differences, but much more certainly with afferent and efferent connectivity.



A feature of this area (MsI) is the prominence of pyramidal neurons of all sizes. The largest, the *giant pyramidal cells of Betz*, vary in height from 30 to 120 μm and in breadth from 15 to 70 μm, being most numerous in the part of the area extending over the hemisphere's superomedial border into the paracentral lobule (7.162B). They diminish in numbers down the precentral gyrus towards the lateral fissure and also extend less and less forwards in the gyrus, following the boundary of area 4 (to which they are almost limited, being absent from the premotor or anterior part of MsI). In view of the somatotopical arrangement now to be described, it is tempting to suppose that the size of the larger pyramidal cells is associated with the length of their axons. Giant pyramidal cells in the human motor cortex have been estimated at between 25 000 and 30 000 (Campbell 1905, Lassek 1940), a figure conflicting with the million or so fibres in the medullary pyramid (Lassek & Rasmussen 1939, Lassek 1942). The majority of corticospinal and probably corticobulbar fibres are hence derived from the smaller pyramidal neurons. Many such axons do not originate in area 4; it is interesting to note that its ablation in monkeys reduces the fibres in the pyramid by a mere 25% (Lassek 1942). Obviously most 'pyramidal' fibres have other origins, as will be detailed below.

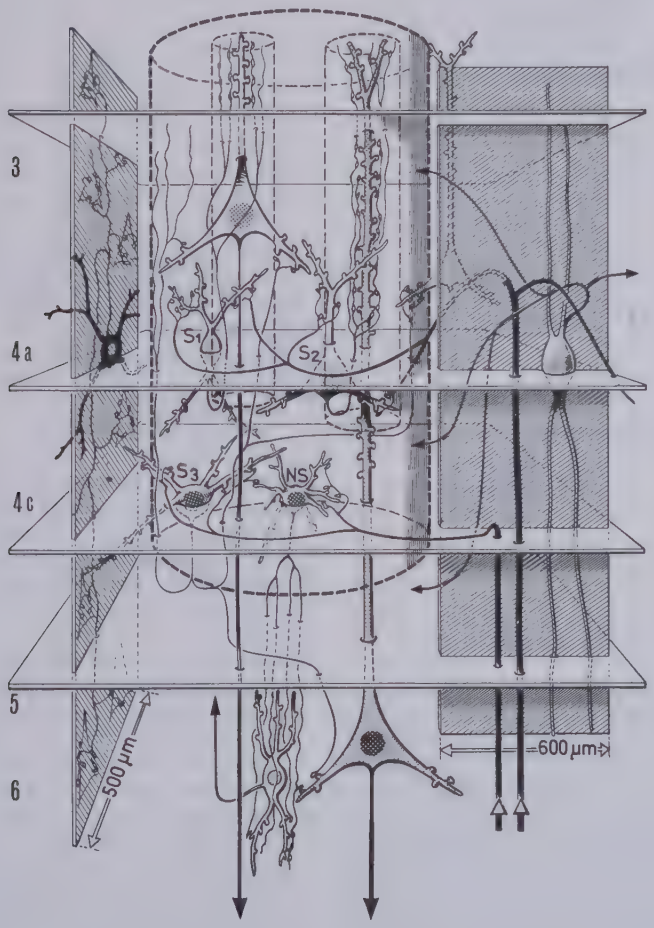
Recognition of simple *contralateral movements*, elicited in different parts of the body by electrical stimulation of loci near the central sulcus, dates from the pioneer study of Fritsch & Hitzig (1870) in dogs. This discovery has been confirmed and elaborated in innumerable subsequent experiments in primates (e.g. Leyton & Sherrington 1917) including man (Ferrier 1874, Penfield & Rasmussen 1950); it has become a tenet of neurology that the area involved is concerned in the mediation of voluntary movements. The order of loci, from the paracentral lobule, is associated with lower limb, trunk (upper part of the precentral gyrus), upper limb, neck and head (7.163A). Much detail of this somatic 'representation' has accumulated, of course, and it is established that the amount of cortex-mediating movement in any region is proportional *not* to the bulk of muscle involved but to the skill with which it is used (7.163A). It is important to emphasize that in the earliest studies of excitability of the 'motor cortex', movements were elicited also from the postcentral gyrus and that the same movement was excited from different loci at different times in the same brain. More careful control of the parameters of stimulation has later confirmed this apparent 'plasticity' (Liddell & Phillips 1950) which is difficult to represent in textbook illustrations. This and other factors have obscured these early findings to some extent; the polemics over the great volume of reports on cerebral motor function, especially regarding the discrepancies between clinical and experimental observations, were at least useful in so far as they refocused attention on facts rather than theories (Bucy 1944).



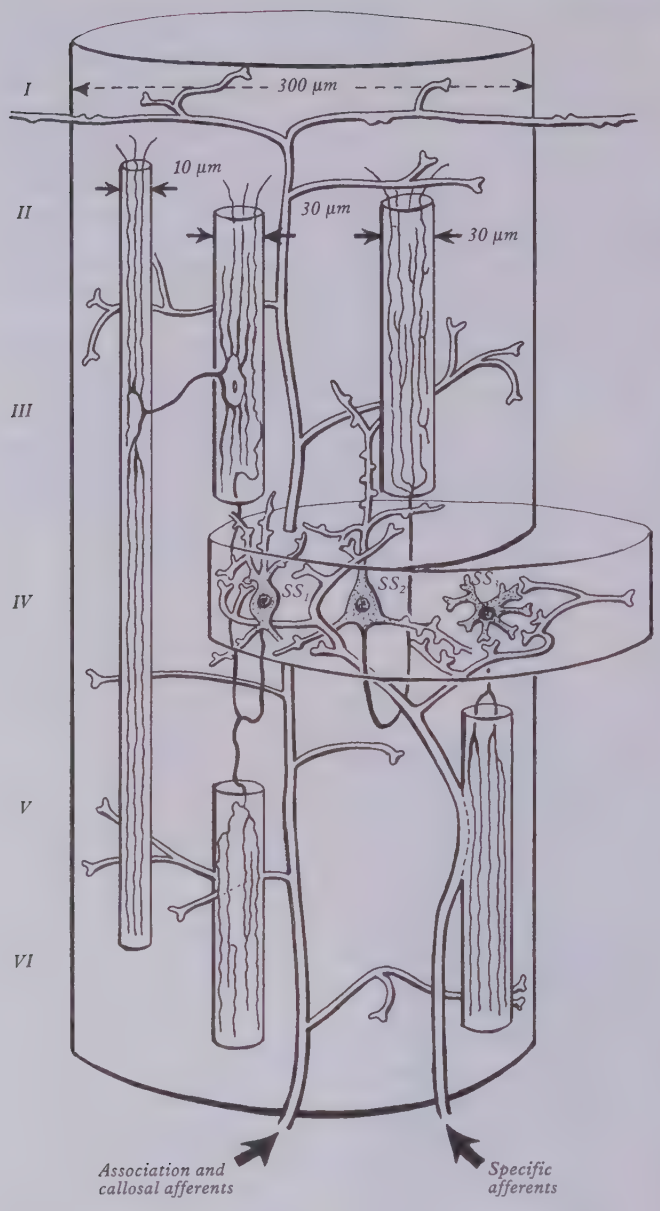
It is now well established that while the whole first somatomotor cortex (MsI, areas 4 *and* 6) is a source of corticospinal fibres, it is not the only one. Both in monkeys (Levin &

7.163A The *motor homunculus* showing proportional somatotopical representation in the main motor area. After Penfield & Rasmussen 1950.

7.163B The *sensory homunculus* showing proportional somatotopical representation in the somaesthetic cortex. After Penfield & Rasmussen 1950.



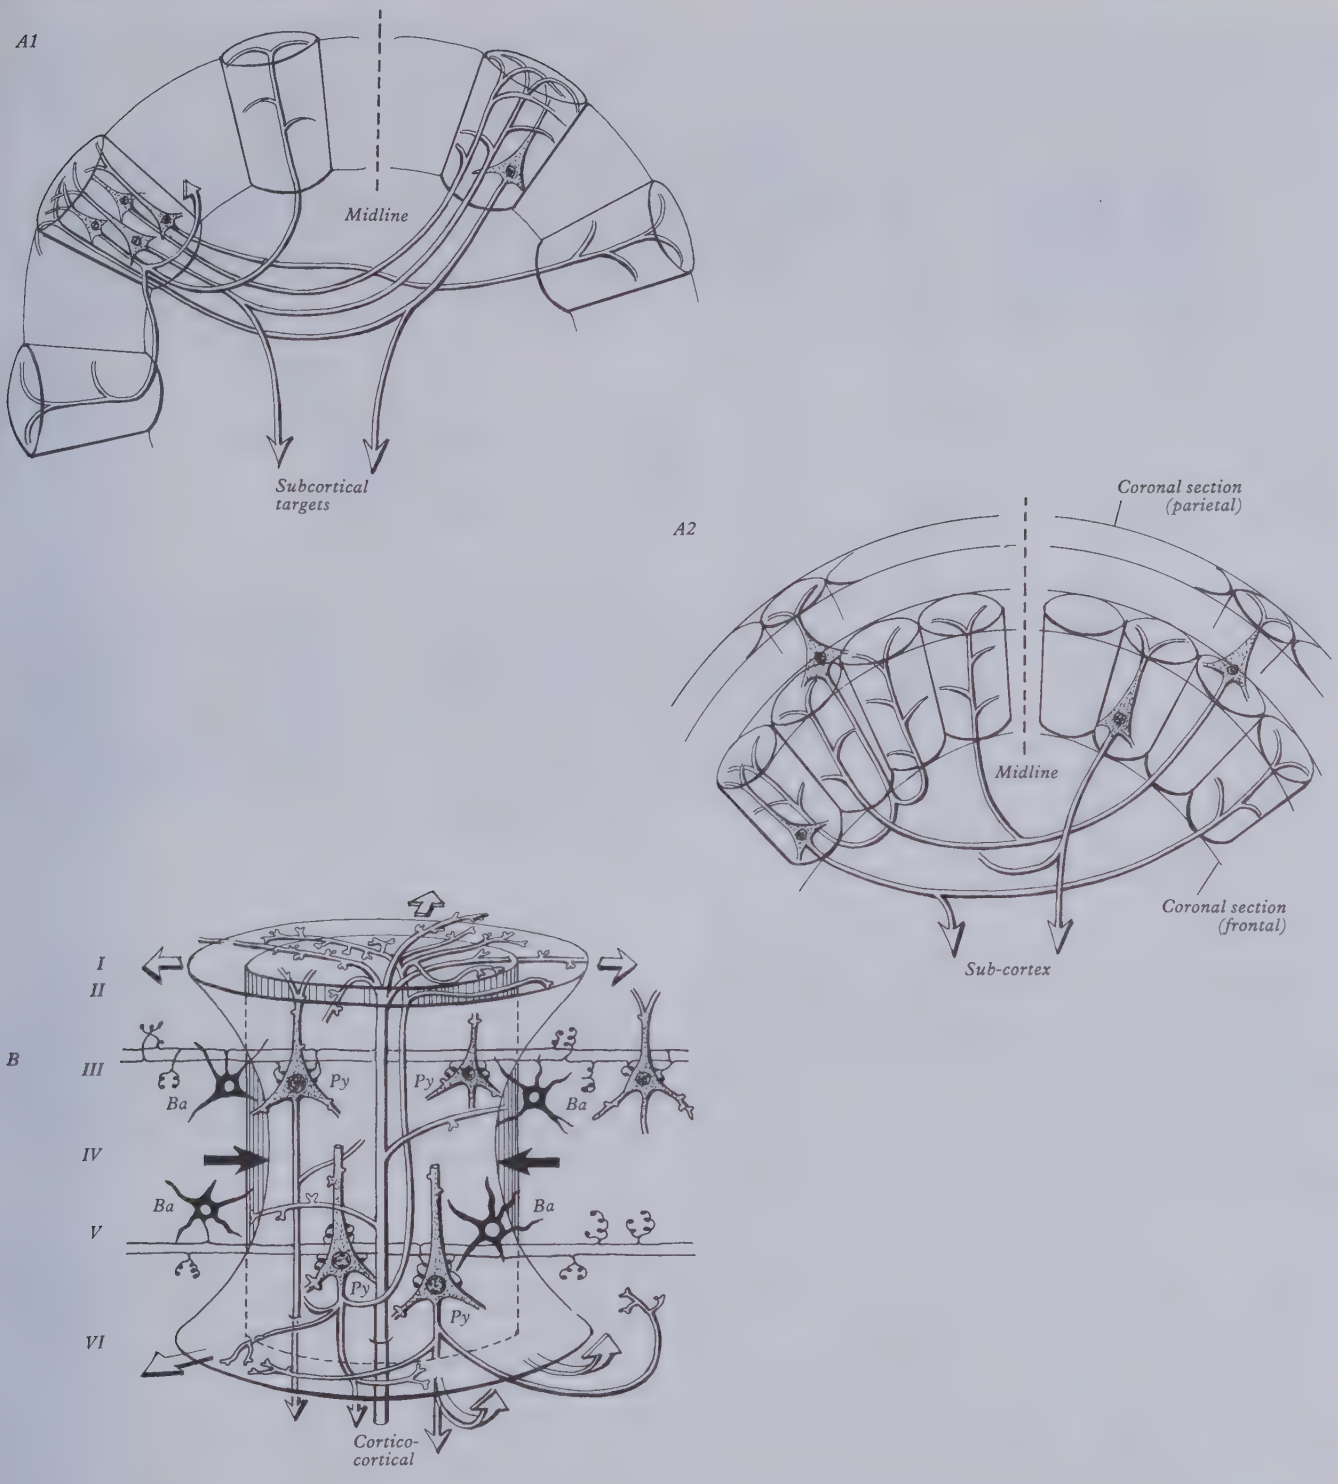
7.164 Stereodiagram of the general features of neocortical neuronal connections (slightly adapted from an original provided by J Szentágothai, University of Budapest, based on his *earlier* publications in 1967 and 1969). The usual convention of laminar enumeration is indicated. Pyramidal cells are shown in magenta, some stellate cells in brown, basket cells in violet, cells of Martinotti in blue and other various forms of intracortical Golgi II cells in green. Of the latter, three particular types only are identified: fusiform (F), neurogliaform (N) and 'wide-field' (W). The connections indicated were in general considered fairly well established, but they were, of course, subject to revision and extension. The excitatory or inhibitory status of many neurons were not conclusively established. Note the vertical and horizontal organization; no obvious discrete 'columns' or 'modules' could be identified. Basket cells were widely held to be inhibitory. Note the contrasting termination fields of 'specific' and cortico-cortical afferents; also of intracortical recurrent collaterals of pyramidal neuron axons.



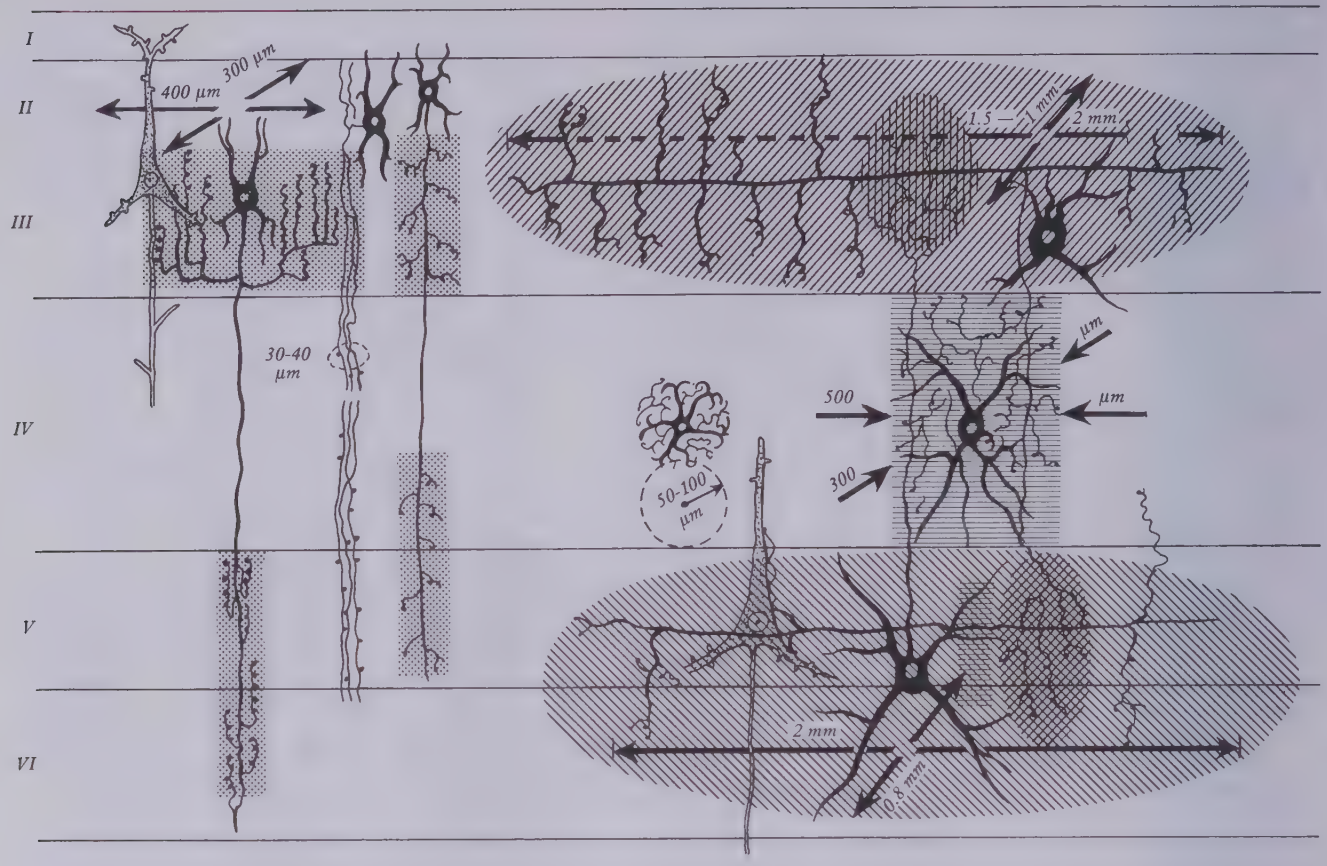
Bradford 1938) and man (Kuypers 1958) the first somatosensory area (SmI, areas 3, 1 and 2) in the parietal lobe is also a source of corticospinal fibres; possibly the second somatosensory area (SmII, approximately equal to areas 40 and 43, p. 1057), below the first area and above the lateral fissure (posterior limb), also contributes 'pyramidal' fibres. Smaller contributions from occipital and temporal lobes have also been described in cats (Walberg & Brodal 1953). Physiological evidence largely accords with these anatomical findings. Fibres descending from this extensive origin vary much in calibre; in the human pyramid 90% were estimated to be 1–4 μm in diameter, only 2% were 11–22 μm, a fraction corresponding closely with the number of giant pyramidal cells (Lassek 1942). Up to 94% of the fibres are myelinated in man (De Meyer 1959).

The primary, first somatomotor area, or MsI, receives fibres from the cerebellum which relay mainly in the thalamic nucleus ventralis lateralis (p. 1002), distributed particularly to its anterior region (area 6) and adjacent prefrontal cortex (area 8) but some pass to area 4. Fibres from the corpus striatum (pallidofugal fibres) after relay (and pre-integration) in the thalamic nucleus ventralis anterior, reach the same cortical regions. It also receives afferents concerned in *other sensory* modalities, probably via the thalamus also but in addition from the hypothalamus and also from many other cortical areas. It is also traversed horizontally by monoaminergic fibres from the reticular system (noradrenergic from A6, serotonergic from B6–8) and cholinergic from Ch4, the nucleus basalis (of Meynert). Electrophysiological studies suggest that corticospinal neurons are influenced not only by somatosensory impulses but also by visual, acoustic, 'non-specific', thalamic, reticular and cortico-cortical afferents (p. 1003). Interaction of all (or some) of these on pyramidal neurons in general inevitably demands an intricate deployment of axons, dendrites and synapses. (For a structural/functional review of the primate motor cortex consult Phillips 1981.)

Illustration 7.164 was a tentative epitomization of the kind of structure involved and envisaged as applying to the *neocortex generally*, provided by Professor J. Szentágothai (1969). It is basically *radial* or *columnar* as being demonstrated in other parts of the cerebral cortex (somaesthetic and visual), the pyramidal neurons being extended vertically, with abundant vertical and more restricted horizontal associations with afferents through connections with intrinsic interneurons, some excitatory and



7.165A A stereoscopic view of the elementary neuron circuit in sensory cortical areas. The horizontal planes are entirely arbitrary and are included to aid stereoscopic visualization; they are unrelated to the cortical lamination (arabic numerals on the left, indicating the 'non-absolute' character of the lamination in such a diagram). Specific sensory afferents (heavy black vertical lines on the right) terminate (separately) on the spiny stellate neurons (S1) and the so-called star pyramids (S2) of upper lamina IV and in lower lamina IV on another type of spiny stellate neuron (S3) as well as on neurogliaform non-spiny stellate neurons (NS). Ascending relay of sensory afferent impulses is twofold: (1) within *narrow* cylindrical spaces (indicated with dashed outlines) by horsetail-shaped axon arborizations of S1 and S2 type neurons and primarily to selected individual (or small groups of) pyramid cell and (2) within *wider* cylindrical spaces (heavier dashed outline) from ascending S3 type neurons, probably mainly to basal dendrites of a much larger group of pyramidal cells. Descending relay is more widely and more indiscriminately distributed by descending branches of the spiny stellate neurons and star pyramidal neurons and occurs in narrow columns by the vertically orientated axonal lacework of neurogliaform non-spiny stellate neurons (NS). The vertical plane on the left shows the strictly orientated axonal arborization of a large basket cell; the vertical plane on the right, orientated at right angles to the basket cell plane, shows a large stellate neuron with vertically orientated dendrites and part of its extended axonal arborization which is strictly confined to this plane. From Szentágothai 1975 with permission.



7.165B Some features of a cortico-cortical module redrawn from a stereodiagram (provided by Szentágothai 1978). All neurons and contacts shown are presumed to be excitatory. Pyramidal neurons, their axonal efferents and inhibitory interneurons are not included for clarity. The module consists of a tall cylinder 300 μm in diameter extending through the full thickness of the cortex; ascending centrally, with lateral and terminal branches is one representative of a cortico-cortical afferent (either association or callosal). The 'flat cylinder' also about 300 μm in diameter is the 'termination space' of a specific thalamocortical afferent; overlap of the latter and the module varies greatly from minimal, through the condition illustrated, to virtual coincidence. Synaptic contacts through one or more excitatory interneurons transforms the flat (almost tangential) termination space of the specific afferent into narrow (10–30 μm), *radial* cylindrical spaces or sub-modules. Stellate interneuron SS2 has a recurrent axon, its arborization ascending to lamina II; the microglioform neuron (right) has a descending arborization; SS1 has both a descending and an ascending arborization, the latter synapsing with a *cellule fusiforme à double bouquet dendritique*, the axon of which again bifurcates forming a long vertical slender (10 μm) arborization and which possibly encloses, and is excitatory to, a single pyramidal neuron. It should be noted, however, that a significant proportion of neurons with all these cytomorphologies have been demonstrated as having their inhibitory counterparts (see 7.167).

some inhibitory. (It is of considerable interest that this early diagram was preceded by an even earlier theoretical attempt to define the co-ordinates needed for the analysis of *higher integrative units* in neural tissues, Szentágothai 1967.) These concepts accord with studies of individual motor neurons by microelectrode techniques in monkeys (Landgren et al 1962, Phillips 1981) and cats (Asanuma & Sakata 1967), which show that some motor neurons at least, though excitable from a larger area, can be most easily stimulated within a cylindrical section of cortex about 1 mm in diameter. At this stage the radial or columnar disposition of the pyramidal neurons dominated the picture and attempts were continued to establish the three-dimensional relationship to them of afferents and stellate interneurons, their synaptic contacts and excitatory or inhibitory status. There was little to indicate that radial arrays formed discrete circumscribed modules or columns and, in Szentágothai's view, if they existed they would 'mutually interpenetrate' into one another's cortical spaces. Electrophysiology of the somaesthetic cortex (Mountcastle 1957 et seq.) and visual cortex (Hubel & Weisel 1962 et seq.) provided, however, powerful evidence for functionally discrete radial columns or modules. The search for their structural counterpart was renewed, but now with particular emphasis on the distribution of *specific thalamocortical afferents*. Illustration 7.165 is a later summary of the '*module-concept*' (*elementary neuron circuits*) in cerebral cortical organization (Szentágothai 1975); many details are mentioned in its lengthy caption. In it: 'An attempt is made to bring earlier circuit models of *primary sensory* cortical areas into better line with recent observations on (1) the distribution of *excitatory feedback connexions* in cortical tissue volume, (2) (the then: Ed.) putative inhibitory interneurons and distribution of *inhibition in well defined space modules*, and (3) direct (monosynaptic) cortical target cells of specific sensory afferents, and modes of relay to secondary neurons. Even though the concept of cortical circuitry on larger "*integrative units*" containing *smaller modules* (or *fields*) of specific (excitatory and inhibitory) neuronal actions, proposed in 1967 and 1969, had gross deficiencies in the light of newly emerging data, the basic idea of how to look at the functional organization of the cortical neuron network may still be useful as a conceptual framework for the functional interpretation of structural data.'

The expectancy in the previous remarks progressed within a few years to a major publication (Goldman & Nauta 1977), further surveyed by Szentágothai (1978) in which it is held that the '*true*' *cortical module* is *not* primarily based on thalamocortical afferents but on *cortico-cortical* connections (long and short ipsilateral association fibres, together with homotopic and hetertopic contralateral commissural fibres). These *cortico-cortical modules* are columns, initially regarded as cylinders 200–300 μm in diameter extending through the full thickness of the cortex; each receives *and* originates all the fibre types mentioned and they are presumed to occur in all neocortical areas (and in all mammals yet studied). Some of their features were reviewed in the paper quoted but results of their further investigation were awaited with interest. As pointed out elsewhere (pp. 1071, 1072) details of *human* association fibres are, as yet, only known in relation to gross bundles and quantitative data are lacking; further some cortical areas lack callosal fibres e.g. those representing the 'distal limbs' (hands and feet) and much of the visual areas V1–5, callosal fibres being limited to narrow *strips* between the numbered areas. The following decade involved an explosive expansion of neuroanatomical, neurophysiological and chemoarchitectonic techniques, increasingly, and most powerfully, *in combination* on the same specimen. This has served to confirm and refine the cortico-cortical module as *one* of the dynamic central concepts whose consideration is mandatory when cortical functional microarchitecture is being addressed. Stimulating recent reviews of these topics are provided by Szentágothai (1985, 1987) on whose publications illustrations 7.166 and 7.167 are based. The former shows, in elemental form, the large-scale connectivity involved and, in a single module, one dynamic variation that would accompany one set of inhibitory/excitatory interactions; the latter is an analysis of seven well-established types of inhibitory (GABA-ergic) interneurons variously involved; their lengthy captions should be perused for details. (A complete acceptance

7.166 Stereoscopic diagram illustrating the principle of (cortico-cortical) modular architecture of the neo-cortex. Part 'A1' shows cortico-cortical connectivity on the large scale: *supragranular pyramidal cells* (in laminae II and III; two cells of the outer row in left middle column) connect preferentially with columnar tissue spaces in the ipsilateral or in the contralateral cortex. *Infragranular pyramidal cells* (lower row of cells in middle column at left and one cell in one column at right) send their axons to subcortical targets, but some of them are addressed to (or give major collaterals to) contralateral cortical columns. Local (intracortical) connectivity extending over approximately 10 neighbouring columns is neglected in this diagram. Part 'B' shows the architecture of a single (cortico-cortical) column (vertically hatched inner cylinder) of 200–300 μm width and extending through the entire depth of the cortex, radically stripped down to a few essentials. A single cortico-cortical afferent arborization is placed into the centre of the drawing (representative for a few of the 10 cortico-cortical afferents coming probably from the same source). Representative pyramidal cells of the supragranular (Py_3) and the infragranular layers (Py_5) are indicated in outline. Relatively long range inhibitory cells are represented by two large basket cells (Ba_3 and Ba_5) for the upper and the lower row each (see 7.167) in full black. Elements (and direction) of excitatory nature are indicated in outline, inhibitory cells (and directions of connections) are shown in black. Terminal branches of cortico-cortical afferents and pyramidal cell collaterals extend over the limits of the basic cylinder in lamina I and lamina VI; this is emphasized by outline arrows pointing in outward direction in the two layers. Conversely, dark arrows indicate that horizontally oriented basket (and other inhibitory) cells would tend to narrow down activity in the columnar unit. The original cylinder (vertical hatching) would hence become distorted dynamically into the shape of an hourglass (rotation hyperboloid; stippled). Adapted from Szentágothai 1985, 1987, with permission of the author. Part 'A2' is an attempt to illustrate cortico-cortical connections on a large scale, both ipsilateral and contralateral, between two coronal sections at different fronto-occipital positions. Provided by J Szentágothai 1988, personal communication.

7.167 Diagrammatic illustration of the seven types of well characterized (GABA-ergic) inhibitory interneurons. In order to facilitate recognition of dendrites and axons, the dendritic trees are simplified and drawn with exaggerated thickness. Fields of axonal arborization (where necessary) are indicated by hatching and stippling. Horizontal arrows indicate maximal (observed) extension of the axonal arborizations in the sagittal and oblique arrows in the coronal directions; the extension of the axons in depth can be derived from the cortical layering indicated at left margin. (1) Large basket cell of the upper (supergranular) group (Somogyi et al 1983) (2) large basket cell of the infragranular group (3) 'clutch cell' terminating mainly in lamina IV (Kisvárday et al 1985) (4) columnar basket cell (Szentágothai 1983) (5) microglioform cell (both dendritic and axonal arborization most generally spherical (6) 'cellule a double bouquet' of Ramón y Cajal (7) axo-axonic inhibitory interneuron (Szentágothai 1978). There are more local interneuron types known that are probably also GABA-ergic, but they were not included, because their axonal arborizations have not yet been sufficiently well characterized. The spatial relations between cell types 1–3 have been adapted from a diagram of Somogyi & Soltész (1986). After Szentágothai 1987 with permission.

that a cortico-cortical connection-based unit is *the exclusive universal module* of cortical structure must not render one oblivious of the other structural parameters and connections, e.g. corticostriate, corticoreticular, corticothalamic etc. and sometimes their reciprocals that, if chosen, would generate their own varieties of module, perhaps subordinate to or imposed on the foregoing. Perhaps in cases such as these, the term *apposite cortical module* could be applied, relating it to its particular context: Ed.). The references, in the reviews quoted, to multiple mutual interconnections of (non-discrete) '*hypercolumns*' or mutually overlapping '*concentric hypercolumns*' and cascade action through an infinity of *re-entrant loops* through corpus striatum, thalamus, hypothalamus, limbic and reticular systems and the cerebellum, each speculatively with their distinctive hierarchies of modules, should perhaps disinhibit innovative thought! Further details of the neuronal population and connectivity of the elementary cortico-cortical module cannot be pursued at length here but a few major points, estimates and relevent references will be noted. The axons of pyramidal neurons more superficially placed ('supragranular') in laminae II, III, and scattered in IV, are exclusively destined for other cortical areas, mainly ipsilateral (association) but some contralateral (callosal). The axons of deeper pyramidal neurons ('infragranular') in laminae V and VI have, in most cases, a target destination in a subcortical centre of grey matter but a substantial proportion have large collateral branches that form callosal fibres destined for the contralateral cortex. Rough estimates of neuronal connections are remarkable (Szentágothai 1987); of the *total cortical neuronal population* over 70% have axons passing some distance from their origin. Of these about 50% of the total establish cortico-cortical connections. The remaining cortical efferents in the *great majority* of cases have destinations in subcortical centres through which, as mentioned, they establish *re-entrant cortical loops* of greater or lesser complexity. The same publication reviews a number of 'general brain theories' based on a host of methodological approaches, but some necessarily incorporating the kind of estimates and concepts just touched on. Particularly relevant to the cortico-cortical module envisaged is the *numerical uniformity* of the mammalian neocortex noted elsewhere (p. 1043) and demonstrated by Rockel et al (1980) and Powell (1981), modular architecture of primate frontal association (prefrontal) cortex by Goldman-Rakic & Schwartz (1982) and Goldman-Rakic (1984) and primate neocortical neurogenesis by Rakic (1984a, 1984b). Slight variations in the basically modular neurogenetic approach could easily explain the regional emergence of the cerebellar cortex and telencephalic limbic (dentate gyrus, cornu ammonis, subiculum) and neocortex.

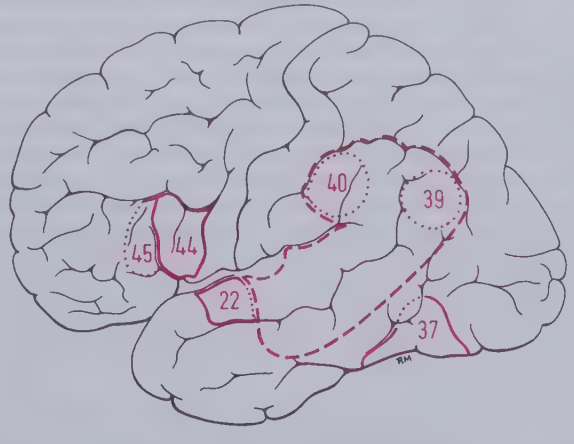
However the so-called *plasticity* of response of the 'motor' cortex may be explained, anatomical evidence favours a fixed, specific relation between pyramidal cells and their effectors. At all corticospinal tract levels a somatotopical arrangement has been shown. It should be emphasized that experimental stimulation of

exposed cortical areas is highly artificial and does not distinguish between direct excitation of pyramidal cells, or even their axons, and of the innumerable intracortical elements connecting with them. However, studies with microelectrode techniques are beginning to point in the same direction.

Before dealing with specific regions of the somatomotor cortex, it is necessary to note that experimental cortical stimuli never produce elaborate co-ordinated movements but only simple activities between synergists and antagonists. The movements elicited are unrelated to particular skills or the motor experience in the individual. This is to be expected; such stimulation leaves out of account other efferent paths and a wide range of afferents from the cerebellum, corpus striatum, thalamus, hypothalamus and other areas mentioned above (see Porter 1985).

Extending into the middle frontal gyrus from a part of the precentral gyrus concerned with facial movement is the **frontal eye field**, occupying much of Brodmann area 8, invading area 6 and probably area 9 (7.168). Stimulation is most effective in area 8 and elicits conjugate ocular movements, especially to the contralateral side but perhaps in other directions. Movements of the head and pupillary dilation may also be elicited from the frontal eye field. For a review of earlier work on these responses see Crosby (1953). Little is certain concerning its efferent projection; degenerating fibres have been traced in monkeys as far as the midbrain but their ultimate end is not established; none have been traced with certainty to motor nuclei innervating extraocular muscles; they may influence these through intermediary cell masses or 'centres' in the brain stem. However, voluntary and reflex eye movements are certainly mediated by the frontal eye field and its projection. Like the rest of the first somatomotor area, this region also receives association fibres, many from the occipital cortex, and also thalamic afferents from the juxtalaminar part of its dorsomedial nucleus (Scollo-Lavizzari & Akert 1963), to which the central zone of the frontal eye field (area 8) reciprocally projects (Rinvik 1968). A **second frontal eye field**, rostral to the above, has been demonstrated in monkeys and hypothecated in man (Crosby et al 1952).

The motor speech area (of Broca), an extension of the primary somatomotor cortex into the inferior frontal gyrus, almost coincides with area 44 and part of 45 (7.169). Little reliable knowledge exists of its connections but subjacent to it are large numbers of association fibres for connections between many other cortical areas. Most information as to its function is from results of ablation or stimulation in experimental animals and man (Penfield & Roberts 1959). Ablation may abolish vocalization, usually producing motor *aphasia* or paralysis *of speech* in man, in the left or 'dominant' hemisphere. In some individuals the leading speech area is on the right and in some there is perhaps no dominance (p. 1064).



Damage to the motor speech area does not entail *paralysis* of the *musculature* involved, all of which is also amenable to stimulation of the appropriate parts of the primary motor area in the precentral gyrus. Stimulation of the motor speech area leads to various effects, according to the parameters of stimulus; speech in conscious patients may be inhibited or simple acts of vocalization, such as the utterance of a vowel sound, may ensue. Responses in experimental animals are simple movements of the face, lips and larynx and perhaps vocalization. Stimulation in macaques produces contractions in individual laryngeal muscles (cricothyroid and thyro-arytenoid) and combinations of them (Hast et al 1974). It is emphasized that human responses, as in the somatomotor cortex, are always simple. By stimulation of the human cortex similar effects can be elicited from other areas, one in the frontal lobe, the supplementary motor area (MsII), another curving round the caudal end of the lateral sulcus, occupying a large region in the parietal and, more extensively, the temporal lobes. This latter is the **second motor speech area of Wernicke**. All three regions, *anterior*, *posterior* and *superior motor speech areas*, develop in the dominant hemisphere; while corresponding contralateral parts of the cortex have in some patients apparently taken over the functions of a damaged area in the dominant hemisphere, they are ordinarily uncommitted to speech.

Figure 7.169 shows these areas but other and more complex 'maps' of cortical areas reputed to be concerned in speech have been propounded. Language, in all its permutations (speaking, listening, reading and writing) is a most intricate activity. It would be surprising if this, by far the major form of human communication and perhaps the main distinction of mankind, did not in fact involve widespread volumes of the central nervous system. There is lack of information concerning the connections of various cortical areas believed to mediate these activities; it is likely that other, subcortical mechanisms will prove to be involved, though not yet implicated, despite the intensely active speculation prompted by the problems of aphasia; the pulvinar has been suggested as associated with speech 'centres' (Ojemann et al 1968). The inconclusive nature of evidence in this highly interesting field limits discussion, or should! Consult the excellent reviews available (Brain 1961, Penfield 1966, Millikan & Darley 1967). (See also p. 1064.)

The supplementary motor area (MsII) must now be briefly considered. This is, like MsI, sensorimotor but, being predominantly motor and in the frontal lobe, it is conveniently described here; its sensory activities, about which less is known, will be merely alluded to with the somatosensory cortex. Its situation on the medial hemispheric surface has been noted (p. 1027); it is anterior to, probably confluent with, the medial extension of the first somatomotor area into the paracentral lobule mediating leg and perineal movement. It is thus in the medial frontal gyrus

7.168 Superolateral surface of the left cerebral hemisphere showing the frontal motor eye field, corresponding to parts of Brodmann areas 6, 8 and 9. The perimeter of this area is delineated by an interrupted line to indicate uncertainty as to its precise extent.

7.169 The superolateral surface of the left hemisphere showing the motor speech areas of Broca (44, 45) and Wernicke. The latter is variously depicted by different authorities and is tentatively indicated by the large parieto-temporal area enclosed in an interrupted outline, which itself includes areas 39 and 40. Areas 22 and 37 are considered by some to be respectively auditory and visuo-auditory areas associated with speech and language.

(area 6 and probably in part area 8). Movements of the contralateral limbs can be elicited from the area in monkeys and mankind (Penfield & Welch 1951) but thresholds are higher than in the primary somatomotor cortex, as in other accessory areas; movements are sometimes ipislateral or bilateral. A somatotopic pattern (7.161) exists in monkeys (Woolsey et al 1952) but has not been demonstrated in man. Efferent fibres have been traced into the spinal cord in cats (Nyberg-Hansen 1969), most ending contralaterally. There is a *bilateral* projection to the thalamus and to the gracile, cuneate and pontine nuclei, contrasting with similar but unilateral projections from the primary somatomotor cortex. The contributions of these two areas to integration of movement are probably different but details are too ill-defined to warrant discussion (Travis 1955).

The second somatosensory area (SmII), preponderantly sensory, will be considered in detail with the parietal primary sensory cortex. Since, however, it is also *somatomotor*, its less well-established motor features are included here to complete the picture of the 'motor cortex'. Movements of most parts can be elicited from it; the loci of stimulation show somatotopic organization in primates, including man (Adrian 1941). Its projection fibres have been followed to the cervical spinal segments in monkeys (Brodal & Angaut 1967) and to the thalamus, dorsal column and pontine nuclei in cats, in this resembling other somatomotor areas. Little can yet be said regarding its significance in motor function.

The prefrontal area corresponds approximately to all parts of the frontal lobe not so far particularized, hence including much of the frontal gyri, orbital gyri (orbitofrontal area), most of the medial frontal gyrus and the anterior part of the cingulate gyrus, etc. The great development of the frontal lobe is held to be the major distinction of the human cerebrum. So-called *silent areas* have long been regarded a specially notable feature of the human cortex; the prefrontal area is usually assigned to this category. If, however, silent or association areas were to be regarded as cortex with connections predominantly or exclusively by association fibres, the prefrontal region certainly does not qualify. (Neither, in the light of modern knowledge, does *any other area*.) In addition to the elaborate afferent and efferent connections with areas in all cerebral lobes, it has abundant links with the *thalamus*, *corpus striatus*, limbic system, *hypothalamus* and reticular system and projects to the *cerebellum* via the nuclei pontis and perhaps to some *cranial motor nuclei*.

Through *superior* and *inferior fronto-occipital fasciculi* the frontal lobe appears to be connected with the occipital, parietal and temporal lobes. *Commissural* connections link the corresponding parts of the frontal lobes through the corpus callosum and frontal fibres may decussate to other lobes.

Massive *anterior* and *frontal thalamic radiations*, principally from the nucleus medialis dorsalis (MD) of the medial thalamic nuclear group (p. 1002), pass to lateral (areas 9 and 10) and orbital regions of the frontal lobe, both of which reciprocate to the same thalamic nuclei. Anterior thalamic nuclei also establish reciprocal connections with the medial frontal and anterior cingulate cortex. These thalamic nuclei receive many afferents from the mamillary body and thus the hippocampus (p. 1001), which also connects directly with anterior thalamic nuclei via the fornix. Connections of the anterior and medial thalamus with the hypothalamus (p. 1002) therefore bring this also into afferent relation with the prefrontal cortex, *from* which corticohypothalamic projections have also been described. The *prefrontal corticopontine projection*, though less massive than that from frontal motor areas (4 and 6), is equally attested; both relay with specificity in paramedian members of the nuclei pontis (Nyby & Jansen 1951). The orbitofrontal region projects to the paramedian hypothalamic nucleus.

Even this brief survey of prefrontal connections suggests complex interactions in *somatic* and *visceral activities*. The orbital surface has attracted particular attention; simulation in monkeys (Kaada 1960) depresses the respiratory rate, blood pressure and gastric motility; inhibition of induced cortical and reflex movements and emotional reactions have been noted. Ablation of the primate orbitofrontal cortex leads to hyperactivity, restlessness, inattentiveness; somewhat similar results follow ablation of the anterior cingulate region. The posterior orbitofrontal cortex and anterior cingulate gyrus are often considered 'limbic' (p. 1028). Behavioural studies in monkeys subjected to *anterior* frontal ablations adduce similar but often conflicting findings (Warren & Akert 1964, Sanides 1964); the sum total of fact remains slender.

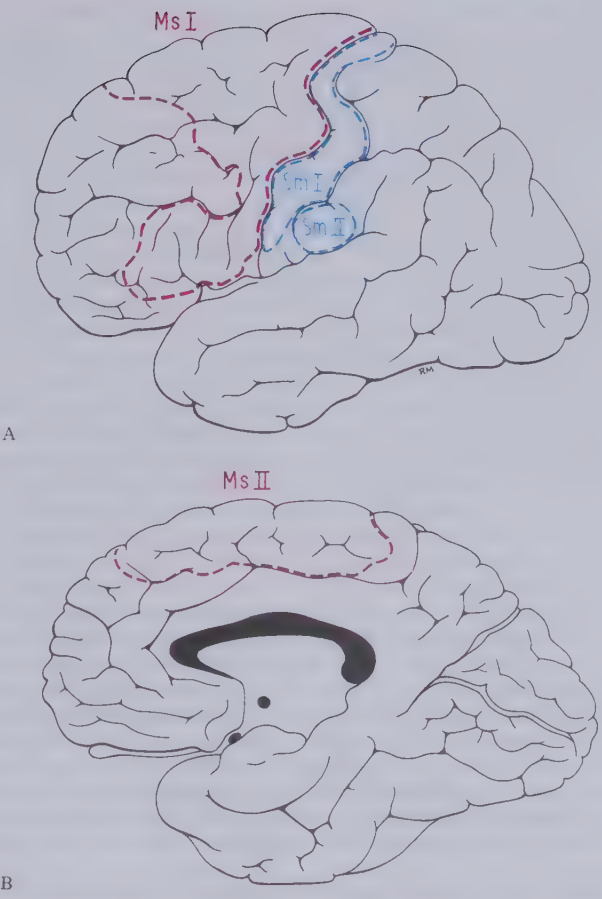
Functioning of the prefrontal area has been illuminated a little by the results of lobotomy and leucotomy, performed on human patients to ameliorate certain mental disorders now treated pharmacologically. The effects of these operations, usually bilateral, resembled those due to extensive disease of the frontal lobes. Abolition of the distressing aspect of illusions and of severe somatic pain were prominent, results according with the concept that this cortical area is concerned with the 'affective tone' of sensations rather than discriminative or localizing aspects. Some observers reported diminution in intellectual capacity but limitation of the operation to the orbitofrontal area or cingulate gyrus was claimed to affect only the emotional balance of personality, suggesting that the superolateral parts of the prefrontal area are more concerned with 'intellectual' processes (Lewin 1961). Patients with extensive frontal lobe damage, from whatever cause, almost always exhibit permanent and largely undesirable changes. Though more tractable and docile, they also show less initiative, untidiness, disregard for others and/or general tenets of behaviour and a marked lack of concentration, all of which might be summed up as retrogression from the human condition, a vague statement but certainly appropriate to the current dearth of information.

THE PARIETAL LOBE

Posterior to the central sulcus, occupying most of the postcentral gyrus and extending on to the medial surface of the parietal cortex in the paracentral lobule, is the primary or *first somatosensory area* (SmI, areas 3, 1 and 2). Posterior to it is a large 'silent' area of parietal lobe, occupied in part by the second speech area (vide infra). In the lowest part of the postcentral gyrus (extending a little into the precentral) is the *second somatosensory area* (SmII).

Anterior to the medial extension of SmI is the *third somatosensory area*, the supplementary 'motor' area (MsII). Thus, the region of the cortex centrally situated in the hemisphere and the great arrival station for somatic afferents and for the departure of somatic efferents, consists of *four separate*, though *juxtaposed sensorimotor areas*: two, primary and supplementary motor areas, have for long chiefly been regarded as efferent projection cortex, MsI and II; the other two are prominent recipients of afferent projections, primary and secondary somatosensory areas, SmI and II. As 7.161, 170A,B show, all four areas evince a somatotopic pattern in cats and monkeys; evidence that this is largely so in man has been quoted (p. 1041). The motor aspects of all four areas are mentioned above; it remains to consider involvement in sensory functions. (While the foregoing is partly correct, it places excessive emphasis on *one* class of connection and totally ignores the other classes of afferent and efferent common to all neocortical areas.)

The first somatosensory area (SmI) has interesting cytoarchitectonic variations. Its anterior part (area 3), bordering the central sulcus and extending into its depths to meet the *agranular* cortex of area 4, is of *granular* type but also contains scattered medium and small pyramidal cells; the area resembles the striate cortex, e.g. the outer band of Baillarger is broad but not so prominent. However, the posterior part of the postcentral gyrus (areas 1 and 2) differs particularly in its smaller content of less densely packed granular cells (p 1039). (Such subjective comments ignore the relative cortical thickness and surface area involved.) The boundary, if such exists, between pre- and postcentral areas in the central sulcus is disputed but may be important to the interpretation of experimental results (Rinvik 1968).



Projection from the *nuclei ventralis posterior lateralis* and *medialis of the thalamus* (VPL and VPM) to the primary somatosensory area is well attested; it is through this radiation that exteroceptive and priorioceptive modalities of sensation are mediated. Unit recording technique, retrograde degeneration and the newer techniques (p. 1039) have established a specific pattern of localization between the cortex and thalamus, associated with a

somatotopic form of organization in the postcentral gyrus like that in the adjoining first somatomotor area, including an allocation of cortex in proportion to skill rather than size in representation of bodily parts. This pattern has been studied in the human cortex by noting the type of sensation and region to which it is referred when loci are stimulated in an exposed cortex at operations (Penfield & Jasper 1954). With carefully gauged stimulation sharp localization can be established. Localization of vesical, rectal and genital sensations has thus been set in the *lowest* part of the *medial* region of the human postcentral area. The sensations aroused are mostly *contralateral* but may be solely *ipsilateral* (oral region) or *bilateral* (larynx, pharynx and perineum).

Experimental studies have largely confirmed the localization demonstrated in the human somatosensory cortex. Natural and artificial stimulation of peripheral receptors have also been shown to evoke potentials in the *precentral* area (Abel-Fessard & Liebeskind 1966). Ablation of the somatosensory cortex revealed a *direct* thalamic radiation to the 'motor' area (p. 1049), an elegant demonstration of the latter's sensorimotor nature. Degeneration studies (e.g. Le Gros Clark & Powell 1953) have provided more exact data on the specificity of the thalamocortical projection; the nucleus ventralis posterior lateralis exhibits a discrete localizational pattern of connection with areas 3, 1 and 2, suggesting a functional significance in the structural differences between them, as mentioned earlier (p. 1051). Unit recording has confirmed this, revealing area 3 as activated only by cutaneous stimuli whereas area 2 is concerned with proprioceptors (Albe-Fessard & Liebeskind 1966). This implies the transverse deployment of modalities *across* the long axis of the precentral gyrus (Mountcastle & Powell 1959), with a segmental or dermatomic projection to such transverse strips of cortex as a further refinement of somatotopic localization (Powell & Mountcastle 1959). Each modality-specific locus appears to be linked with a *vertical column* (module) of cells in the cortex, like those in the visual area (p. 1059). Anatomical evidence in monkeys demonstrated a cortico-cortical connection from the first somatosensory area (Brodmann 3, 1, 2) to area 5 in the parietal lobe (Pandya & Kuypers 1969). This connection, analysed further (Pearson & Powell 1978), is isotopological but reversed in the anteroposterior axis, so that area 3 projects to cells posterior to those receiving fibres from areas 1 and 2. Some anatomical evidence supports modality convergence in area 5, which accords with previous investigations (Mountcastle et al 1975) and provides a basis for 'association'.

The specificity of somatosensory neurons concerned with joint receptors is particularly marked, as in the thalamus. Some cortical units respond to displacement in one direction and continue to discharge even during a static position. Such arrangements, if applicable to man, would provide a neuronal basis for the 'joint sense' hypothecated in much earlier studies (Stopford 1922). Fast adapting units activated by bending hairs and others adapting slowly to deformation of skin have been identified. Similar studies suggest that the afferents from receptors in striated muscle terminate in units sited in the somato*motor* cortex and that impulses may reach them by paths independent of the cerebellum, as part of a basis for awareness of stretch in muscles. These findings imply a difference in sensory properties of pre- and postcentral parts of the main sensorimotor area, which are, however, linked by short association fibres in both directions (Pandya & Kuypers 1969). As in most, if not all, sensorimotor areas, the first somatosensory area has abundant reciprocal thalamic connections (p. 1004), corticothalamic projection comparing in its point-to-point specificity with thalamocortical radiation (Rinvik 1968). In connection with this apparently unvarying specificity at the cerebral level of some modalities, a study of the cortex in mice is most interesting (Woolsey & van der Loos 1970); barrel-shaped groupings of nerve cells were detected in part of the somatosensory area (SmI) related to the head and muzzle; some evidence suggests that these 'barrels' may be equated with individual vibrissae of the animal's muzzle (Waite 1977). This and a study of spatial distribution of synapses in the same cortical area in neonatal dogs (Molliver & van der Loos 1970), though not applicable to the human cortex, illustrate the intricate quantitative kind of analysis under investigation.

Commissural connections with the opposite primary somatosensory area are restricted to representation of the face, trunk and proximal parts of the limbs (Pandya & Vignolo 1969, Jones & Powell 1969). Commissural projections in monkeys terminate in bands (Jones et al 1975, Shanks et al 1975), as in the visual and motor cortical areas. Shanks et al (1978) have shown that in these bands short intrinsic connections propagate repeated representations of the bodily regions, comparable with retinotopic repetitions in the visual cortex (p. 1058).

7.170 Superolateral (A) and medial (B) surfaces of the cerebral hemispheres showing the sensorimotor areas. See text for details and compare with 7.157, 162. These areas can only be applied tentatively to the human cortex, and they are hence delineated with interrupted outlines.

Much less is known of the **second** and **third somatosensory areas** (SmII and MsII). The former is in the superior lip of the lateral fissure's posterior ramus, adjoining the insula in monkeys (7.161); it occupies a similar position in man. Evoked potentials indicate somatotopic organization in SmII, the face area being the most anterior, the leg most posterior. Single units associated with tactile and vibrational senses occur in the area; stimulation of Pacinian corpuscles evokes higher potentials than in primary somatosensory area (McIntyre et al 1967). The second somatosensory area projects to the thalamus but its connections have not yet been studied in detail. It also projects to the dorsal column nuclei, like other somatosensory areas. Details of such descending projections in monkeys have been much studied (Weisberg & Rustioni 1977) and are of special interest in the inhibitory modulation of transmission through the dorsal column nuclei.

The third somatosensory area, equivalent of the supplementary motor area, is in sensory functions little understood. It receives thalamocortical fibres and projections leave it, some of which are not motor, but details are uncertain. Stimulation in conscious patients is said to evoke generalized sensations referred to the head and abdomen, but no sensory somatotopic pattern can be ascribed to it.

The second speech area of Wernicke (7.169), being partly in the parietal lobe, must be mentioned here. It occupies only a small parietal area but extends more extensively into the temporal lobe

(p. 1061). The rest of the parietal lobe, between the main somatosensory and the visual areas, is 'silent' and corresponds more or less to the inferior parietal gyrus, areas 39 and 40 (Critchley 1953). Its connections, as far as they are known, are in part association and commissural but concerning these little clear detail is available; however, there is also a reciprocal connection with *all* the parts of the lateral thalamic nuclear group (p. 1003). Corticospinal and corticosegmental projections have been suggested, the latter to brain-stem motor nuclei, especially the oculomotor group, directly or through intermediary nerve cells. These connections are specially apposite to the description of a supplementary motor area in areas 5 and 7 in macaque monkeys (Crosby et al 1959). The strategic position of the parietal association areas close to all cortical regions concerned with general and special modalities of sensation, coupled with multifarious connections, is highly suggestive of complex and integrated activities. Most evidence is derived in man from clinical observations of the behavioural defects consequent on pathological lesions or ablations and extrapolation of similar results in primates deliberately damaged. The reports available are confusing. Muscular debility, slowing of reflex activity, disorders of speech, loss of awareness of bodily parts and other forms of *agnosia* have all been observed. A particular form of agnosia, long associated with parietal lobe damage, is *astereognosis*, failure to interpret the three-dimensional nature of objects when handled without vision. *Interpretation* has been strongly advocated as the prime parietal activity in man (Penfield 1966), in connection with language on the dominant side and in a more generalized sense on the other. The parietal lobe is perhaps a region of high activity in learning processes and certainly has reached a uniquely high development in mankind. Considering the general nature of the evolutionary process it is unwise to attribute a qualitatively unique nature to the operations of human parietal areas but their import in behaviour, especially discrimination and interpretation, is amply attested by clinical evidence and animal experimentation. (See also p. 1064.)

7.171 Superolateral (A) and medial (B) surfaces of the cerebral hemispheres showing the visual areas in the occipital lobe. The striate (17), parastriate (18) and peristriate (19) areas correspond approximately to the Brodmann areas as indicated and also to visual areas I, II and III. See text for details.

THE OCCIPITAL LOBE

Almost the whole occipital lobe is occupied by Brodmann areas 17, 18 and 19 (7.171A,B). Though area 17, the **striate** or **visuosensory cortex**, was originally regarded as the sole terminal of the optic radiation, the lateral geniculate body (p. 1016) has been shown to radiate also to areas 18 and 19 in cats (Glickstein et al 1967) and monkeys (Wilson & Cragg 1967); in these, like area 17, spatial arrangement of the radiation is related to the retinae in an orderly manner (Garey & Powell 1967, 1968). All three areas project to the thalamus (lateral geniculate body or pulvinar) or brain-stem motor nuclei or both. Short and long association and commissural fibres link the *three visual areas*, ipsi- and contralaterally, and to other areas in both hemispheres. (For an exhaustive critique consult Polyak 1957.) Occipitopontine fibres are described but their human status is uncertain. Area 17 is co-extensive with the visual stria of Gennari but demarcation between areas 18 and 19 is less easy by the usual cytoarchitectonics; Braak (1977) has introduced a method depending on staining of lipofuscin granules and this sharply distinguishes these two areas and even structural subdivisions in them but their functional significance is not clear.

The striate cortex (area 17), or **first visual area**, occupies the upper and lower lips and depths of the posterior part of the calcarine sulcus (7.171A,B), extending into the cuneus and lingual gyrus. As a cytoarchitectonic area it can easily be defined by the visual stria and its cortical thinness. Posteriorly it is limited by the lunate sulcus (and polar sulci above and below this), extending only to the human occipital pole, though reaching its lateral aspect in other primates. Anterior to the area is the medial parieto-occipital sulcus but below the calcarine sulcus it may extend further. The stria becomes less obvious towards the occipital pole, a change correlated with retinotopical organization (vide infra), its prominence being inversely related to distance from the central retinal area.

Histologically, area 17 is *granular* or *koniocortex* (p. 1046); densely packed stellate cells greatly outnumber its few pyramidal cells. For details consult Polyak (1957), Crosby (1960), Colonnier (1964, 1967, 1968, 1974); only the salient features will be mentioned here. (1) the deeper stratum of the pyramidal layer (III) contains *large stellate cells*, almost replacing the large pyramidal cells of this layer in other types of cortex. (2) The outer band of Baillarger in lamina IV is accentuated as the *visual stria*, containing termination of the optic radiation and probably association fibres. (3) The ganglionic layer (V), commonly consisting of pyramidal cells, here contains a few large, *solitary cells (of Meynert)* of a modified pyramidal shape, about 30 μm in diameter and distributed in a single row. Their dendrites extend widely in the cortex and their axons are the projection of the visual cortex, traversing the optic radiation to the superior colliculus and possibly motor nuclei of the extraocular muscles. A study of Meynert's cells of rhesus monkeys (Chan-Palay et al 1974) showed their potential for widespread, intricate connections; each cell's dendrites were estimated to display 36 000 spines, its apical dendritic field in lamina I being about 400 μm and 800 μm for basal dendrites in lamina V. Distribution density of Meynert cells varies, being greatest (8000/cm²) in the region representing the macula. (For a more extensive reappraisal of the numbers and basal dendritic patterns of Meynert cells in the macaque monkey see Winfield et al 1981, 1983.) (4) External and internal granular layers (II and IV), especially the latter, contain larger numbers of more densely packed small stellate cells than any other cortical area. This laminar pattern is based on Brodmann's; other patterns, particularly Cajal's, have some vogue; a review by Billings-Gagliardi et al (1974) advocates a return to Brodmann.

Although the striate cortex contains only 3% of the cerebral surface, approximately 10% of cortical neurons are said to be in it. In cytoarchitectural details areas 18 and 19 approximate respectively to the polar and parietal types of cortex (p. 1046), the stellate cells being less prominent, the pyramidal cells more so. Myelin and axonal stains have been used to investigate the visual

area's fibre structure, especially the striate cortex (Sholl 1955, Colonnier 1964); in general it resembles arrangements elsewhere (p. 1049) but the dendritic fields, in their quantitative aspects, have been studied more intensively in this neocortical area than perhaps any other except the postcentral gyrus, stimulated in part by the demonstration of a columnar organization in the somatosensory area, as already noted, and thereafter in the striate cortex (vide infra). So far physiological techniques are providing more illuminating evidence than structural.

The status of area 17 as the primary visual area is long established, both by electrical stimulation in man and by its connections with the lateral geniculate body, and through this with the retinae (p. 1016). The *retinotopical organization* in the lower parts of this visual pathway has now been shown to obtain to cortical level. Each area receives impulses from two ipsilateral half retinae, representing the *contralateral* half of the binocular visual field. As already described (p. 1016), the patterns of retinal impulses do not undergo simple relay in the geniculate bodies, where some processing occurs, but exclude interaction of a biretinal nature (for details see p. 1017). Such processing has been studied most intensively in the striate cortex, especially by single unit recording technique. The *geniculate radiation* spreads as it swerves through the white core of the occipital lobe, its fibres terminating in strict point-to-point deployment in the striate area: the peripheral parts of retinae activate the most anterior parts in the area, the macular regions activating a relatively large part adjoining its posterior end. Moreover, superior and inferior retinal quadrants are connected with corresponding areas of the striate cortex. In the classic studies of the effects of injuries of the occipital lobe in warfare, similar retinotopic results were obtained (Holmes & Lister 1916, Teuber et al 1960).

Experimental findings in a wide range of mammals, especially primates (see p. 1016 for references), were corroborated by stimulation of the human cortex (Penfield & Jasper 1954); the visual impressions thus elicited were simple, such as flashes of light, but were referred to a specific locus in the visual field according to the location of the cortical stimulus. Eye movements are also produced by such stimulation. When areas 18 and 19 are stimulated more complex visual images are reported, indicating that they are concerned in elaboration of the information reaching area 17.

Most interesting recordings have been obtained from single neurons responding to various forms of retinal stimulus; while earlier studies were chiefly pursued in cats (Hubel & Wiesel 1962, 1963, 1965, 1971, Wiesel & Hubel 1963a,b), there was little reason to doubt that in principle the results were applicable to the human striate cortex, especially since the cytoarchitectonic areas involved in cats can be equated with those in primates (Otsuka & Hassler 1962), in which unit recording has also been studied (Hubel & Wiesel 1977). Each unit appears to correspond to a defined retinal receptive field and can presumably be excited only from it. Units responding to *various modes* of stimulation have been identified; some react to white light, especially in the stripes or edges between light and dark, contrasting with the smaller circular receptive fields demonstrated in the lateral geniculate body. Excitatory units surrounded by inhibitory zones have also been repeatedly described. Many units are sensitive to the orientation of stimulus, responding only to vertical, horizontal or oblique linear stimulation. More complex units occur, some responding to a particular direction of a moving stimulus. These observations represent integration from simpler units. Further studies by Hubel & Wiesel (1968) have revealed striate cortical neurons, in cats and especially monkeys, responding preferentially to stimuli from either the right or the left eye, a phenomenon misleadingly termed *ocular dominance*; vertical (and oblique) exploration by unit-recording has shown that these neurons (with common responses) are deployed in the vertical columns, through *all* layers of the striate cortex, as described below. Certain columns may be binocular in their response in cats but in monkeys this is doubtful, all being right or left orientated. Further evidence of greater development of such 'dominance', perhaps, in the simian cortex resides in the greater facility with which they are found and explored; these workers consider that they are of greater diameter in monkeys. It has proved possible to refer most neurons involved to particular cortical laminae and to equate their distribution with those of the terminals from the lateral geniculate projection. The significance of these findings is not entirely clear but they confirm segregation of 'information' from each retina at least as far as the striate cortex. The validity of these observations has been confirmed by other techniques, e.g. autoradiographic identification of labelled substances (3H-proline) injected directly into the feline eyeball (LeVay et al 1978). By transneuronal transport in the lateral geniculate body such substances reach the striate cortex, particularly lamina IV, corresponding in distribution most clearly with the columnar arrangement. Studies in cats (LeVay et al 1978) and monkeys (Hubel et al 1977) suggest that these neuronal arrays are to some degree plastic, since they are altered by monocular deprivation in early postnatal life. Later work has confirmed the identification of columnar unitary loci which respond to stimulation from one retina, though some are excited simultaneously from both; a columnar organization coded according to colour responses has also been supposed. Similar results have been obtained in monkeys, increasing the likelihood that they correspond to human visual activities.

These studies, carried out with constant reference to the laminar pattern in the striate cortex, suggest a *columnar* structure in accord with the functional organization in vertical 'units'. The concept of 'chains' of neurons linked vertically in the cortex is, as noted, comparatively old (p. 1041) and more recent work, with the advantages of improved staining and electron microscopy, has confirmed and elaborated this view, and not only in the striate cortex. Synaptological studies and the results of degeneration experiments show that afferents of an area such as the striate cortex feed impulses into a limited columnar group of interneurons, the result of their excitatory and inhibitory interactions, which reach a pyramidal cell for translation to the subcortical neurons or to some other region. Such *columnar units* are not completely independent, being linked to others by recurrent axons, by tangential fibres in the superficial cortical lamina (I) and by spatial overlap. For the development of concepts of neocortical columnar architecture see p. 1051-1054 (and references) and, e.g. compare the publications of Szentágothai in 1967, 1969 and 7.164 with a revised 'module concept' (1975) summarized in 7.165. In the latter, the evolving *cortical module* (with *submodules*) concept was based on the specific thalamocortical afferent and hence seemed particularly appropriate to the striate cortex. However, in a major review published later (Szentágothai 1978) this view was revised and the '*true cortical module*' was held to be centred on the origins and terminations of small bundles of cortico-cortical fibres, i.e. association and commissural fibres (see 7.166, 167). It is appropriate to note that in each cortical unit neurons in cortical laminae II and III project to other cortical areas (such as 18 and 19), those in lamina V to the superior colliculus and in lamina VI back to the lateral geniculate nucleus.

The effects of lateral geniculate lesions in cats provide detailed patterns of the terminations of geniculocortical fibres in all three visual areas (Rossignol & Colonnier 1971); in area 17 degenerating terminals are mainly in lamina IV but a few vertical axons reach lamina I to spread tangentially in it; in area 18 their main termination is also in lamina IV, but in area 19 the afferent terminals are less numerous and spread through layers IV, V and VI. These results confirm the wide region of afferent visual projection in the occipital lobe and accord with the difference of activity in the three visual areas. Such experiments entail the infliction of large, almost total lesions of the lateral geniculate body. Only discrete lesions can demonstrate the specific point-to-point relation between geniculate projection fibres and visual cortical areas. Such specificity can also be shown by observing the results of cortical lesions by retrograde degeneration in the geniculate body, where columnar series of neuronal groups in all six layers are affected (p. 1016). This effect is only achieved when cortical lesions involve the whole thickness of the cortex (Rose & Malis 1965). By a similar combined 'attack', the functional details of visual *areas* II and III are being gradually clarified; in both, details of columnar units are accruing, the units responding to more complex stimulation and being almost all *biretinal* in their receptive fields.

Hubel & Wiesel (1978) have been able to carry the above concepts further, in monkeys, providing at least an initial integration

in understanding of the *modus operandi* of the striate cortex. By the transport of radioactively labelled amino acids from one eye via both lateral geniculate bodies to their striate cortices, they have revealed not only neuronal columns correlated with ocular dominance but also a particular arrangement of these throughout the striate cortex (see also LeVay et al 1978). This pattern is based in lamina IV, which receives most of the geniculate projection and contains so-called 'simple' neurons responsive to uni-ocular, circularly symmetrical, retinal stimuli. The pattern comprises curving and branching stripes, about 0·5 mm in width in macaques, separated by unreactive intervals of similar width and similar pattern. The reactive (radioactively labelled) stripes contain cortical 'columns' associated with the injected eye; intervening, non-reactive stripes correspond to the unaffected eye. Therefore interaction between signals from corresponding retinal areas must occur elsewhere in the striate cortex, perhaps in association with 'complex' cells in laminae II, III, V or VI, some of which respond to binocular stimuli. A second type of columnar pattern has been revealed in the striate cortex by combined unit recording and the radioactive tracer technique, showing the sites of high utilization of glucose, the stimulus being orientation of linear objects. Columns associated with such stimuli display a pattern of whorled or 'swirling' 0·5 mm wide stripes like those concerned in uni-ocular reception; but the 'stripes' of the two techniques (radioactively labelled amino acids and unit recording with glucose utilization) form different patterns which intersect at frequent points. Hubel & Wiesel have hence hypothecated a cortical arrangement of repeated unitary columns through the whole thickness of the striate cortex, each unit responding to a stimulus in terms of its position and orientation (its column being concerned, however, purely with uni-ocular input). The theory does not attempt to explain the cortical mechanisms involved in colour, the kinetic or spatial (stereoscopic) aspects of stimuli. These studies have provided the most detailed facts and ideas in manipulation of signals in any part of the cerebral cortex, though they do not, admittedly, approach the integratory processes of perception.

Parts at least of the visual area must be considered sensorimotor, inasmuch as eye movements can be elicited from them. In monkeys this (third) *occipital eye field* (7.171A,B) is confined to visual areas I and II (17 and 18), stimulation producing conjugate deviations in various directions, especially to the opposite side. Head turning, facial movements and sometimes responses in the upper limbs may occur (Rieck 1959, Bender 1964). This occipital motor eye field (III) has reciprocal connections with the *frontal eye fields* I and II which are considered to be involved in the mediation of vision in the voluntary ocular movements held to characterize activity of the frontal eye fields. Motor responses from area 18, including accommodation, are, on the contrary, thought to be reflex in natural activities and involved in following and fixation movements. Area 18 may project *to* the pulvinar, which has a reputed but controversial link with the lateral geniculate nucleus. Projection *from* the pulvinar to areas 18 and 19 is established but with disagreement over details (Locke 1961). Efferent fibres descend from the occipital motor eye field, particularly area 19, to the superior colliculus and nuclei of the ocular motor nerves, to the latter probably through interneurons, such as the para-abducens nucleus (p. 1107), interstitial nucleus, nucleus of Darkschewitsch, and posterior commissural nuclear complex (Carpenter & Peter 1971). These projections must be distinguished from the corticogeniculate projection (pp. 1017, 1203), evidence for which is chiefly physiological (Widen & Marsan 1961). Several workers have detailed corticofugal connections from areas 17, 18 and 19 to the thalamus, tectum and pretectal region, particularly in cats, in which some retinal representation has been demonstrated (Updyke 1977) in the projection from area 19 to the pulvinar.

All three visual areas are intimately linked by short association fibres, which are probably especially specific in a spatial sense between areas 17 and 18; thus preservation of the topographical relation in connections between all three areas has been demonstrated in monkeys by Cragg (1969) and Zeki (1969, 1974); according to Zeki (1977) spatial representation displays a 'mirror-image' reversal between adjoining visual areas, as appears to occur in connections between other adjacent 'sensory' areas (Somatosensory Area, p. 1056). Zeki emphasized the propagation of '*mosaics*' of retinal representation from the striate to 'prestriate' cortex, the latter including not only peri- and parastriate areas (Brodmann 18 and 19) but perhaps more remote regions, in particular the so-called fourth visual area (V4 and V4a), extending between area 19 and the occipital end of the superior temporal gyrus (7.171A). Zeki's concept involves the projection of each unitary retinal area at repeated points in all the visual areas, the response of cortical loci varying in modality with different loci responding to orientation, contour, depth, colours and movement. In this there is a possibility of equating such responsive loci and their well-established columnar architectonics with the results of unit recording. Retinally-linked loci in major visual areas probably serve different visual modalities; e.g. area 17 appears to emphasize orientation, whereas columnar loci in area 18 are more concerned with stereoscopy. Beyond this, in areas 19 and V4, retinal representation extends into the modalities of colour and movement. Picturesquely, one may imagine the total pattern of retinal excitation as propagated from area to area, the cortical units in each adding a particular modality to the total sensory pattern. Association and commissural fibres connect all visual areas, particularly 18 and 19, to many parts in the ipsilateral, and to a much lesser extent the contralateral hemispheres. Particular mention should be made, however, of the commissural connections between the visual cortices. The origins and terminations of *callosal fibres* are restricted to *narrow bands between* areas 17, 18, 19 and the occipital end of the superior temporal gyrus (i.e. bands *between* VI, 2, 3, 4, 4a). These bands process information from the *vertical meridian* of the retina; i.e. the narrow vertical retinal strip whose ganglionic cells have axons that bifurcate and pass into both optic tracts (Dr T P S Powell, personal communication).

Vision and ocular movement may therefore be affected by lesions remote from the visual cortex or from motor fields; e.g. the course of the optic radiation, swerving through the temporal lobe (Meyer's 'loop') entails homonymous field defects in temporal lobe tumours (Falconer & Wilson 1958).

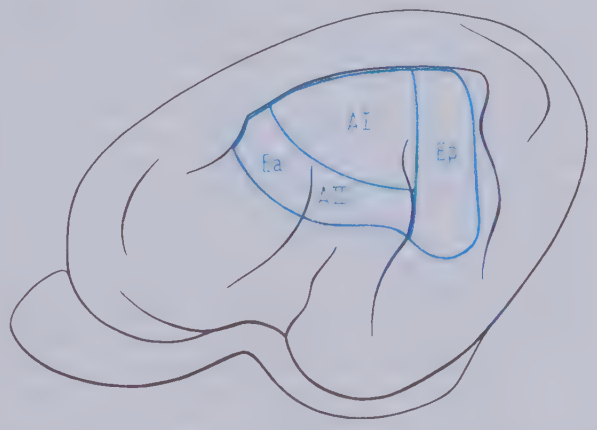
THE TEMPORAL LOBE

This has lateral and inferomedial surfaces, the former with superior, middle and inferior temporal gyri, the latter including medial and lateral occipitotemporal gyri (collectively the fusiform gyrus) separated from the parahippocampal gyrus by the collateral fissure (7.145A, 7.151). The human temporal lobe (apart from limbic lobe structures, p. 1028) is regarded as highly evolved and relatively recent in phylogenetic development. It is much involved in hearing, language and perception.

Part of the superior temporal gyrus is 'rolled' into the lateral fissure's posterior limb during human fetal development, thus hiding two short gyri which ascend obliquely backwards posterior to the insula's limiting sulcus. These anterior and posterior *transverse temporal gyri* almost correspond to areas 52, 41 and 42 (7.142); many other temporal cytoarchitectonic regions have been described, but only those mentioned, together with area 22, adjoining them on the lateral aspect of the superior temporal gyrus, can be reliably equated in man. In Campbell's original description in 1905 the *acoustic area* covered rather more than area 41, to which subsequent observers restricted it when defining a classic acoustic area, a leading feature of the gyrus (7.157A). As will be seen, Campbell's view has been revived.

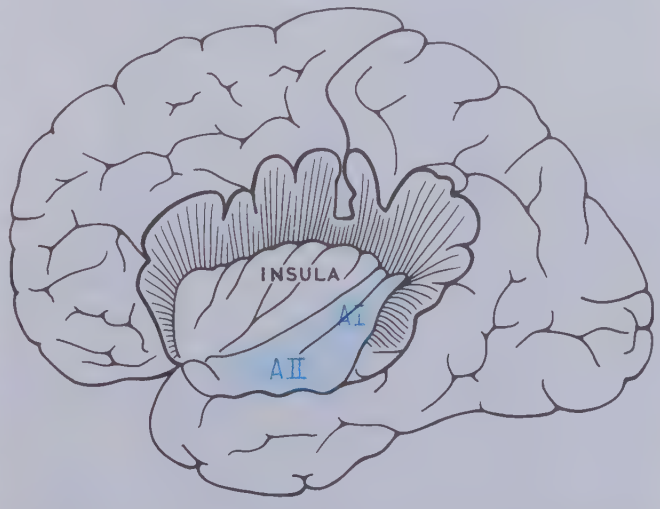
Area 41 is a variant of the granular cortex, but thicker than the visual and somatosensory cortices (Bailey & von Bonin 1951). Its surroundings, such as area 22 (7.157A), are a parietal type of cortex; beyond this the temporal lobe is largely of frontal type, like the main areas of the parietal and frontal lobes. Both frontal and parietal types of cortex show an admixture of pyramidal cells and (an apparent, subjective) 'diminution' in stellate cells. For further details consult authorities referred to on p. 1039 and Braak (1978).

The acoustic area, classically defined, approximately equals area 41; but for reasons explained below this is now termed the **first acoustic area** (AI). It extends slightly on the superior temporal gyrus but is largely *in* the lateral fissure as the anterior transverse temporal gyrus. Earlier evidence for the acoustic nature of this area was reviewed by Whitfield 1967; its



cytoarchitecture has been described in detail by Sousa-Pinto (1973), claiming that area AI so defined corresponds exactly to the projection of the lateral part of the ventral nucleus of the medial geniculate body (in cats). Attempts to define this projection area more accurately have extended it (Rose & Woolsey 1949), and the results of cortical stimulation (evoking head and ear movements) and recording cortical potentials excited by localized stimulation of either the cochlea or the cochlear nerve (Woolsey & Walzl 1942) have confirmed this. Much of this work has been on cats, less often monkeys (Sousa-Pinto 1973); hence details of these accessory areas cannot be confidently translated in their entirety to man (7.173). The **second acoustic area** (AII) is inferior to AI in the equivalent of the superior temporal gyrus, the ectosylvian gyrus in cats. Flanking AII are *anterior* and *posterior ectosylvian areas*, Ea and Ep (7.172); even more areas have been described. There is evidence that all the areas named, except Ea, receive projections from the medial geniculate body. Ablation of AI leads to degeneration only in the rostral part of the medial geniculate body, which receives fibres from the inferior colliculus (p. 986); but other parts in the medial geniculate complex of nuclei project to all areas except perhaps Ea, including part of the insula (Morest 1964). Some fibres in the acoustic radiation may divide to terminate in more than one area and this may in part explain some equivocal results. Short association fibres link AI to AII and Ep, but not Ea. (For detailed development see Krmpotić-Nemanić et al 1979.)

Geniculocortical projection has been 'mapped' in AI in chimpanzees (Walker & Fulton 1938) and its representation in this (Woolsey & Walzl 1942) was earlier considered *tonotopical*, i.e. a localization pattern based on sound frequency; but this was strongly denied in the human first acoustic area (Penfield & Jasper 1954), remaining a major controversy (Evans 1968). Stimulation in conscious patients merely produced ill-localized simple patterns of sound or noise, buzzing, humming or ringing; but in the adjacent accessory areas (perhaps equivalent to those in cats) more complex acoustic phenomena were elicited. The topological relations between acoustic areas and various medial geniculate subnuclei have been investigated by retrograde transport of horseradish peroxidase from small cortical lesions (Winer et al 1977), suggesting that only the laminar part of the ventral medial geniculate nucleus projects to one acoustic area (AI), all other parts of the complex projecting to several acoustic areas. It was also noted that the pulvinar projects to the acoustic areas. Despite much unit recording from AI, this problem has not been settled; but it seems highly likely that there are units responding to specific frequencies, even if not in any particular array. Other units, excited by the *variation* of frequency in time or direction, have been described (Whitfield & Evans 1965), these specific arrays resembling the visual cortex.



Efferent fibres descending from the acoustic areas to the brain stem have been noted elsewhere (p. 1016). These may modulate activities in the medial geniculate body, inferior colliculi and other auditory tract nuclei (pp. 960, 986), but also mediate reflexes by forming connections with the cranial nerve nuclei. Some fibres probably influence the state of contraction of the stapedius and tensor tympani, experiments suggesting that it increases with high-frequency or high intensity sounds (Carmel & Starr 1963). *Association fibres*, in addition to the short ones noted above, link the acoustic areas to other ipsilateral lobes, perhaps particularly the frontal pole, and to the cortex deep in the superior temporal sulcus, which may be loci of convergence of association fibres from all sensory areas. Little is known of the commissural fibres (but the lateral lemniscus is a *bilateral* tract). Lesions in the human medial geniculate body or acoustic cortex do not cause noticeable deafness unless bilateral (an unlikely occurrence). Extensive temporal tumours have minimal effects on hearing but may interfere with acoustic aspects of language interpretation, especially if in the 'dominant' hemisphere. In this connection, note that the posterior motor speech area in the parietal lobe (p. 1057) extends into the temporal lobe posterior to the acoustic region, practically surrounding it according to some (7.169). This proximity doubtless has implications in the cortical organization of speech, hearing and language.

The vestibular area, as regards its site, is a focus of disagreement; but in monkeys it is said to be near the part of the somatosensory area (SmI) concerned with the face, in the postcentral gyrus, area 2 (Jones & Powell 1970). Area 2 is particularly involved in sensations from deep tissues and joints; the spatial proximity of a vestibular area to this appears interesting; it is said to receive projections from the vestibular nuclei but this is largely without anatomical evidence. Unlike the acoustic pathway, the vestibular projection appears almost entirely crossed. Some degree of somatotopical specificity in the connections of the vestibular cortex and the vestibular nuclear complex have been reported (Massopust & Daigle 1960) but anatomical evidence and physiological data remains sparse and conflicting. Another view must be mentioned; this depends on the recording of equilibratory responses in man and implicates part of the superior temporal gyrus, anterior to the acoustic areas (Penfield 1957).

Apart from the acoustic areas, a possible vestibular area and an extension of the posterior motor speech area, the neocortex of the temporal lobe contains no other functionally identified regions; but the remainder cannot all be simply disregarded as 'silent' cortex; the existence of numerous association fibres connecting parts of the lobe and areas in other lobes is certain, though precise details are few. Connections with visual areas (between areas 18 and 19 and 37) and with the parietal lobe (between areas 7 and 40 and 22) probably mediate complex integration between sensorimotor areas in temporal, occipital and parietal lobes. Thus, the more posterior parts of

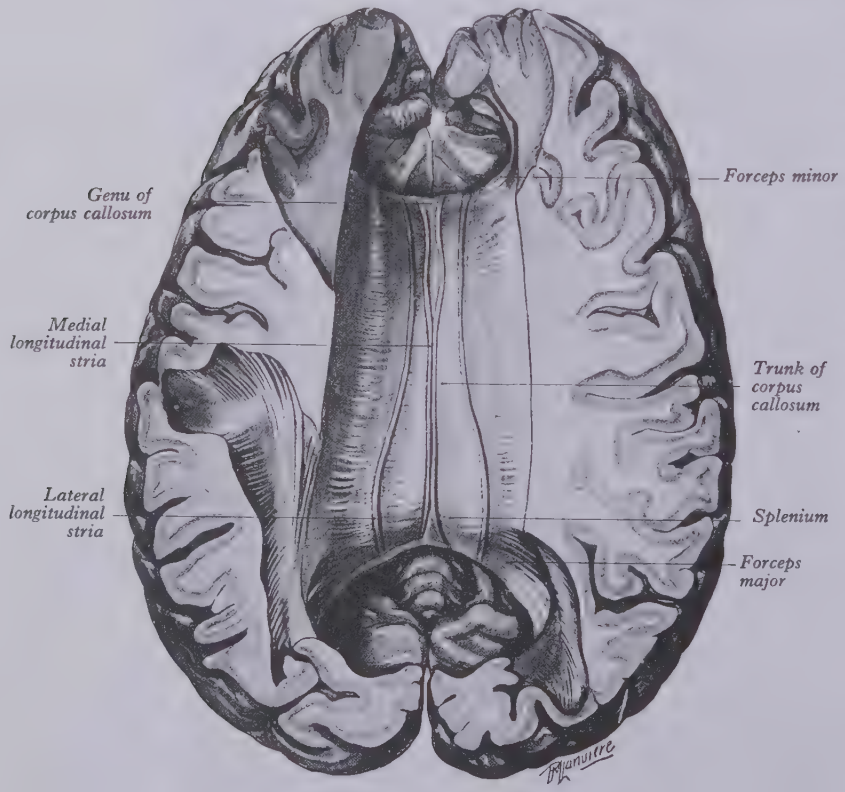
7.173 Superolateral surface of the left cerebral hemisphere from which the opercula have been cut away to expose the insula and the adjoining anterior and posterior transverse temporal gyri and their continuity with the superior temporal gyrus. The area shown in blue contains the classic acoustic area, AI (equal to Brodmann area 41 and parts of areas 42 and 52) and the secondary acoustic area, AII (extending into area 22).

the temporal lobe are perhaps more concerned with somatic activities especially with linguistic communication. The results of human stimulation naturally provide the basis for such views (Blum et al 1950). The anterior region appears even more multiform in its association of somatic and visceral activities; apart from the intrinsic association connections, it is linked to the limbic system (p. 1028) through connections of the parahippocampal gyrus with the hippocampus, with the piriform lobe (p. 1033) and the amygdala (p. 1034); the temporal pole, area 38 (7.125B), is also involved. Effects on blood pressure, respiration and gastric motility, usually depression, have been elicited by stimulation; but the major evidence in mankind depends on defects following partial temporal lobe ablation to relieve epileptiform attacks. Stimulation before lobectomy, which usually leaves the acoustic and motor speech cortex intact, may elicit complex memories of auditory, visual or combined content. After lobectomy a confusing plethora of manifestations have been described in an extensive clinical literature. Effects on speech, auditory memory and interpretation of auditory and visual phenomena have been noted (Milner 1967, Falconer 1967). A form of visual agnosia or 'psychic blindness' in which patients are unable to recognize visual significance, coupled with a change in dietary habits, a tendency to examine objects with the mouth, hypersexual behaviour and loss of emotional responses together constitute a syndrome named after Kluver & Bucy (1937); see also Terzian & Ore (1955); but in these instances lobectomy also involved the amygdaloid body, hippocampus and part of the parahippocampal gyrus; subsequent experiments have shown that these sequelae are only in part due to temporal lobectomy involving only the neocortex.

Of late, the temporal lobe has been loosely associated with memory; but, except for the possible participation of the parahippocampal gyrus in what was first ascribed to the hippocampus and associated structures, i.e. 'short-term' memory, there is little evidence of any entities in the temporal lobe or elsewhere which could be 'sites' of 'long-term' memory.



OTHER CORTICAL AREAS

The insula (7.143, 144A,D, 173) has been described (p. 1027); it adjoins and is overlapped by all lobes save the occipital. Histologically the posterior part of its cortex resembles the parietal (p. 1047); its anterior region is variously described as agranular or like the piriform cortex (Bailey & von Bonin 1951). Its connections are largely uncertain, but many have been claimed; short association axons between it and all its opercula are described; it is said to be connected to the lateral olfactory gyrus and piriform lobe (p. 1033). Thalamic connections (centromedian nucleus) have been suggested (Le Gros Clark & Russell 1939, Locke 1967). For a review of the numerous efferent and afferent connections with many neocortical areas, limbic areas and dorsal thalamic nuclei see Augustine (1985). Contralateral motor responses in the face and limbs have been elicited in macaques and gibbons, and somatotopy may exist in this possible supplementary field (Showers & Lauer 1961). Stimulation in man excites visceral motor and sensory effects, such as belching, gastric movements, nausea and abdominal 'sensations' (Penfield & Rasmussen 1950). Increased salivation in man and experimental animals has been elicited, with vasomotor effects in the latter. The insula has also been regarded a gustatory area by some. Many other functional associations have been claimed. (For reviews see Kaada 1960, Augustine 1985.)

The 'suppressor areas' reported by earlier experimenters in various cortical sites, particularly a vertical strip anterior to area 4, have been sources of controversy and criticism (Druckman 1952). Suppression of motor activities from such areas is now thought due to a generalized 'spreading depression', not associated with any particular area. This unexplained phenomenon is characterized by a long depression of neuronal activity, perhaps for several minutes, during which all responses are suspended or distorted (Leao 1944). However, the presence throughout the neocortex of fine, sometimes monoaminergic fibres, possibly exerting paracrine effects (p. 993) merits note.

The cingulate gyrus is discussed everywhere with the limbic system (p. 1028) but its anterior part, corresponding to area 24, must be mentioned here. In microscopic structure it has features in common with pre- and postcentral areas. It exchanges projections with the thalamic anterior nuclear complex and may have connections with the corpus striatum, hypothalamus and midbrain tegmentum (reticular formation). Commissural fibres via the corpus callosum have been described and association fibres probably link it with the frontal and parietal cortex anterior and posterior to the main sensorimotor region (Showers 1959).

Stimulation in macaques has been held to evoke contralateral and bilateral movements, with some form of somatotopic pattern (Showers & Crosby 1958). This supplementary motor area may extend into the posterior part of the cingulate gyrus but this requires confirmation. In patients, stimulation of the anterior cingulate area may elicit changes in pulse, respiration and blood pressure but the most reliable information comes from the results of surgical division or removal of the anterior cingulate gyrus, often involved in frontal leucotomy. Cingulectomy alone appears to relieve abnormal aggressiveness and obsession, yielding a milder, more placid personality (Tow & Whitty 1953). Similar effects are recorded in monkeys (Glees et al 1950). Cingulate gyrus ablation has been claimed as a useful manoeuvre for intractable pain (Folty & White 1962). This mixture of somatic motor and sensory, emotional and visceral activities at least accords with the intermediate position of the anterior cingulate gyrus between the limbic system and the neocortex proper.

7.174 The corpus callosum, superior aspect, revealed by partial removal and dissection of the cerebral hemispheres.

THE SEPTUM PELLUCIDUM

This is a thin vertical partition (7.148, 176) composed of two laminae, largely separated by a narrow *cavity of the septum pellucidum*, an extrapial space and therefore not communicating with the brain's ventricular system. Seen from the side the septum is a triangle, its base anterior and apex posterior. It is attached: above, to the lower surface of the corpus callosum's trunk; below and behind, to the anterior part of the fornix; below and in front, to the upper surface of the corpus callosum's rostrum; directly in front, to the corpus callosum's genu. Each lamina forms part of the wall of the anterior horn and central part of the lateral ventricle, being therefore lined by ependyma on its ventricular side and pia on its medial aspect. The wall encloses

important groups of *septal nuclei* and their fibre connections (see *septal areas*, p. 1035 and *dorsal fornix*, p. 1039; for development, see p. 194).

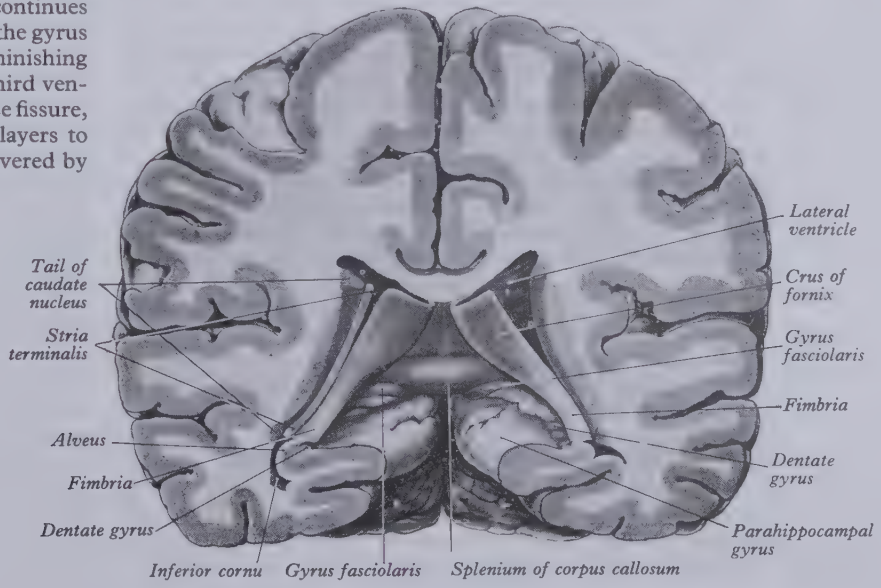
THE CORPUS CALLOSUM

The corpus callosum is the major transverse commissure connecting the cerebral hemispheres; it incidentally roofs in the lateral ventricles. Its mammalian development is proportional to the surface area and volume of the neocortex; it is maximal in human brains (Rakic & Yakovlev 1968). Its position and size is well appreciated in median sections (7.57, 140A,B, 145A,B). It forms an arch about 10 cm in length, its anterior end being about 4 cm from the frontal poles and its posterior end about 6 cm from the occipital poles. The *genu*, its anterior end, recurves postero-inferiorly in front of the septum pellucidum, then diminishes rapidly in thickness and is prolonged posteriorly to the upper end of the lamina terminalis as the *rostrum*. The *trunk* arches back and is convex above, ending posteriorly in the expanded *splenium*, its thickest part.

The superior surface of the callosal *trunk* (7.174) is covered by the *indusium griseum*, extending anteriorly around the genu, then on the inferior aspect of the rostrum, to continue into the paraterminal gyrus; in it are narrow longitudinal bundles of fibres, two on each side, the medial and lateral longitudinal striae (p. 1036); posteriorly the indusium griseum is continuous with the dentate gyrus and hippocampus through the gyrus fasciolaris (7.175).

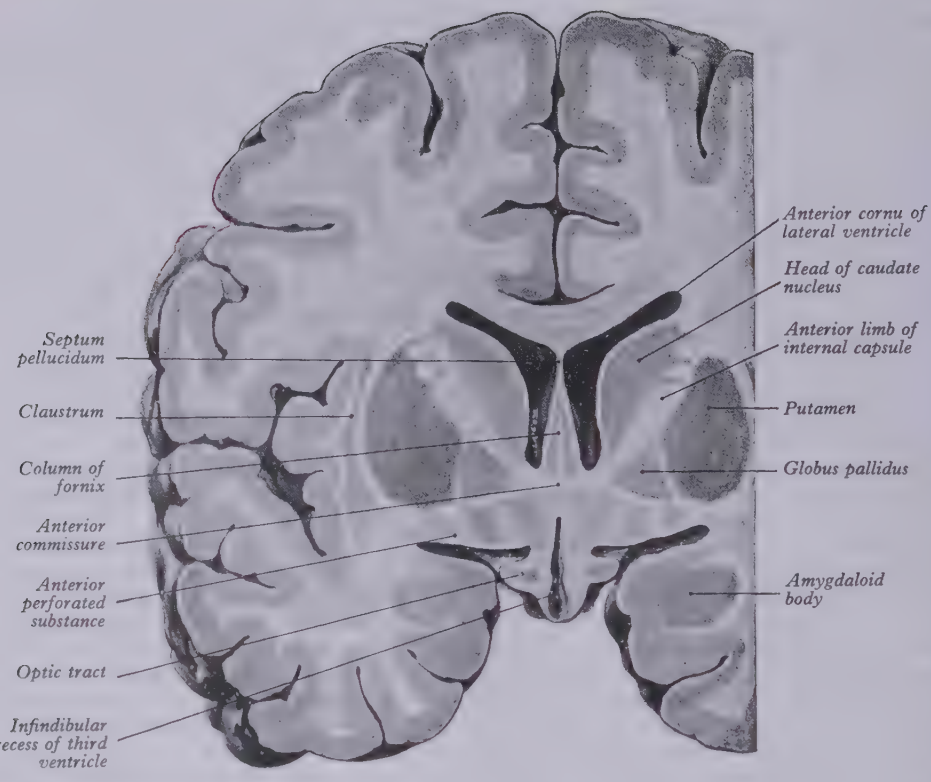
In the median region the trunk is the floor of the great longitudinal fissure, where it is related to anterior cerebral vessels and lower border of the falx cerebri, which may contact it behind. On each side the trunk is overlapped by the gyrus cinguli, separated by the callosal sulcus. Its inferior surface is concave in its long axis but convex transversely. The septum pellucidum is attached to it anteriorly to an extent depending on septal length and disposition of the fornix (7.140). Posteriorly it is fused with the fornix and its commissure. On each side its inferior surface roofs the lateral ventricle (7.192, 198), covered by ependyma.

The *genu* connects the trunk to the rostrum. Its anterior surface, related to the anterior cerebral vessels, is covered by the indusium griseum and longitudinal striae. To its posterior surface the median septum pellucidum is attached; on each side it is the *anterior* wall of the lateral ventricle's anterior cornu.



The *rostrum* connects the genu and lamina terminalis; its superior surface is attached to the septum pellucidum and, on each side, forms part of the narrow floor of the lateral ventricle's anterior cornu (7.145A, B). On its inferior surface the indusium griseum and longitudinal striae pass back to the paraterminal gyrus.

The *splenium* overhangs the posterior ends of the thalami, the pineal gland and tectum but is separated from them by several structures. On each side the crus of the fornix and gyrus fasciolaris (7.175) curve up to the splenium; the crus continues forwards on the *inferior* surface of the callosal trunk but the gyrus fasciolaris skirts *above* the splenium, then rapidly diminishing into the indusium griseum. The tela choroidea of the third ventricle advances below the splenium through the transverse fissure, the internal cerebral veins emerging between its two layers to form the great cerebral vein. Above, the splenium is covered by the commencing indusium griseum and is related to the falx cerebri with the inferior sagittal sinus and to the cingulate gyrus on each side of it. Posteriorly the splenium is near the tentorium cerebelli, great cerebral vein and the beginning of the straight sinus.

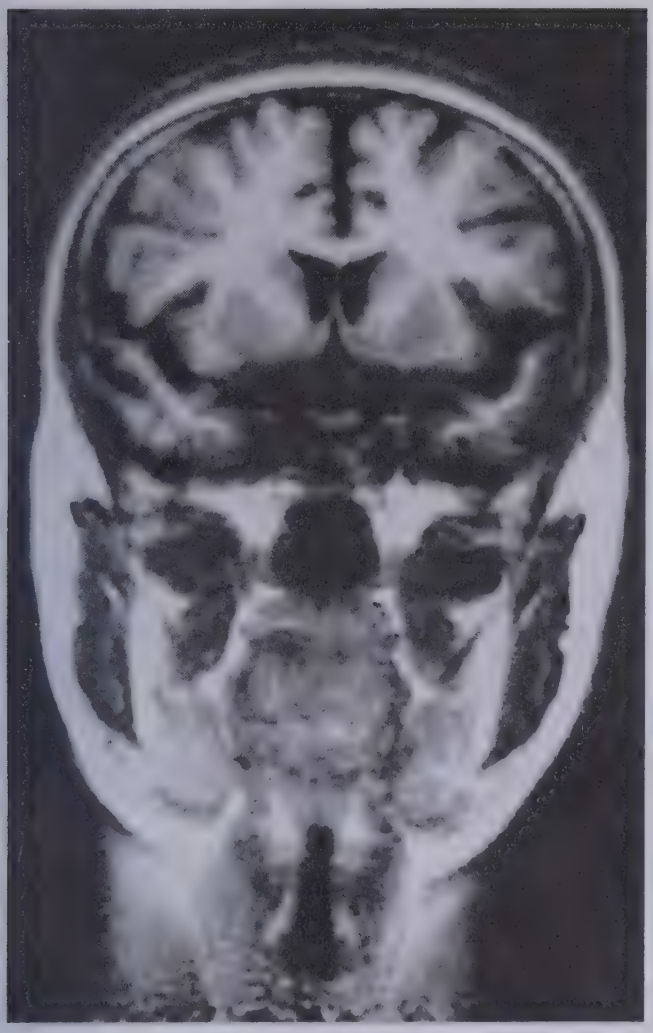


Nerve fibres of the corpus callosum radiate into the white core of each hemisphere, dispersing to the cerebral cortex. Commissural fibres forming the rostrum extend laterally *below* the ventricular anterior cornua, connecting the orbital surfaces of the frontal lobes; fibres in the genu curve *forwards* to connect the lateral and medial surfaces of the frontal lobes, as the *forceps minor*; fibres of the trunk pass laterally across (intersecting with) the projection fibres of the corona radiata (7.187, 188), connecting wide neocortical areas of the hemispheres. Fibres of the trunk and splenium which form the roof and lateral wall of the posterior cornu and the lateral wall of the inferior cornu constitute the *tapetum* (p. 1029). The remaining fibres of the splenium curve back medially into the occipital lobes as the *forceps major*, which bulges into the *medial* wall of the posterior cornu as a curved *bulb of the posterior horn*.

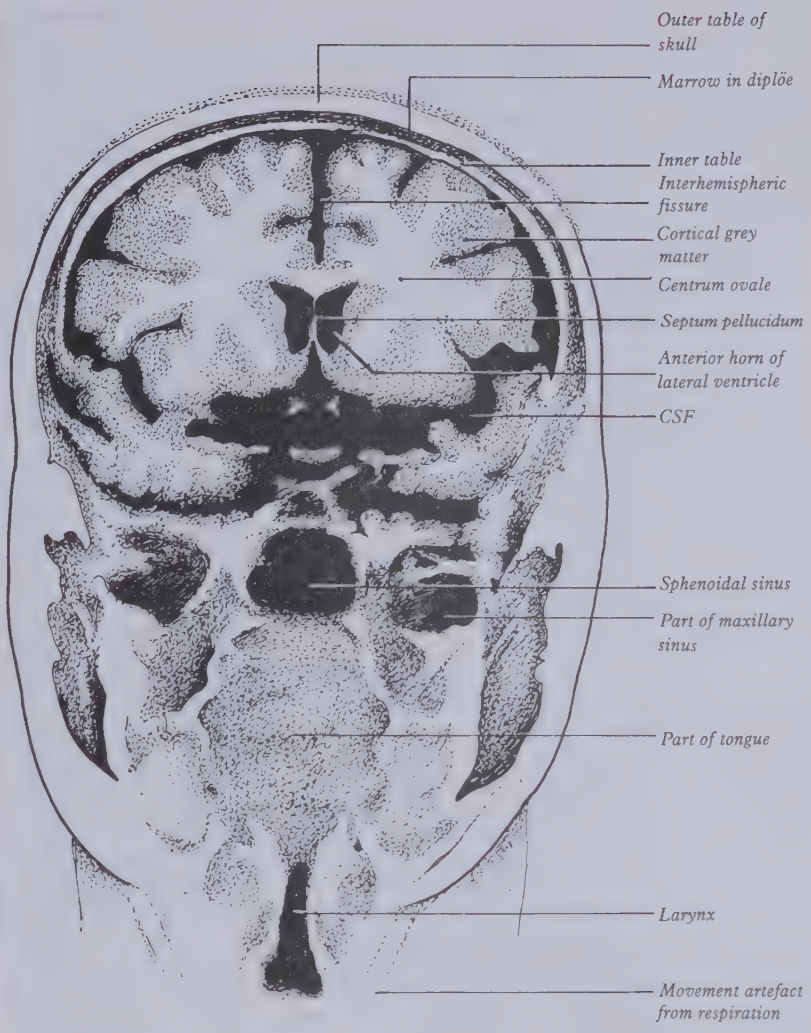
Despite its size and the enormous number of its commissural fibres, limited information is available concerning the precise functional roles of the corpus callosum, apart from the obvious inference that it links the hemispheres, perhaps to ensure that they act as an entity (however, vide infra). The total of its fibres is unknown in man, but in cats there are 700 000 in each square millimetre (Myers 1959). A detailed analysis of callosal connections is lacking for many regions; but initial investigations have been made in the visual area (Zeki 1970, 1974) and postcentral gyrus (Jones & Powell 1969). In somatic sensory areas (SmI and SmII) connections are limited to the same contralateral area, but right and left loci concerned with the hand and foot appear to lack commissural connection. These views have been strongly confirmed and amplified (Dr T P S Powell, Oxford, personal communication 1983): 'there is considerable experimental evidence, and from use of modern techniques, that there are no callosal connections between the cortex containing the representations of the distal limbs. These conclusions are based not only from a correlation of the experimental anatomical work with the maps of the representations from the evoked potential states but also from a correlation of anatomical tracing and microelectrode recording in the same animal. Not only is this so for the somatic sensory cortex in the post-central gyrus but it is also true for the motor cortex and area 4 in the pre-central gyrus.

'It is totally definite that the callosal connections between the visual cortex of the two hemispheres connect only representations of the vertical meridian of the retina (or visual field). The callosal connections are restricted to narrow bands of cortex, each only 1–2 mm wide, precisely at the boundaries between the different visual areas of the occipital lobe. There is such a band at the

7.175 Anterior aspect of a coronal section of the cerebrum from which the posterior parts of the thalami have been removed to reveal the splenium and parts of the limbic system. (Note that the denate gyrus is not equally exposed on the two sides.)



7.176 A coronal section of the cerebrum immediately caudal to the optic chiasma and passing through the anterior commissure.



boundary between area 17, the primary visual cortex and the adjoining area 18, and also bands between the other three or four visual areas that have been identified in the pre-striate cortex. It is probably true to say that the regions of cortex connected are related to the very narrow middle region of the retina within which the ganglion cells are now known to send axons which branch and send a branch into the optic tract of both sides.' Commissural linkages are considered highly specific, both associating the 'corresponding' columnar cortical units in bilateral functions, in addition to heterotopic loci.

A congenital absence of corpus callosum is rare, usually found at autopsy, and the clinical history lacks diagnostic features (Unterharnscheidt et al 1968). In recent decades large parts, and in some cases all of the corpus callosum, have been divided with apparently little disturbance of function (Akelaitis 1942). Nevertheless, the accumulated experience of the results of brain damage (Milner 1974), especially to the temporal lobe and corpus callosum, experimental studies of commissurotomized cats (Butler 1966) and chimpanzees (Myers & Henson 1960) and particularly the studies of Sperry (vide infra for references) on the effects of the division of the human corpus callosum—all this evidence has not only illumined the function of this great commissure in the transfer of information (including memorized data) across the midline of the cerebrum but has also confirmed a long-suspected asymmetry of function, leading to a concept of 'dominance' usually by the left hemisphere. This has become a major arena of cerebral research. Though it is impossible even to survey here the profuse and even prolix literature recorded by clinicians, experimenters (anatomical and physiological), psychologists, behaviourists and others, references to major contributions will enable the interested reader to enlarge his knowledge elsewhere.

CEREBRAL ASYMMETRY OR HEMISPHERIC DOMINANCE

A concept of asymmetry of function and structure in the cerebrum is by no means modern, although it has only recently attracted intensive study. It arose in the nineteenth century with developing views on cortical localization of function. Early protagonists of asymmetry were Bouillard (1825) and Dax (1834), both concerned with speech, and Weber (1834) who believed asymmetry is detectable in sensory functions. But it was Broca's observations (1861), on a case of motor aphasia, which were perhaps not only the first indication of cortical localization but also the first convincing evidence of *unilateral* representation of function in the cortex. The correlation between pathological changes in the area often now known as Broca's area (p. 1055) and an almost complete defect in speech clearly pointed to a close linkage between speech and, in this case, the left cerebral hemisphere. Further patients and similar clinico-pathological deduction by others confirmed this finding. The view was further elaborated into a concept of the left hemisphere as *dominant* and the right as in some manner a *minor* hemisphere, perhaps partly prompted by an exaggerated identification of language with the cognitive processes; perhaps also the high incidence of right-handedness was seen as a corroboration factor, the more skilful hand under command of the more intelligent hemisphere. Others were less dogmatic; Hughlings Jackson (1868), while confirming Broca's clinical findings, was wary of extending the undoubted unilateral motor speech 'centre' in the left hemisphere into a concept of left cerebral dominance or an exclusively 'verbal' hemisphere. He considered that the neglected right or 'minor' hemisphere might be of equal functional import in somewhat vague terms, such as involvement in ideational, non-verbal cognitive activities. As will appear, he was closer to modern concepts than his contemporaries. However, the idea of dominance persisted into the twentieth century, though it did not become part of general neurological teaching until much more recent times. Perhaps this was due to a dearth of data, especially of the experimental type. Further studies of motor aphasia were added in confirmation of Broca's speech 'centre' and defects following damage to other cerebral regions in some instances vaguely suggested asymmetry of cortical function, or sometimes the reverse. Inevitably the corpus callosum demanded attention; a commissure of such size, containing an estimated 200 million nerve fibres in mankind, cannot be ignored. But the observed effects of agenesis or extensive injury proved difficult to assess and many observers accepted that even severe damage produced little change in cerebral performance. Retrospectively it is easy to appreciate that this was due to the

7.177A Oblique coronal magnetic resonance image of the brain at the level of the anterior cornua of the lateral ventricles. Supplied by Philips Medical Systems; photography by Sarah Smith.

7.177B Diagram of 7.177A (Illustration: J Halstead).

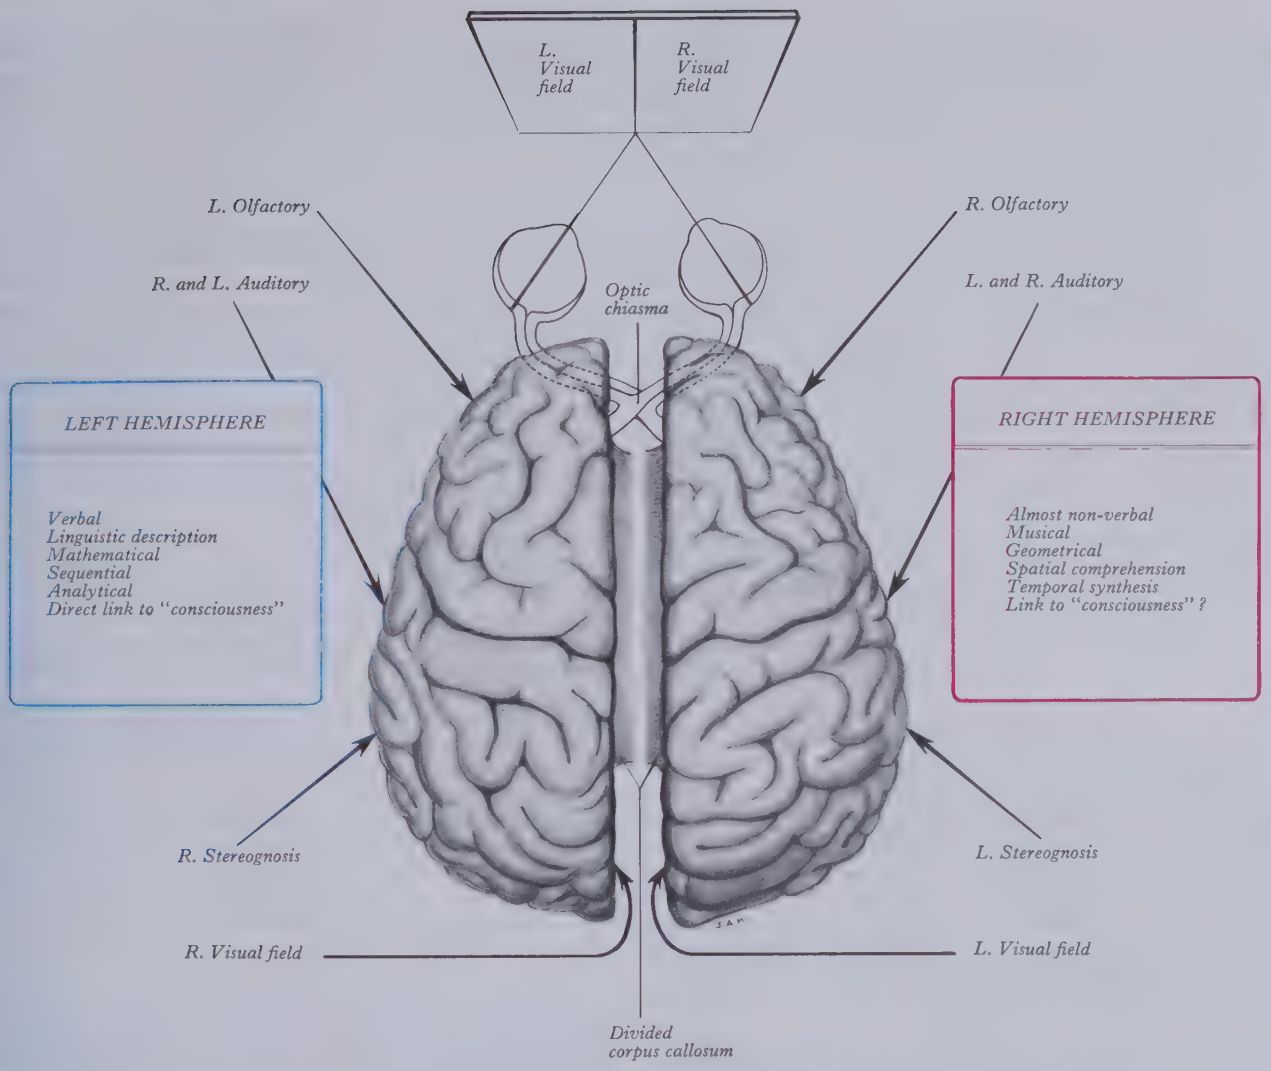
relatively crude and inappropriate tests available. The introduction of adequate testing transformed the scene; but at this point it is necessary to turn briefly to '*handedness*', the human preference for right or left hand.

The close association of the cortical areas concerned with motor 'control' of speech and the right hand in the same, usually left, hemisphere inevitably evoked much statistical re-examination of the incidence of right and left hand-preference, a fascinating problem in itself. A large literature of data and even more speculation surrounds the subject (Hicks & Kinsbourne 1978). Forelimb preference in mammals other than man is not easy to assess; while such preferences are considered to exist, they are never so clear and universal as they are in human beings; nor is there the same high frequency of a 'dominant' right hand. This is 'preferred' in about 90% in all races and cultures (Chamberlain 1928, Komai & Fukoka 1934, Hécaen & Ajuriaguerra 1964, Annett 1967, Hicks & Kinsbourne 1978). A genetic basis for hand-preference has been confidently postulated for mankind (Nagylaki & Levy 1973) but this is still an issue of some (diminishing) disagreement. Such a genetic lateralization postulate has naturally been extended to the development of a dominant (verbal) cerebral hemisphere and this influence is widely accepted. Single gene (Annett 1964) and double gene (Levy & Nagylaki 1972) models have been proposed to explain the observed data of familial incidence of hemispheric dominance (often coupled with data on hand-preference); but neither model accounts completely for the distribution of variants; such studies have shown that hemispheric asymmetry is far from simple in its incidence. If an individual does not conform to the large majority of left-sided 'verbal' and right-handed people, he is not automatically the reverse. A few (2% according to Zangwill 1967) who are right-handed nevertheless display evidence of right cerebral dominance and similar discordance between hand-preference and cerebral dominance occurs more often among the left-handed. Occasionally lateralization of function may be difficult to assess, especially in respect of hand-preference. True ambidexterity may occur and a limited degree of bilateral hemispheric function is more often suggested but less easily established. In hand-preference, especially, genetic influence may be complicated by cultural imitation in a largely right-handed population. How far this may, in childhood, produce secondary effects on cerebral dominance is uncertain; but it is certainly unwise to adopt a dogmatic attitude with regard to manual or cerebral asymmetry; the apparent anomalies in their distributions render theorizing on the genesis of asymmetry at present merely speculative.

Studies of cerebral dominance have been greatly improved by the introduction of sodium amytal injections into the cerebral circulation (Wada 1949). Unilateral injection, despite cerebral arterial anastomoses, temporarily suspends, or greatly diminishes, function in the corresponding hemisphere; the 'speech' or dominant hemisphere is thus easily deduced in patients or volunteers, who may then be observed in greater detail by appropriate tests. This method has complemented and sometimes extended the opportunities already afforded by injured patients in the investigation of peculiarities in the two hemispheres. Recorded data have become almost confusingly

profuse, especially with the widespread interest of experimental psychologists in this field.

The contribution to the study of cerebral asymmetry by assessment of functional defects following cerebral lesions has been collectively large, though scattered through a large number of necessarily limited observations. Historically this is the oldest mode of study (cf. Broca) and also the newest (cf. Sperry, below), as pointed out by Milner (1974) who has herself made a large contribution, particularly on patients submitted to cerebral lobectomies, frontal and temporal. The association of temporal lobes and hippocampi with the function of memory has been established for many years; a particular interest in the effects of unilateral temporal lobectomies resides in the revelation of asymmetrical memory defects (Milner 1958, Milner et al 1964, Blakemore & Falconer 1967, Milner & Teuber 1968). Left temporal lobectomy impairs learning and memorization of verbal material, visual or auditory, whereas the right lobe appears concerned with the acquisition and retention of visual and auditory experience of a non-verbal nature. Right lobectomy damages the ability to follow mazes, in terms of vision and proprioception. Some lobectomies, of course, involve more than the cortex and may include hippocampal and amygdaloid tissue. Localization of function is therefore sometimes crude and uncertain but there is no doubt of the observed asymmetry.



Though all the avenues of enquiry mentioned above have contributed substantially to unmasking asymmetry of function, by temporary or permanent partial blockage of function in one hemisphere, the most fruitful source of observation has undoubtedly been the *isolation* of otherwise intact hemispheres from each other, though not from the external environment, by therapeutic division of the corpus callosum, and to a lesser extent by the same procedure in experimental animals, including monkeys. Before considering this evidence, however, it is necessary to turn briefly to strictly anatomical contributions.

Though anatomical observation inevitably enters into the interpretation of the effects of disease, injuries and experimental lesions, it might also be supposed that marked functional asymmetries, gradually exposed during a century and more of observation, would be associated with ascertainable structural differences, quantitative and even qualitative. Evidence of such anatomical asymmetry is, however, small and equivocal. Stimulated by the views of Dax (1834) and the discoveries of Broca (1861), some of their contemporaries and also Broca himself (1875) considered the left hemisphere to be heavier; but others recorded the contrary opinion. Not one in the long sequence of structural investigators of the cerebral cortex appears to have noted significant differences between the right and left sides; Braitenberg (1977) has re-emphasized this by his own observations. Because of its proximity to Broca's area (on the left) and its association with hearing, the superior temporal gyrus (and adjoining speech area of Wernicke, p. 1059) has been a focus in the search for asymmetry. Predominance in size of the left superior temporal gyrus has been described (Geschwind & Levitsky 1968, Le May & Culebras 1972, Hyde et al 1973). The first observer cited claimed a left areal superiority in 80% of human brains. (Adequate surveys of transverse temporal gyri are lacking.) A decade earlier two authorities, Von Bonin (1962) and Bodian (1962), had pronounced opposite views on the significance of such structural asymmetries in respect of cerebral dominance, even when convincingly demonstrated, Bodian opining that a search for such differences would be sterile. The general lack of observations in this field, and their uncertainties, corroborates this view so far; but it may be that structural asymmetries are of a more subtle nature. Di Chiro (1962) noted reciprocal differences in calibre between the superior and inferior anastomotic veins of the two hemispheres, which might denote, if confirmed, some divergence of vascular requirement; but this comparatively crude angiographic study has not been amplified. It must be concluded, therefore, that for the present at least a strictly anatomical approach to the problem has proved negative.

Although nineteenth-century interest in asymmetrical control of speech continued into the twentieth (e.g. Penfield & Roberts 1959), the work of Sperry and his collaborators in the sixties and beyond has proved the outstanding contribution and stimulus in this field (Sperry et al 1969, Gazzaniga 1970, Sperry 1970, 1974, 1977). The fact that he was already investigating 'split-brain' preparations in experimental animals and could collaborate with the pioneers (Bogen & Gazzaniga 1965) in complete division of the corpus callosum to alleviate severe, bilateral epilepsy, proved most productive. Sperry (1961) had elaborated, during work on monkeys, an array of ingenious testing techniques which could be applied, extended and further refined in observation upon human patients, with the great advantage of verbal communication, allowing access to subjective phenomena which could only be hypothecated in monkeys from motor behaviour. The essence of such techniques is the isolated presentation of a variety of sensory cues (visual, auditory, or tactile) to the right or left hemisphere and also isolation from each other of such stimuli or cues presented simultaneously or sequentially in these different modes. The most commonly employed stimuli are visual cues, projected with great care in either the right or left half of the total binocular visual field; but auditory and even olfactory cues have been extensively used and the hands are frequently included (though these are in the performance of motor tasks, in which tactile and proprioceptive stimuli are also highly significant).

Although corpus callosal *commissurotomy* is not a frequent operation, many patients have now been studied postoperatively and a mass of experimental results has been recorded in such patients and also in considerable numbers of patients and volunteers subjected to amytal injection, both by Sperry, his team and other workers. Sperry's findings have been largely corroborated, with some extensions and modifications, often of a semantic nature (Dimond & Beaumont 1973). They are epitomized in 7.178. There has been so much corroboration of functional asymmetry in the cerebrum and such detailed analysis of peculiarities of each hemisphere, that there is a distinct danger of overstatement. As in any fruitful field of discovery, the original impetus is towards *analysis*, to establish differences and details. As will be emphasized below, it is necessary, as a corrective, to preserve also an impulse towards *synthesis*. The two hemispheres are, despite differences, *complementary* and are in normal circumstances undeniably continuous. Phenomena revealed by their artificial separation have now been studied by a host of workers in much detail; only the examples of asymmetric qualities which are best established can be summarily recounted here.

In the surgically 'split' brain, a brief signal presented in the left half of the binocular visual field is received only by the right hemisphere, with no possibility of transfer of information to the left. (The stimulus must be brief enough, usually about 0·1 second in duration, to counter momentary ocular movement from midline fixation.) If the right is the 'minor' hemisphere, as it usually is, no verbal response can be obtained and the patient is unaware (so he says) of the occurrence of the signal when questioned. (He may volunteer statements but their content is unrelated to the experimental situation.) Nevertheless, the patient (or experimentee if sodium amytal is used) must in some manner, apparently outside the consciousness associated with his left hemisphere, recognize signals, especially actual objects, with his right hemisphere. This is shown, e.g. by his ability to *remember* an object displayed to him momentarily and to pick it out subsequently with his *left* hand, unaided by vision, from an array of dissimilar things presented to his searching hand. Whatever comments his isolated left hemisphere likes to make on his performance (of which he has no knowledge in this verbalizing, talkative hemisphere), these phenomena demonstrate that the right hemisphere is able to carry out much that is characteristic of a conscious brain: he 'sees', recognizes, employs memory and directs successfully the corresponding hand. A large series of such experiments, employing a wide variety of visual, auditory and tectile cues and recorded by many observers, demonstrates beyond doubt that each hemisphere can, when separated, act to a marked extent as an independent unit, with its own ability for perception, learning, memorization and motor control; hence, of course, the expression 'split brain' and the assumption that two separate consciousnesses can co-exist in the individual. However, it is only the verbally skilful hemisphere (usually left, sometimes right) which can communicate directly, explicitly and intelligently with other consciousnesses in the medium of language, thus

7.178 This diagram is an adaptation (with the author's permission) of the original 'split-brain' schema, published by Professor R W Sperry in 1964, of hemispheric attributes as revealed by complete division of the corpus callosum. The right and left halves of the total visual field are projected into the contralateral hemispheres and are completely isolated, the right hand being 'controlled' from the left hemisphere. The olfactory and auditory inputs also project to separated hemispheres, but in the former case ipsilaterally and in the latter bilaterally with a contralateral bias. On each side of the diagram the abilities listed refer to the adjoining hemisphere; they are to be taken as extremely generalized attributes, which are likely to be modified as research in this field progresses. The diagram represents, of course, arrangements in an individual with left cerebral dominance or preference.

uniting its own conscious world with the exterior. The other, the so-called 'minor' hemisphere, is severed or 'split' from such communication and, moreover, from communication with the 'dominant' hemisphere. Nevertheless, this isolated right hemisphere is even able to recognize the meaning of the names of objects, presented either visually or aurally, and to correlate this recognition with memories of similar experiences and to carry out appropriate motor behaviour, though this half-brain, apparently conscious, is out of touch with any observer, who has no access to its activities except through its motor responses (excluding those of speech).

These astonishing findings have persuaded some interpreters to an even firmer belief in the dominance of the verbal hemisphere and to assign to it a major, if not exclusive role in a supposed brain–consciousness linkage. Some workers have even been led to question the need for two such 'brains' (e.g. Teuber 1974). The enthusiasm for analysis has undoubtedly led to an over-emphasis of the peculiarities of each hemisphere, tending to obscure the normal unity of the two halves of the cerebrum. Whatever may be hypothecated with respect to consciousness, it is clear that in some of the attributes of consciousness, such as spatial conception, geometrical perception and perhaps 'musicality', the minor hemisphere is the more able partner and must participate in the conscious activities of the united hemispheres.

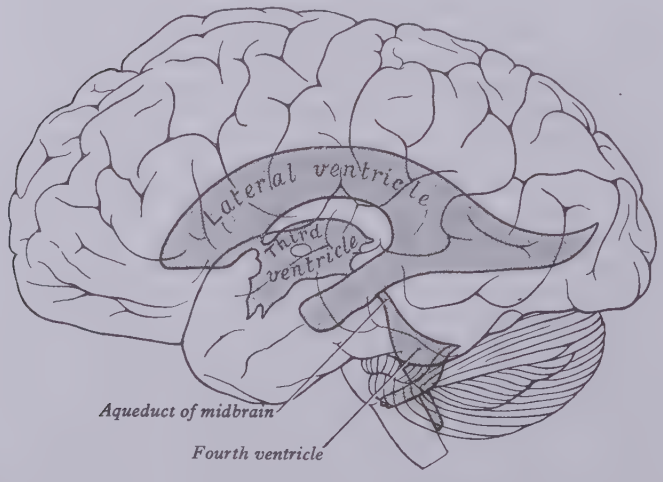
It is easy, of course, to overlook the fact that in the diencephalic region and, caudal to this, unity persists even after commissurotomy. As Young (1978) has picturesquely stated, the split personality of commissurotomized patients, dual though it may seem, falls asleep as one, though his two eyes appear to take different views of his environment when he is questioned on awakening. It is not surprising, perhaps, that such patients exhibit so little deficiency or duality in ordinary activities, in which they are also able to explore the visual field freely with both eyes, to use both hands and to rotate the head, thus duplicating in each hemisphere a representative array of signals from the entire sensory field and not merely from one side or the other. It is only by the careful techniques evolved by Sperry and his co-workers that defects are unmasked.

Specialization of hemispheres in an asymmetrical, unilateral manner, so that in the total cerebrum certain abilities are sufficiently correlated with one hemisphere to be assignable to it, is at present beyond explanation, despite interesting theorization. Such arrangements are not, however, wholly unexpected. The existence of two central mechanisms, bilaterally related, for any generalized function is not easy to understand or even accept, without evidence of some linking or co-ordinationg locus. The operation of two such central mechanisms, each dealing with half of what is continuously appreciated as an unbroken visual field

has always posed such a problem and appears to evoke some unitary integrating activity, although Sherrington (1906) was prepared to regard the *simultaneous* occurrence of dual sets of neuronal events as sufficient explanation. But evidence for the transference of visual and other information across the midline of the cerebrum is impressive and memory stores of each hemisphere appear to be accessible to the other and to be probably bilateral at least in part.

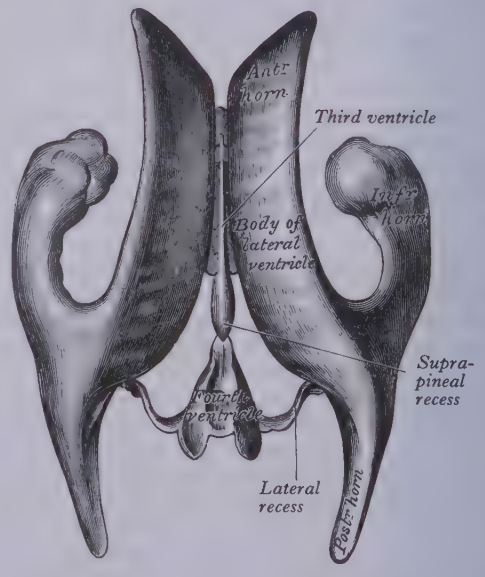
All such phenomena would in hypothesis demand a large connection between the hemispheres and this of course exists and must provide the anatomical matrix for extensive communication and presumably integration between right and left activities. Though so much research in this field has been focused on functional hemispheric differentiation, with special emphasis at first on the unilateral mediation of speech (thus leading to the concept of dominance), it is nevertheless becoming clearer in later investigation that the laterality of many functions is merely greater on one side and not exclusive to one or other hemisphere. Even in verbalization, some ability has long been assigned to the 'minor' hemisphere (Albert & Obler 1978). Moreover, concepts of what constitutes a discrete 'function' may be in themselves misleading. Though I may *describe* a complex three-dimensional structure to another individual through a series of symbolic sounds called language, chiefly organized into an intelligible sequence by left hemispheric activity, it seems equally probable that I am *conceiving* an image or idea of the object I wish to describe in my right hemisphere and that in the absence of linguistic description the concept may remain largely limited to the 'minor' brain.

The too facile ascription of labelled functions or abilities to one or other side has been criticized by Milner (1974), who has redirected attention to the 'parallelism' of right and left activities. Broadbent (1974) has also emphasized integrative action of the hemispheres (an interesting reminder of the title of Sherrington's classic text!) regarding speech, e.g. as a combined production of both. Such considerations favour a growing tendency to abandon the terms 'dominant' and 'minor'; it is clearly more rational to accept a complex but complementary asymmetry of distribution of ability within the whole cerebrum. Inevitably this will entail a degree of right and left predominence, though perhaps only in so far as we impress our own semantics upon the complete organization. Eccles (1973 and in Popper & Eccles 1977) has professed a preference for the term 'dominance', from his own interpretation of the dominant, verbalizing hemisphere as the mediator between the external universe and internal consciousness. He has resuscitated an old postulate due to Sherrington (whose student he was) that some part of the cerebrum would prove to be a site of what Eccles calls a *liaison* between brain and consciousness; but he goes further in designating the *dominant* hemisphere as a *self-conscious* cerebral region. Although we are here being returned to the nineteenth-century association of speech and cognitive processes in a common locus, evidence from Sperry's patients and other sources does also support such a view. But the apparent inaccessibility to any verbal communication of the 'minor' hemisphere and its apparent oblivion to its own activities are both revealed by the artificial separation. However useful this isolation may be in the analysis of cerebral abilities, it may also mislead; it must be followed by a re-synthesis to explain the operations of a normally united and singular brain.



These fascinating studies are currently providing a most fertile common ground between neuroanatomists, neurophysiologists, experimental psychologists and even philosophers, in a general endeavour towards understanding the human brain and hence of what we call *our selves*. It is an exciting prospect, particularly because it centres around the great problems of communication between the private world of the individual and his external environment of countless similar individuals, each locked in a private prison except insofar as communication succeeds. Perhaps, as understanding increases, we shall dissolve our differences and disperse our doubts and then perhaps in the happily optimistic words of Young (1968) 'a new form of laughter will echo through the system'. However that may be, it is pertinent to conclude with a statement by Braitenberg (1973), another distinguished student of man's brain: 'The *neuroanatomy* of neuronal networks will be for quite some time, and perhaps forever, the content that relates the *physiology* of single neurons and synapses to the macroscopic events of *psychology*' (Editors' italics). After analysis must come synthesis.

INTERNAL STRUCTURE OF THE CEREBRAL HEMISPHERES



In the interior of the hemispheres are the lateral ventricles, the basal nuclei and many fibre tracts, both projection and intrinsic.

The Lateral Ventricles

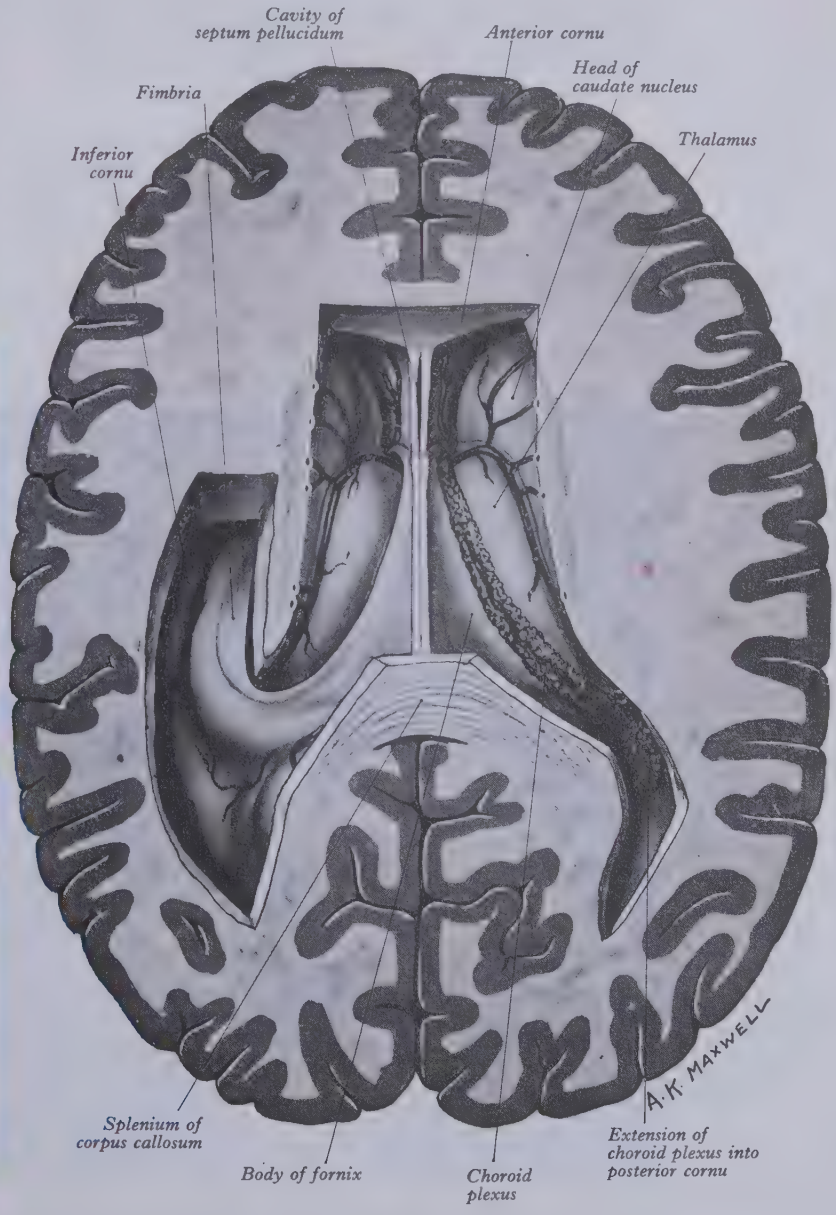
The two lateral ventricles (7.179, 180, 181A,B, 182) are irregular cavities lying inferomedially in the cerebral hemispheres, one on

7.179 Projection of the ventricles on to the left surface of the brain.

7.180 A drawing of a cast of the ventricular cavities: superior aspect (Retzius). Note that, where the lateral recess joins the fourth ventricle, the lateral dorsal recesses of the roof of the ventricle project dorsally on each side beyond the posterior margin of the median dorsal recess. The superior angle of the fourth ventricle and the aqueduct of the midbrain are hidden by the suprapineal recess.

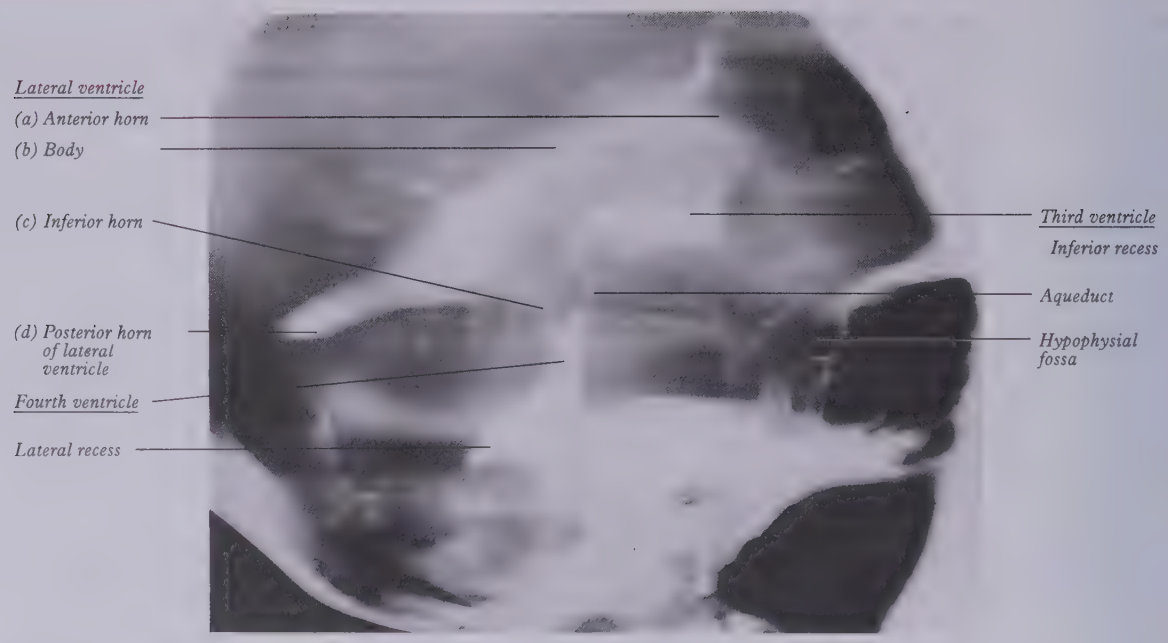
each side, and almost completely separated by the *septum pellucidum* but each communicating with the third ventricle and indirectly with the other through its *interventricular foramen* (p. 1019). They are lined by the ependyma and contain cerebrospinal fluid. Each lateral ventricle has a *central part* and three *cornua* or *horns*: anterior, posterior and inferior (7.180, 181A,B, 182, 191, 193).

The central part (7.181B, 182) extends from the interventricular foramen to the splenium. It is a curved cavity with a roof, floor and medial wall; it is triangular in transverse section anteriorly and rectangular posteriorly. The *roof* is the inferior surface of the corpus callosum; the *floor* slopes steeply downwards and medially, presenting two convexities and two grooves; it is formed, in lateromedial order, by the caudate nucleus, the stria terminalis, thalamostriate veins and the lateral part of the superior thalamic surface. The convex body of the caudate nucleus rapidly narrows as it passes back in the floor; its long axis is directed posterolaterally. The stria terminalis, a bundle of white fibres (p. 1034) and the thalamostriate vein occupy a narrow groove following the medial border of the caudate nucleus and separating it from the convex superolateral surface of the thalamus. The latter may be almost hidden by the choroid plexus, which invaginates the ependyma into the cavity through a slit between the fornical edge and a reciprocal groove on the superior thalamic surface, the ependymal invagination occupying this *choroid fissure*. The body of the fornix widens posteriorly; its thin, lateral margin is parallel to the groove for the stria terminalis. The *medial wall* is formed by the posterior part of the septum pellucidum with the body of the fornix in its lower margin. Posteriorly, where the septum ends, roof and floor meet on the medial wall.



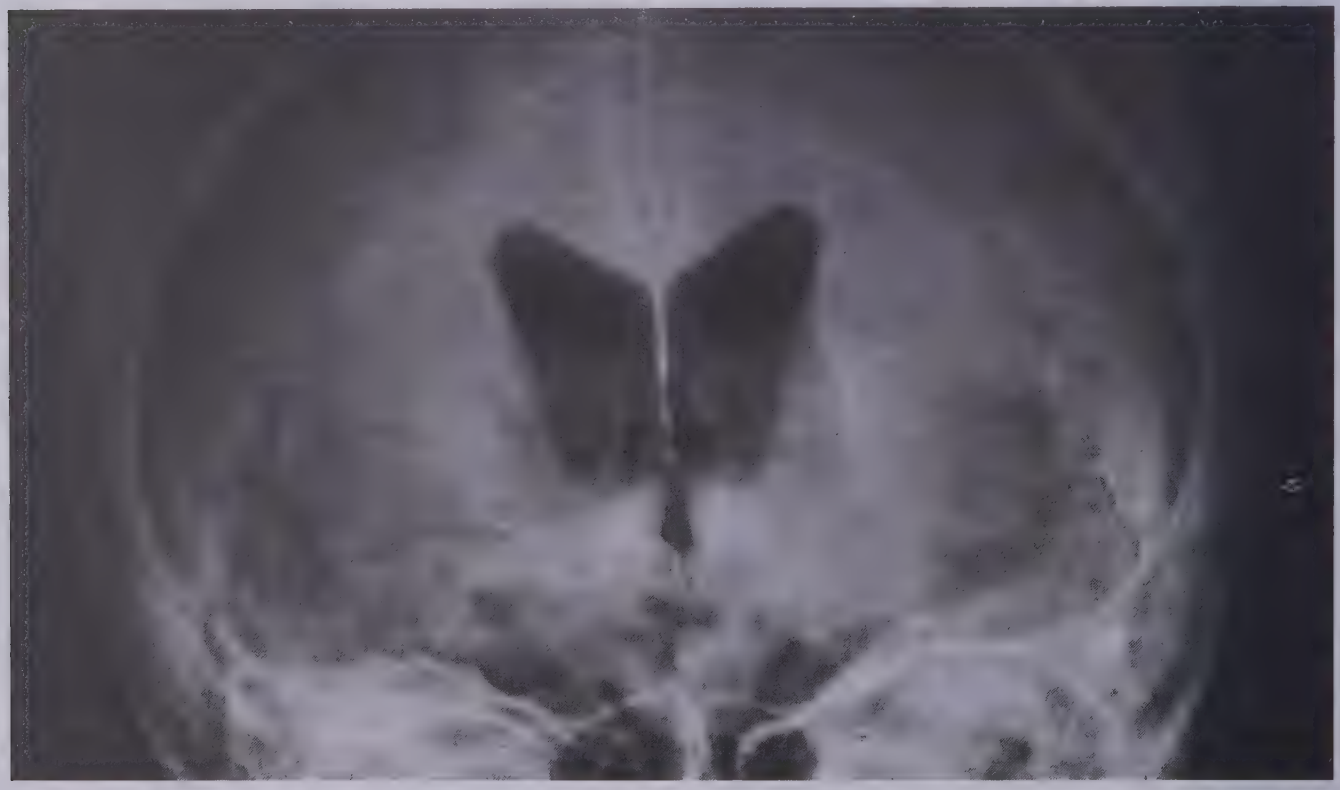
The anterior cornu (7.179, 180, 181, 182) passes anterolaterally and slightly down into the frontal lobe and is continuous posteriorly with the ventricle's central part at the interventricular foramen. In coronal section it is a triangular slit below the anterior part of the corpus callosum, bounded anteriorly by the *posterior* aspect of the genu and rostrum. The *roof* is the anterior part of the callosal trunk. Most of the *floor* is the large rounded head of the caudate nucleus, but medially a small part is formed by the upper aspect of the rostrum (7.195). The *medial boundary* is the septum pellucidum containing the column of the fornix in its posterior edge.

The posterior cornu curves posteromedially into the occipital lobe. Its development is variable and often asymmetrical; it may be absent. Its *roof* and *lateral wall* are formed by fibres of the tapetum separating them from the optic radiation (p. 1073). Splenial fibres forming the forceps major pass medially as they sweep back into the occipital lobe, producing a rounded *bulb* of the posterior cornu in the latter's upper *medial wall*, below which is a second elevation, the *calcar avis*, corresponding to the infolded cortex of the anterior calcarine sulcus (7.184). Posteriorly the lateral and medial walls meet. Kier (1977) has shown that the posterior cornu is the most recent extension of the lateral ventricle, present only in the Anthropoidea. It is symmetrical in the fetus but in adults the cornua are usually unequal in size, a perinatal change which Kier ascribes to unequal folding of the calcarine fissures.

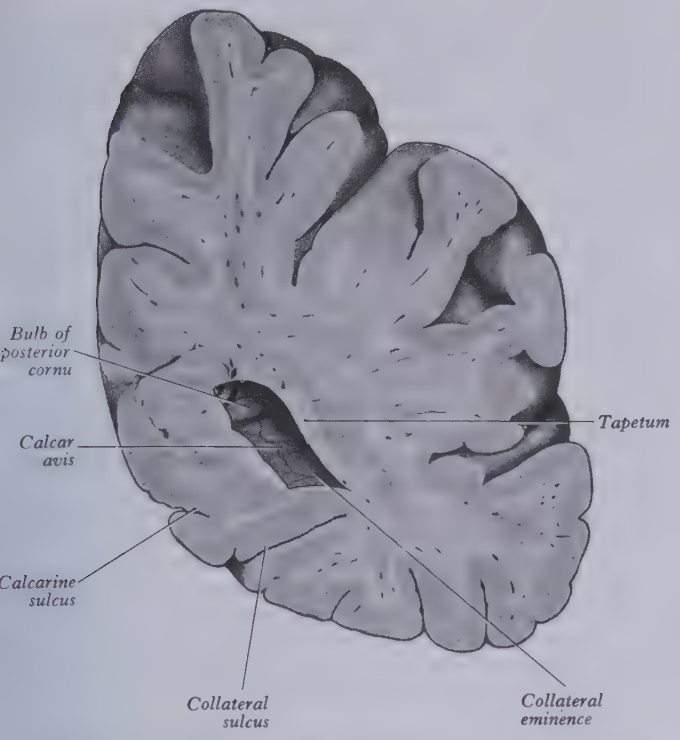


The inferior cornu (7.149, 185), largest of the three, traverses the temporal lobe, curving round the posterior aspect of the thalamus. At first it descends posterolaterally, then curves

7.181 Resin casts of the ventricular system of the human brain (prepared by D H Tompsett of the Royal College of Surgeons of England): A. ventral view; B. left lateral view. Compare with the superior aspect shown in 7.180.

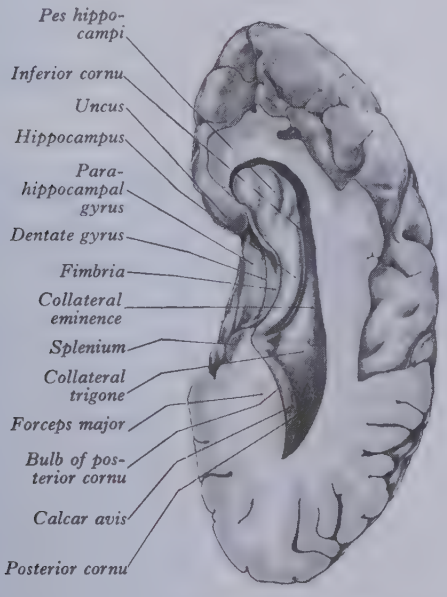


7.182 Horizontal section of the cerebrum dissected to remove the roofs of the lateral ventricles.



7.183A Positive contrast ventriculogram (tomogram), with some air in the anterior part of the lateral ventricle. Supplied by T D Hawkins, Addenbrooke's Hospital, Cambridge; photography by Sarah Smith.

anteriorly to within 2·5 cm of the temporal pole near the uncus, its position usually corresponding on the surface to the superior temporal sulcus. (A trephine hole, with its centre 3 cm behind and 3 cm above the centre of the external acoustic meatus allows a needle, passed towards the tip of the opposite ear, to enter the inferior cornu at a depth of 5 cm from the surface.



The *roof* is formed chiefly by the tapetum of the corpus callosum but the tail of the caudate nucleus and stria terminalis also extend forwards in it and they are continuous with the amygdaloid body at its end (tip, or uncal extremity). The *floor* consists of the collateral eminence laterally, the hippocampus medially (the latter covered by the alveus), continuing as the fimbria of the hippocampus, which continues posteriorly with the crus of the fornix (p. 1039). Between the stria terminalis and the fimbria is the inferior part of the choroid fissure, where the lower part of the choroid plexus invaginates the ependyma and closes (i.e.

7.183B Anteroposterior radiograph of the head after the introduction of air into the ventricular system of the brain. The outlines of the bodies and anterior horns of both ventricles are separated in the midline by the shadow of the septum pellucidum; directly inferior to the latter, the outline of the third ventricle can be seen. Provided by R D Hoare, Dept. of Diagnostic Radiology, Guy's Hospital, London.

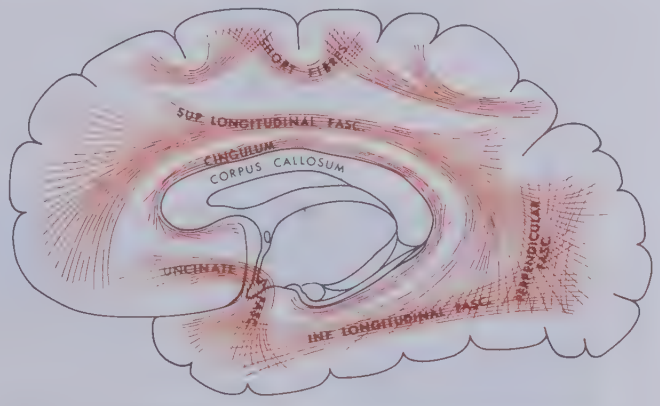
7.184 Anterior aspect of a coronal section through the posterior cornu of the left lateral ventricle.

7.185 The posterior and inferior cornua of the right lateral ventricle, exposed from above.

occupies or 'fills') the fissure and covers the upper surface of the hippocampus.

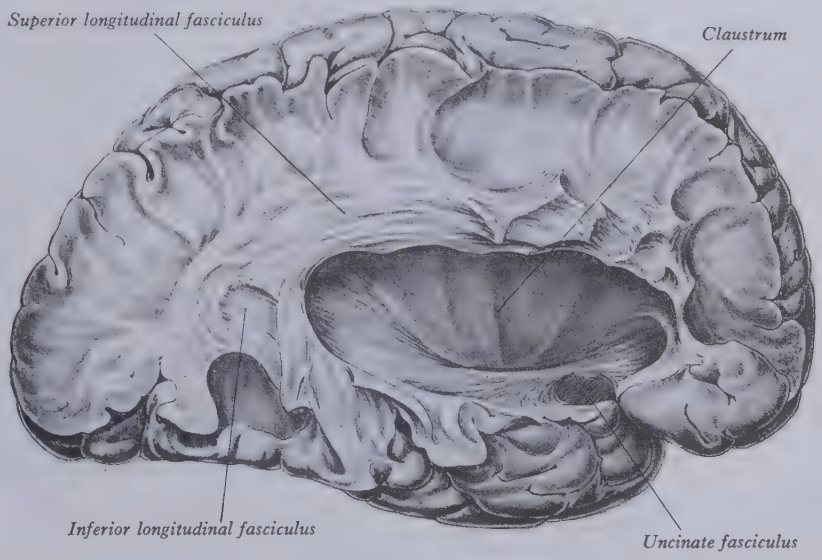
The hippocampus and fimbria are considered on pp. 1036 and 1038 and the choroid plexus on p. 1080.

The *collateral eminence* (7.185), a long swelling lateral and parallel to the hippocampus, overlies the collateral sulcus, its size reflecting the depth of the sulcus. The eminence continues behind into the flattened triangular *collateral trigone*, flooring the ventricle between its posterior and inferior cornua. The capacity of the lateral ventricles (and other chambers related) can be estimated by anatomical and radiological techniques (Weintraub 1953). Levinger & Kedern (1974) devised a technique for estimating the surface area of cerebral ventricles from casts, but so far only in cats.



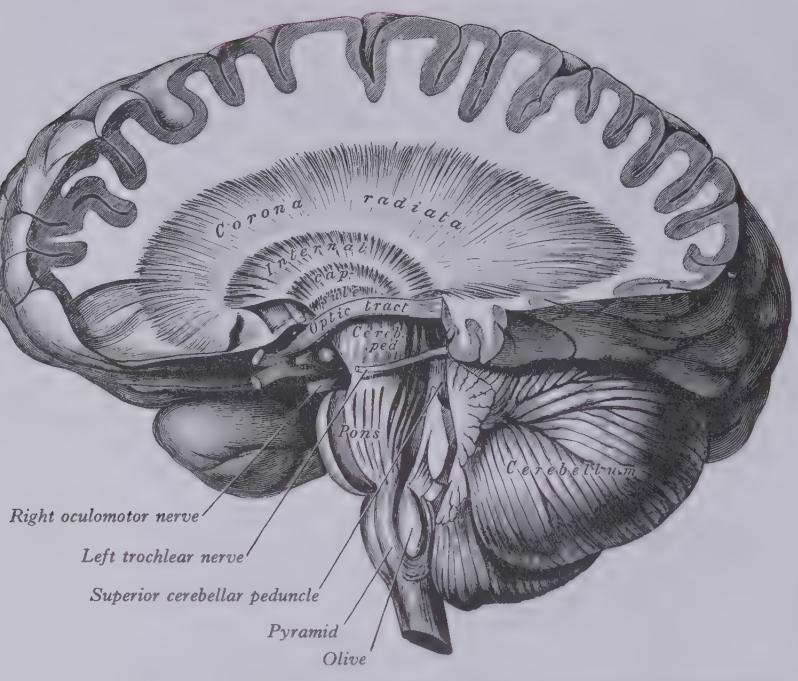
Nerve Fascicles of the Cerebrum

In a hemisphere sliced horizontally about 1·25 cm above the corpus callosum, its central white substance appears as an oval area surrounded by a narrow, much folded lamina of grey matter and studded by red *puncta vasculosa* due to the escape of blood from divided vessels. Transected at the level of the corpus callosum, it displays the continuity of white matter of the two sides, containing nerve fibres of varying size and supported by neuroglia. These may be described according to their course and connections, as: (1) *commissural fibres*, linking corresponding or *homotopic* loci and *heterotopic* loci in both hemispheres; (2) *association* (arcuate) *fibres* connecting different cortical areas in the same hemisphere; some are collaterals of the projection and commissural fibres but most are main axons; (3) *projection fibres*, connecting the cerebral cortex with the corpus striatum, diencephalon, brain stem and the spinal cord in both directions.



(1) **Commissural fibres** are described on pp. 1005, 1034, 1039, 1062.

(2) **Association (arcuate) fibres** (7.186A, B), confined to one hemisphere and all ipsilateral, are grouped as *short*, connecting adjacent gyri, or *long*, connecting more widely separated gyri. The details of many association pathways appear with their cortical areas.



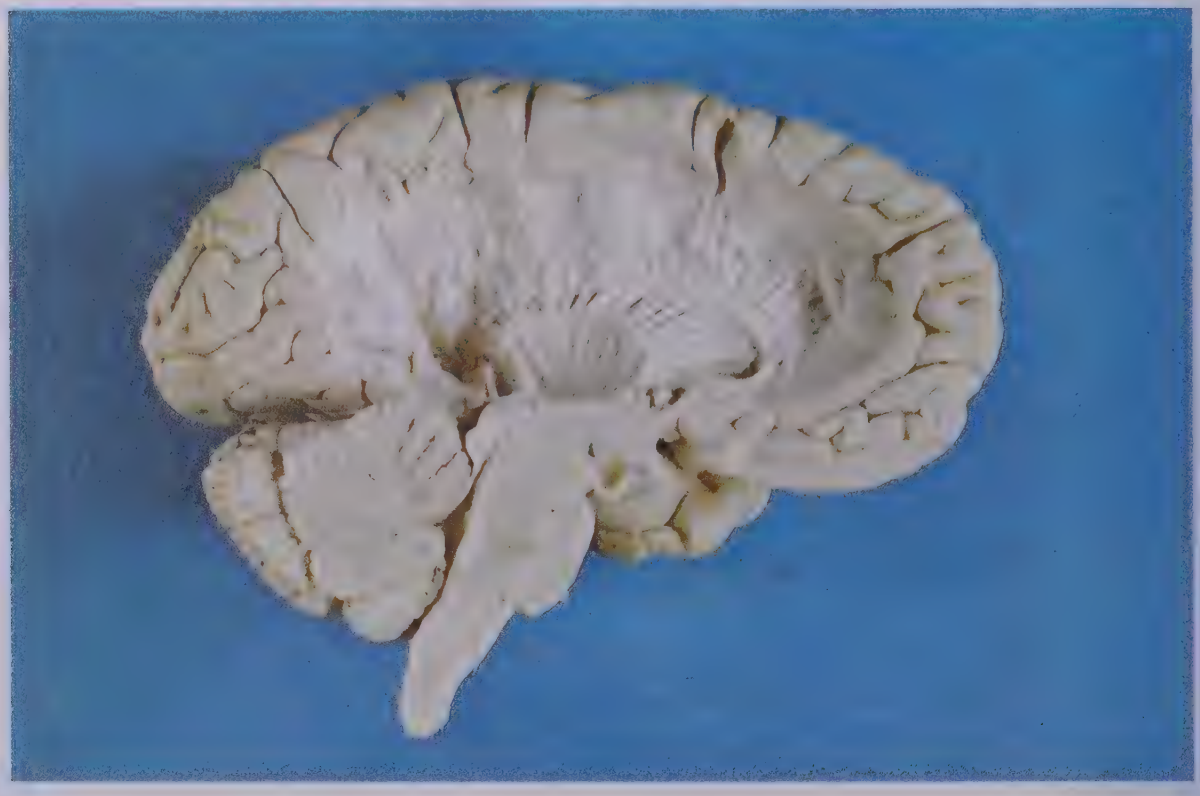
Short arcuate fibres may be entirely intracortical but many pass subcortically between adjacent gyri, some merely from one wall of a sulcus to the other. They are very numerous and easily, but crudely, displayed by blunt dissection in fixed brain tissue.

7.186A The principle arcuate (association) fibres in the cerebrum.

7.186B A dissection showing some of the long arcuate fasciculi of the right cerebral hemisphere.

7.187 A dissection showing the convergence of cortical projection fibres through the corona radiata into the cerebral peduncle and pons.

Long arcuate fibres are grouped, somewhat indistinctly, into bundles which can be dissected in formalin-hardened brains after removal of the cortex and subjacent short acuate fibres. Fibres in each fasciculus vary in length, the longest usually being deepest. Concerning the connections of these bundles little information is available; they are difficult to follow by histological technique and any form of dissection reveals only the crudest details. The following large fasciculi can usually be distinguished: (*a*) the uncinate fasciculus, (*b*) the cingulum, (*c*) the superior longitudinal fasciculus, (*d*) the inferior longitudinal fasciculus, (*e*) the fronto-occipital fasciculus.



(*a*) The *uncinate fasciculus* connects the first motor speech area (p. 1055) and orbital gyri of the frontal lobe with the cortex in the temporal pole; the fibres follow a sharply curved course across the stem of the lateral sulcus. They are near the antero-inferior part of the insula (7.186A, B).

(*b*) The *cingulum*, a long, curved fasciculus starting in the medial cortex below the rostrum, then lies in the gyrus cinguli and follows its curve. Inferiorly it enters the parahippocampal gyrus and spreads into the adjoining temporal lobe. From its convexity fibres enter and leave in groups, giving it a spiked irregular appearance when dissected.

(*c*) The *superior longitudinal fasciculus*, largest of the arcuate bundles, commences in the anterior frontal region and arches back above the insular area and lateral to the massive cortical projection fibres of the internal capsule (corona radiata, vide infra). Contributing fibres to the occipital cortex (areas 18 and 19), it curves down and forwards behind the insular area to spread out in the temporal lobe. Like other long fasciculi, fibres leave and join it throughout its extent but it is impossible to determine the precise connections by gross methods (7.186B); even with the modern techniques of fibre tracing little progress has yet been made in this field.

(*d*) The *inferior longitudinal fasciculus* commences near the occipital pole, its fibres derived perhaps mostly from areas 18 and 19. They sweep forwards, separated from the lateral ventricle's posterior cornu by the optic radiation and commissural tapetal fibres and, after being crossed by the superior longitudinal fasciculus, is then distributed throughout the temporal lobe.

(*e*) The *fronto-occipital fasciculus* starts from the frontal pole, passing back deep to the superior longitudinal fasciculus but

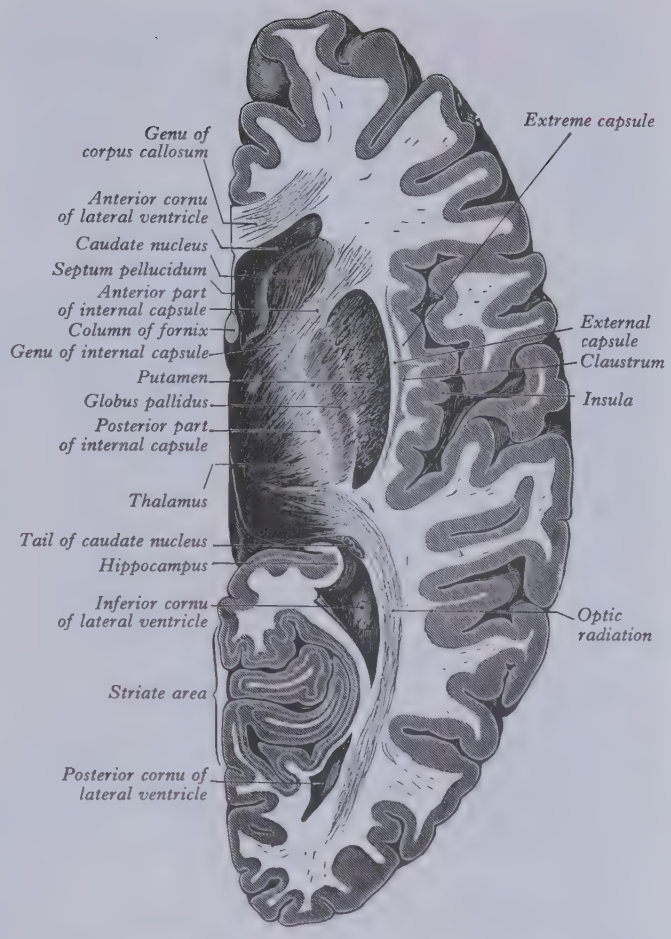
7.188 After median sagittal section of the brain, the left cerebral hemisphere has been dissected from its *medial* aspect to display the fibre bundles of the corona radiata and internal capsule. This entailed the removal of the cingulate gyrus and subjacent white matter, much of the paramedian corpus callosum and fornix, the dorsal thalamus and the head and body of the caudate nucleus. The oval depression previously occupied by the dorsal thalamus can clearly be seen within the curved depression left after removal of the caudate nucleus. Dissection by Andrew Seal, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

separated from it by the projection fibres in the corona radiata (vide infra). It is lateral to the caudate nucleus and therefore near the central part of the lateral ventricle. Posteriorly it fans out into the occipital and temporal lobes, lateral to the posterior and inferior ventricular cornua and the criss-crossing fibres of the tapetum.

These details are based on the results of blunt dissection which can only yield crude impressions of the general disposition of fibres en masse. Accurate knowledge of association fibres can only be established by experimental methods not yet applied to most cortical regions. Studies of visual areas (Le Gros Clark 1941, Zeki 1970, 1974) and the main somatic sensory areas (SmI) (see Jones & Powell 1968) suggest a high degree of specificity in such connections. (See also personal communication p. 1063, the comments on modular microarchitecture pp. 1052, 1059 and homogeneity of most cortical areas p. 1043.)

(3) **Projection fibres** connect the cerebral cortex with lower levels in the brain and spinal cord; they are *corticofugal* and *corticopetal*. Projection fibres converge from all directions to the corpus striatum (7.187), mostly (but not exclusively) medial to association fibres, and intersect commissural fibres of the corpus callosum and anterior commissure. At the periphery of the corpus striatum, they form the *corona radiata*; its *medial* aspect is, however, separated from the lateral ventricle by the fronto-occipital fasciculus and its lateral aspect covered by the superior longitudinal fasciculus. It is continuous with the internal capsule, a curved zone including almost all the projection fibres (vide infra).

The Internal Capsule



In horizontal cerebral section the internal capsule is seen as a broad white band, with a lateral concavity adapted to the convex medial aspect of the lentiform nucleus (7.189–194). It has an *anterior limb*, *genu*, *posterior limb*, *retrolentiform* and *sublentiform parts*. Both limbs are, of course, medial to the lentiform nucleus; medial to the anterior limb is the head of the caudate nucleus and medial to the posterior limb the thalamus. Fibres of the capsule continue to converge as they descend, the frontal fibres tending to pass posteromedially, temporal and occipital fibres anterolaterally. At a lower lentiform level, they are crossed by the optic tract and enter the midbrain, many (but *not* all) of the corticofugal fibres lying in the crus cerebri, where the frontal fibres are medially placed while temporal, parietal and occipital fibres are laterally situated.

The *anterior limb* contains *frontopontine fibres*, from the cortex in the frontal lobe, which synapse with cells in the nuclei pontis and the axons of which enter the opposite cerebellar hemisphere. Anterior thalamic radiations interconnect the medial and anterior thalamic nuclei and various hypothalamic nuclei and limbic structures with the frontal cortex.

The *genu* is usually regarded as containing *corticonuclear* fibres mainly from area 4 and terminating in the largely contralateral motor nuclei of cranial nerves. Anterior fibres of the superior thalamic radiation, between the thalamus and cortex, also extend into the genu.

The *posterior limb* includes the *corticospinal tract* in scattered bundles, the fibres concerned with the upper limb being anterior and followed by those for the trunk and lower limbs. This location of corticospinal fibres anterior in the posterior limb has been accepted since the observations of Charcot (1883) and Dejerine (1901); but more evidence from stereotactic lesions in man suggests that these fibres are *posterior* in the posterior limb. The evidence has been reviewed by Smith (1967) and Hanawayu & Young (1977). Other descending fibres include the frontopontine, particularly from areas 4 and 6, *corticorubral* fibres from the frontal lobe to the red nucleus and fibres from the globus pallidus in the subthalamic fasiculus. Most of the posterior limb also contains fibres of the superior thalamic radiation (the somesthetic radiation) ascending to the postcentral gyrus.

In the *retrolentiform part* are the parietopontine, *occipitopontine*, *occipito-collicular* and *occipito-tectal* and also the posterior thalamic radiation, including the optic radiation, and interconnections between the occipital and parietal lobes and caudal parts of the thalamus, especially the pulvinar.

7.189 Superior aspect of a horizontal section through the right cerebral hemisphere.

The *optic radiation* arises in the lateral geniculate body and sweeps back in the concavity between central and inferior cornual parts of the lateral ventricle, intimately related to the superolateral aspect of the ventricle's inferior cornu and the lateral aspect of the posterior cornu, separated from it by the tapetum.

The *sublentiform part* contains *temporopontine* and some parietopontine fibres, the acoustic radiation from the medial geniculate body to the superior temporal and transverse temporal gyri (areas 41 and 42) and a few fibres connecting the thalamus with the temporal lobe and insula. Fibres of the *acoustic radiation* sweep anterolaterally below and behind the lentiform nucleus to reach the cortex.

Connections between cortex and thalamus are detailed on p. 1000, corticohypothalamic connections on p. 1009 and corticostriate connections on p. 1076. Corticoreticular connections, corticonuclear fibres to all varieties of *sensory* integrating and relay nuclei in the brain stem and spinal laminae are mentioned throughout the text at numerous points. All the foregoing have reciprocal projections but their internal capsular location, in man, is as yet conjectural.

The Basal Nuclei

In each cerebral hemisphere is a group of large subcortical nuclei included in the general term *basal nuclei*. The structures included vary but most commonly are the amygdaloid complex, claustrum, caudate nucleus and lentiform nucleus (7.176, 189, 190, 191, 192). These nuclear masses are heterogeneous in structure, function and phylogenetic history, engendering a confusing terminology among different investigators, the structures being subdivided and regrouped in various ways; commonly used alternatives are

mentioned *passim*. (For critical reviews see Mettler 1968, Webster 1978, Marsden 1985.)

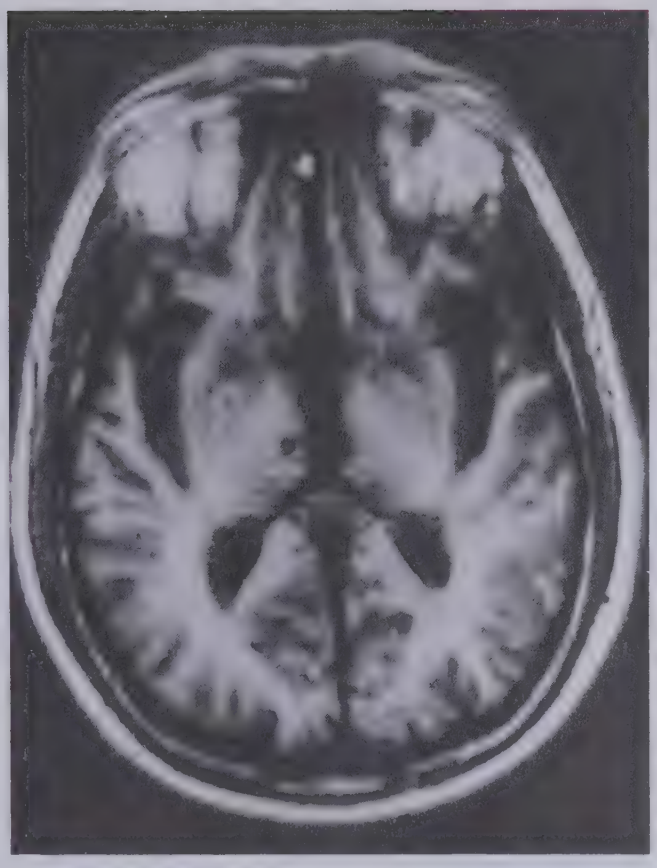
The *amygdaloid body* (amygdaloid nuclear complex, amygdala, *archistriatum*) is discussed with the limbic system (p. 1029). The *claustrum*, a tenuous grey sheet surrounded by white laminae separating it from the insular and lentiform nucleus, is described on p. 1080.

The *caudate* and *lentiform nuclei* are commonly grouped as the *corpus striatum*, the lentiform being divisible into an internal *globus pallidus* and an external *putamen*, structurally distinct. The putamen resembles the caudate nucleus in structure; together they are the *neostriatum* or *striatum*. Thus *striato*fugal fibres leave the caudate nucleus or putamen while afferents, with the suffix 'striate' (e.g. thalamostriate), pass to the putamen or caudate nucleus, not to the *corpus* striatum as a whole. The terms will be thus used here but some neuroanatomists refer to the whole corpus when using *striato-*; sometimes their meaning is uncertain. The *globus pallidus* or *paleostriatum* is often named

7.190 A horizontal section through the brain including the frontal and occipital poles of the cerebral hemispheres. Features appearing in this section are discussed at many points throughout the text. For appropriate labelling compare with 7.189. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

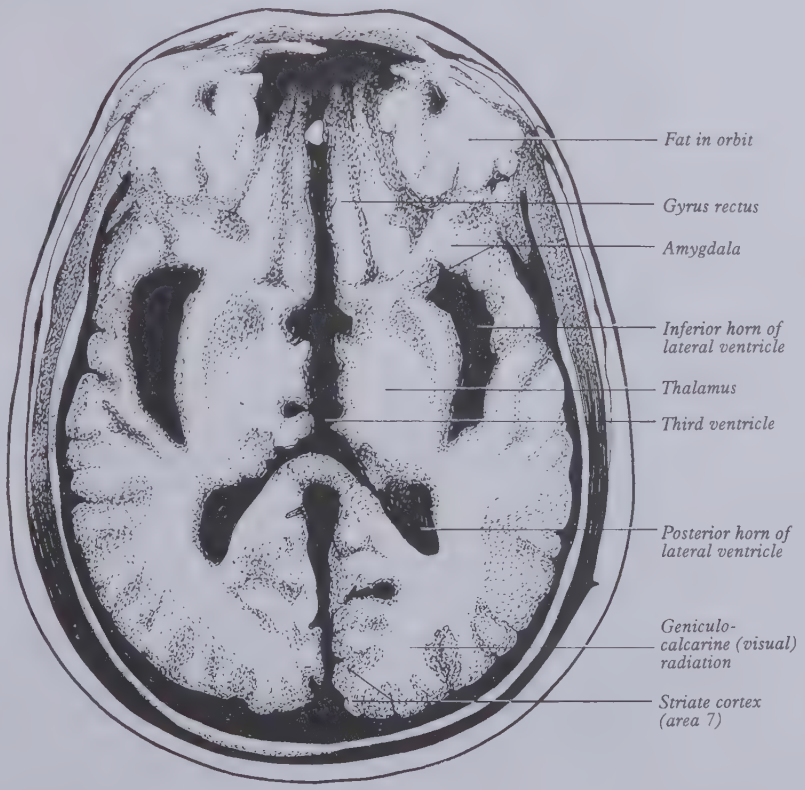
the *pallidum*; hence such terms as pallidal afferents or pallidofugal fibres.

TOPOGRAPHY OF THE CORPUS STRIATUM



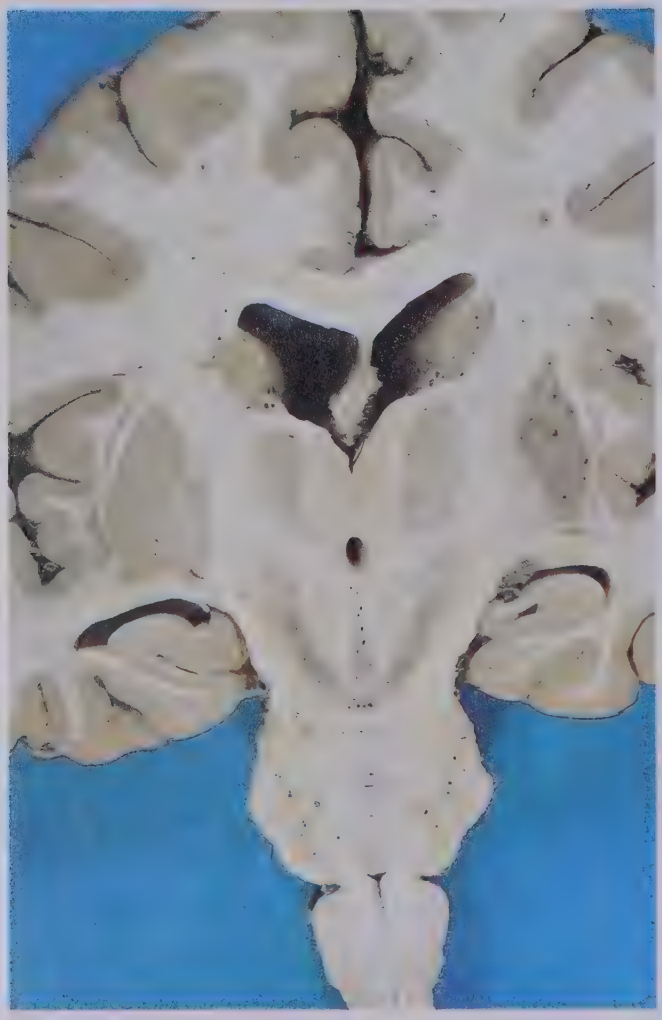
The caudate nucleus is an arcuate mass in the *floor* of the anterior cornu and central part of the lateral ventricle and the *roof* of its inferior cornu (7.182, 188, 189, 190, 192). Its anterosuperior end is the massive *head*, narrowing at the interventricular foramen into the arched *body* which continues to curve and tapers into the ventrally directed *tail*, merging at its apex with the amygdaloid body. Its whole ventricular aspect is covered by ependyma, while in the ventricle's central part and inferior cornu the stria terminalis lies along the medial border of the caudate nucleus. In the ventricle's central part the stria accompanies the thalamostriate vein in a groove between the caudate nucleus and the thalamus; in the inferior cornu it is the upper border of the choroid fissure. In the lateral ventricle's anterior cornu and central part, the lateral *margin* of the caudate nucleus is related to the corpus callosum, separated by the fronto-occipital arcuate bundle (p. 1072) and subcallosal fasciculus (p. 1076); its lateral *surface* is flat and adjoins the internal capsule. Anteriorly the head of the caudate nucleus is fused with the putamen just above the anterior perforated substance; above the fusion strands of grey matter traverse the anterior limb of the internal capsule between the putamen and caudate head; it is the striped appearance here which engendered the term *striatum*. In the inferior cornu the tail curves forwards behind, below and then lateral to the internal capsular fibres entering the crus cerebri and these separate the caudate tail from the thalamus which lies superomedial. Above, the sublentiform part of the internal capsule and fibres from the *external* capsule separate the tail from the globus pallidus.

The lentiform nucleus is like a biconvex lens, its medial surface having a more pronounced curvature (7.130, 181, 182, 189, 190, 192). In section it has two parts, differing in colour; the larger, lateral, darker part is the *putamen*, the smaller, medial part of a lighter tint is the *globus pallidus*. The nucleus is buried in the hemisphere, covered laterally by a thin layer of white matter, the *external capsule*, lateral to which is the tenuous grey matter of the *claustrum*, between it and the insular subcortical white matter (the *extreme capsule*). Medial to the lentiform nucleus is the internal capsule, separating it from the thalamus behind and the caudate head in front. Anterior, superior and posterior to the nucleus is the corona radiata. Its inferior part is grooved by the anterior commissure passing posterolaterally into the temporal lobe (7.182–192); anteriorly its putamen is continuous with the caudate's head. Anterior to the groove there is irregular fusion of grey matter of the corpus striatum with that associated with the anterior perforated substance; lateral striate arteries, entering the brain here, run laterally and turn up close to the lateral aspect of the lentiform nucleus, before piercing it. The lentiform nucleus is above the lateral ventricle's inferior cornu and separated from it by fibres of the external capsule passing medially to the subthalamic region and by the sublentiform part of the internal capsule (p. 1073), the tail of the caudate nucleus and the stria terminalis. More anteriorly, it is separated from the amygdaloid body by the ansa peduncularis.



STRUCTURE OF THE CORPUS STRIATUM

The caudate nucleus and putamen, similar in structure, are highly cellular, well-vascularized and permeated by small bundles of finely myelinated or non-myelinated, small-diameter fibres; because of this, these regions when freshly sectioned are pinkish-grey, contrasting with the pallor of the globus pallidus, which is encapsulated and traversed by numerous, thick, heavily myelinated fibres.



Neurons of the caudate nucleus and putamen are mainly small multipolar cells with round, triangular or fusiform somata, mixed with a small fraction of large multipolar cells; the ratio is about 20:1. The small neurons are considered to be receptive and associative interneurons, receiving the synaptic terminals of many striatal afferents. The large neurons have large and spherical or ovoid dendritic trees; their axons are one source of striatal

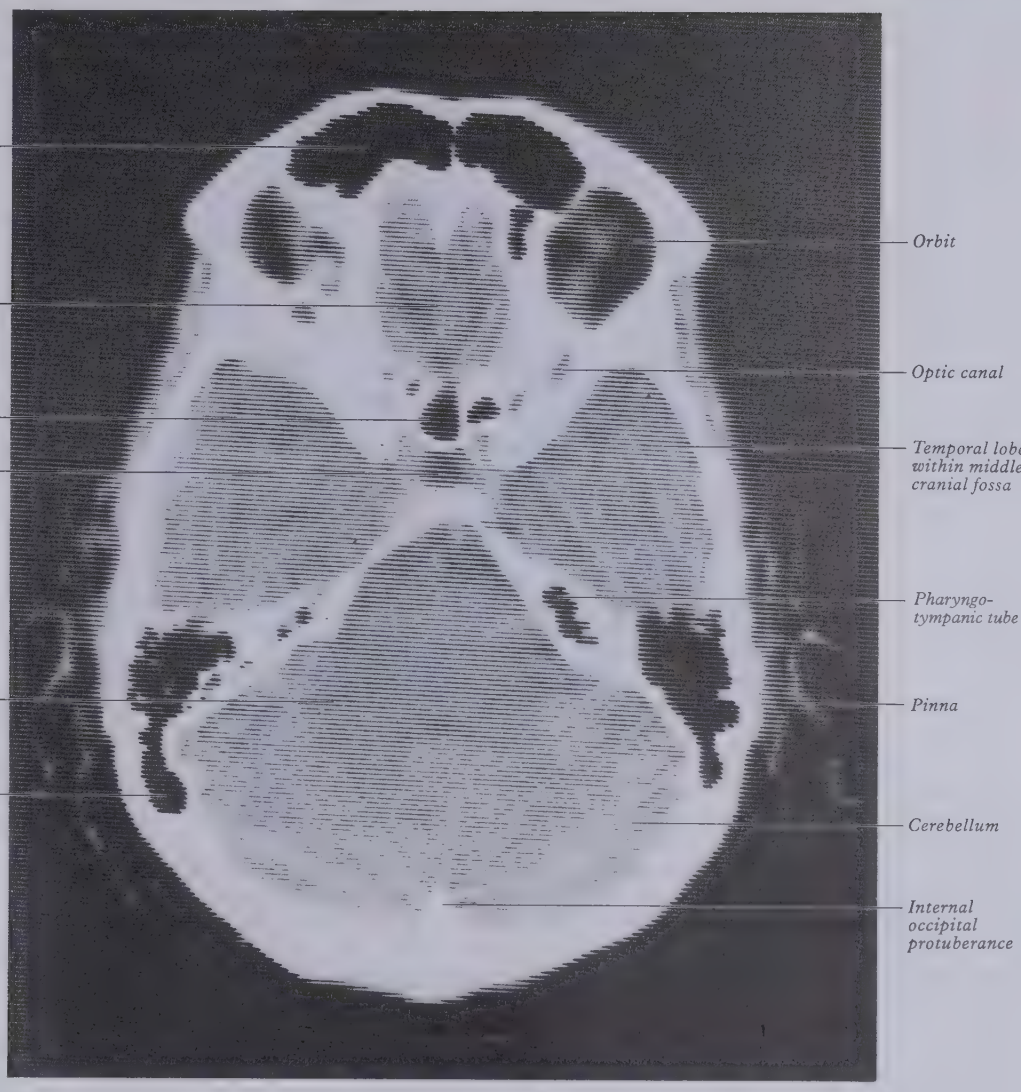
7.192 The central area of the ventral part of the oblique coronal section of the brain shown in 7.122, photographed at higher magnification to show some structural features in greater detail; compare with 7.126, 197 for appropriate labelling. Note in particular: (1) the anterior, medial and lateral parts of the dorsal thalamus, separated by the internal medullary laminae; (2) the relation of the caudate nucleus to the anterior and inferior cornua of the lateral ventricle; (3) the lentiform nucleus, divided into an external putamen and an internal globus pallidus; the latter again divided into internal and external parts; (4) the internal capsule, external capsule, claustrum, extreme capsule and insular cortex; (5) the sectioned profiles of the subthalamic and red nuclei and the substantia nigra; (6) the hippocampus projecting into the floor of the inferior cornu of the lateral ventricle. Other structural features on this section are discussed at many points throughout the text. Compare also with 7.190. Dissection by E L Rees, photography by Kevin Fitzpatrick, both of the Dept. of Anatomy, Guy's Hospital Medical School, London.

efferents (vide infra) but some smaller neurons probably contribute to the striatal outflow. Although the general connections of the striatum with other regions are becoming clearer (vide infra), little is known in detail of its neurons, intrinsic connections and synapses. From the use of the Golgi technique and electron microscopy in various species (Fox et al 1966, Kemp 1968a, b, 1970), some general features have emerged. Striatal dendrites bear spines and axodendritic synapses at the spines and interspinous areas between them, and axosomatic synapses have also been identified; both asymmetrical (Type I) and symmetrical (Type II) synapses occur. Lesions in the cerebral cortex, thalamus or midbrain cause degeneration of asymmetrical synapses, possibly excitatory, on dendrites and (after cortical lesions) also cell somata; but lesions in the caudate nucleus affect type I *and* type II synapses. The latter, possibly inhibitory, are distributed on dendrites, somata and initial axonal segments. Axons of all the striatal neurons studied have collateral branches; type II synaptic terminals may be derived not only from intrinsic interneurons but also from collaterals of neurons projecting to other regions. Histopharmacological studies (Hokfelt 1968) have revealed that in caudate nuclei of rats many synaptic terminals contain 'granulated' vesicles typical of aminergic neurons, perhaps stores of *dopamine*. Other synapses contain vesicles typical of cholinergic terminals.



The globus pallidus has a scattered population of large multipolar neurons resembling lower motor neurons and the large cells of the substantia nigra. Primary dendrites branch infrequently and have few dendritic spines, at which synapses mainly occur, mostly of type II but with a few of type I; scattered between these dendrites are occasional axosomatic synapses of both types. Lesions in the caudate nucleus produce numerous degenerating symmetrical (type II) terminals at dendrites and somata in the globus pallidus (and substantia nigra). Axons of large pallidal neurons provide a profuse, well-myelinated, pallidofugal system (vide infra). The nucleus is separated by the *external medullary lamina* from the medial aspect of the putamen; an *internal medullary lamina* divides it into smaller medial and lateral parts (*pallidum I and II*).

CONNECTIONS OF THE CORPUS STRIATUM

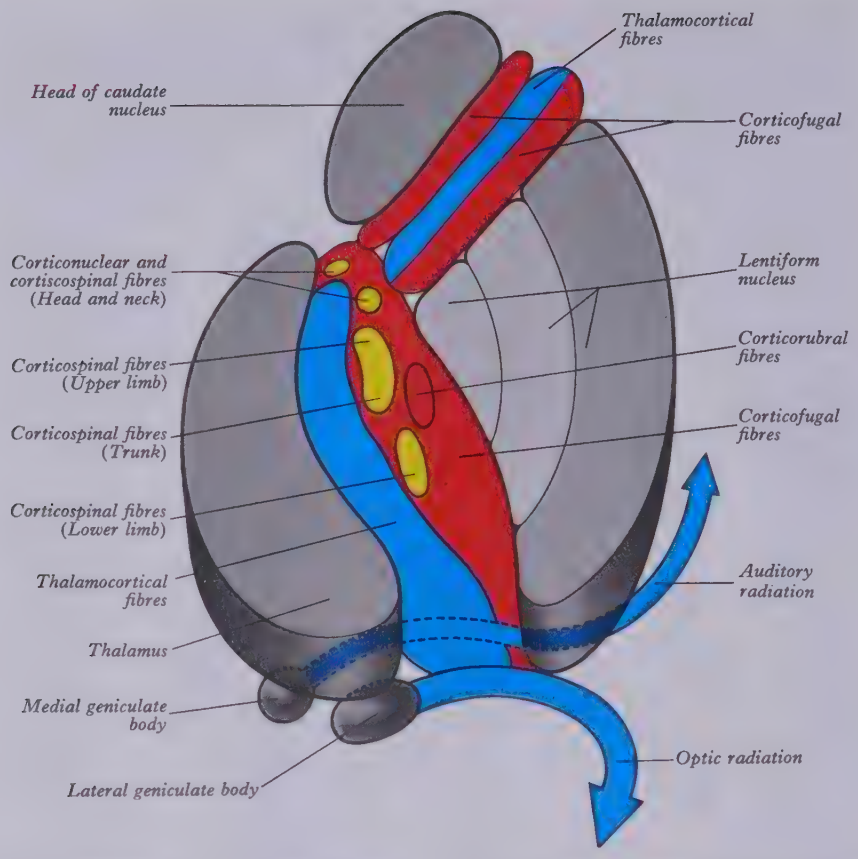
Summary (see 7.197). The neostriatum (putamen and caudate nucleus) is the main striatal receiving station, which then projects to the globus pallidus; the latter provides the main efferent projection but some efferent paths leave the neostriatum directly (and the globus pallidus also *receives* other afferents).

The afferent connections to the striatum are mainly from the cerebral cortex, thalamus and substantia nigra. Although long in doubt, it is now firmly established that *corticostriate fibres* form a widespread system *topically organized* and converging from almost *all parts of the cerebral cortex* to the caudate nucleus and putamen. Experimental animals have included rats, rabbits, cats and monkeys studied by degeneration techniques of Glees, Nauta and by ultrastructural methods (Glees 1944, Whitlock & Nauta 1956, Webster 1965, Carman et al 1963, Carman et al 1965, Kemp & Powell 1970). Jones et al (1977), by retrograde horseradish peroxidase technique, have shown that corticostriate projection in monkeys is from smaller pyramidal cells of lamina V, scattered sparsely but widely in sensorimotor areas and elsewhere in the frontal and parietal regions, in the case of *ipsilateral* fibres, but only in areas 4, 6, and 8 for contralateral projection. Yeterian & Hoesen (1978), by autoradiographic techniques also in monkeys, obtained different results; following intracortical injection of tritiated leucine or proline, they revealed an interesting phenomenon: that areas with marked strong reciprocal corticocortical connections both projected to common sites in the caudate nucelus. Each part of the cerebral cortex projects to a specific site in the caudate–putamen complex, though some overlap occurs. Most projections are from the ipsilateral cortex alone but some striatal sites receive projections from restricted regions of sensorimotor cortices in *both* hemispheres. Since details in these different mammals vary, they will not be further detailed; obviously they cannot simply be extrapolated to the human brain but similar connections probably exist. The most abundant projections are from the sensorimotor cortex, the least from the visual cortex. Corticofugal fibres reach the striatum through both internal and external capsules and from the temporal lobe by sublenticular routes; some direct and crossed corticocaudate fibres run in the *subcallosal fasciculus* with the fronto-occipital arcuate bundle. It is not clear what proportion of corticostriate fibres has the principal terminations in these nuclei, or whether substantial numbers are collateral branches of other corticofugal projections, e.g. the corticospinal tract. Corticostriate fibres form type I synapses with dendrites and somata of striatal neurons and are probably excitatory.

Thalamostriate fibres form another abundant projection to the striatum, derived from the nucleus centromedianus, other intralaminar and midline nuclei and the nucleus medialis dorsalis, some passing directly to end in the caudate nucleus; others traverse the caudate or skirt it, to the internal capsule, passing between its fibres to the putamen. The details of these connections are not all certain. The nucleus centromedianus is said to

7.193 Horizontal computed tomogram through the head at the level of the orbits and middle ears. (Kindly supplied by Dr Shaun Gallagher, Guy's Hospital; photography by Miss Sarah Smith.)

project to many parts of the corpus striatum. Studies in monkeys (Powell & Cowan 1956) showed its projection to be topically organized and confined to the putamen, while others (Mehler 1966) claimed that its projection was to a band including the whole mediolateral extent of both putamen and caudate nucleus. Intralaminar and dorsomedial thalamic nuclei are thought to project largely to the caudate nucleus.



Nigrostriate fibres, long considered by some to provide an important afferent system to the striatum and globus pallidus, have become firmly established and prominent in relation to theories of the genesis of Parkinsonian tremor (Calne 1970). Increasing evidence, from electrophysiology (Purpura et al 1967, Feltz & Mackenzie 1969, Connor 1968), neuroanatomy (Adinolfi & Pappas 1968, Nauta & Mehler 1969) and neuropharmacology (Calne 1970) not only confirmed such a pathway but suggested that its neurons, at least some, utilize *dopamine* as transmitter (via infra).

Nigrostriate fibres from neurons in the partes compacta et reticularis of the substantia nigra ascend through the caudal subthalamus to the internal capsule, where their bundles interlace with capsular fibres producing a comb-like appearance, whence the term *comb bundle*. Some fibres reach the caudate nucleus, the remainder continuing to the putamen and globus pallidus. Carpenter & Peter (1972) have identified degenerating terminals in parts of the caudate nucleus and putamen following lesions of the pars compacta of the substantia nigra in monkeys, describing a topological nigrocaudate correlation. Further afferents may reach the striatum from the subthalamic nucleus and nearby neuronal aggregate.

Amygdalostriate fibres were demonstrated to be rich in the rat (Kelley et al 1982) and a 'limbic'/'non-limbic' mosaic division of the neostriatum was mooted (Gerfen 1984). Nieuwenhuys (1986) pointed out that the 'limbic' part of the neostriatum contained at least 17 varieties of neuromediator and included it in his paracrine core of the neuraxis (p. 1039).

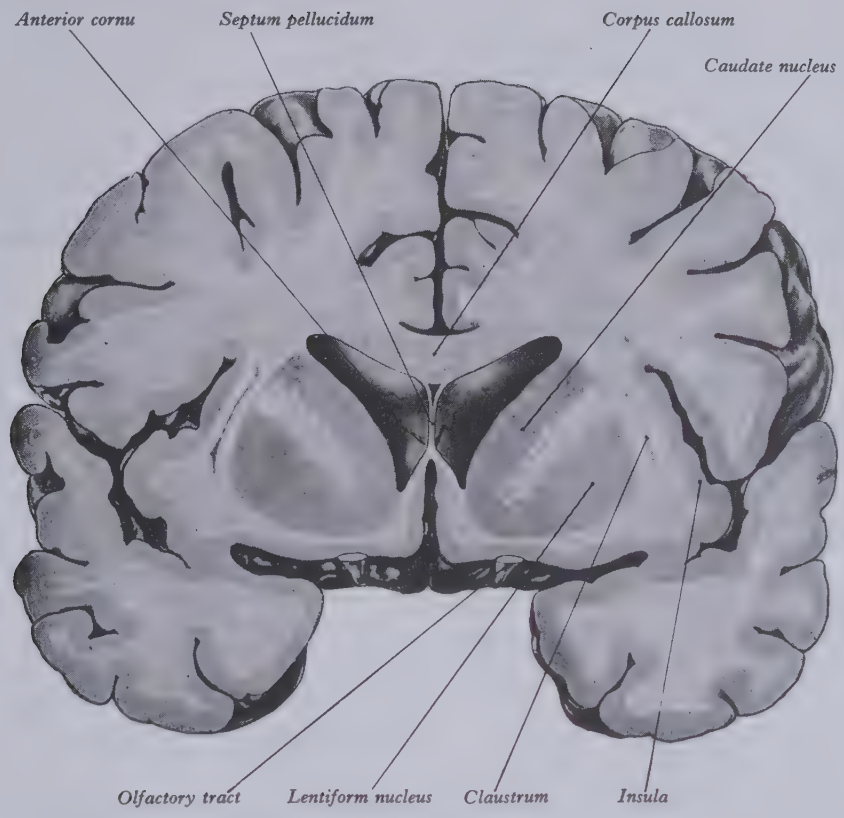
Striatofugal connections are mainly to the *globus pallidus* but *striatonigral* and *striatothalamic* fibres have been described, retracing the pathways just detailed to reach the substantia nigra and thalamus. Both caudate nucleus and putamen project in a topical manner to neurons of the globus pallidus. The lateral putamen projects only to the external pallidal segment, its more medial part and the caudate nucleus projecting either to both pallidal segments or to the internal alone. Other striatofugal connections have been described, including projections to the subthalamic nucleus and restricted parts of the inferior olivary nucleus; but these are uncertain.

Afferent connections to the globus pallidus are principally topically organized *striatopallidal fibres* from the putamen and caudate nucleus, as noted. Other afferents arrive from the subthalamic nucleus, substantia nigra, thalamus and cerebral cortex. Subthalamic fibres reach mainly pallidum I in the *subthalamic fasciculus* (p. 1007). *Nigropallidal fibres* have been described as part of the comb bundle mentioned above; the neurons forming

7.194 Diagram of the main components of the internal capsule. Descending motor fibres are shown in yellow, corticofugal fibres to the thalamus and pons, etc. in red and ascending fibres in blue. From Strong & Elwyn's *Human Neuroanatomy* and Kretschmann (1988). However, see also in text references concerning alternative views about the position of the corticospinal and other fibres.

this tract are dopaminergic. Whether nigrostriate or nigropallidal fibres predominate in *human* brains is uncertain. In addition to the extensive corticostriate projection mentioned above, fibres are said to accompany these from many cortical areas, but ending in the globus pallidus. *Thalamopallidal fibres* may also arrive from intralaminar, centromedian and dorsomedial thalamic nuclei. These somewhat variable results have been obtained by examination of several species, sometimes using different methods, and details or even the existence of some connections in human brains requires confirmation.

The pallidofugal system is by far the quantitatively largest outflow; its fibres are thick, well myelinated and form a complex group of paths, the main ones being: (1) *ansa lenticularis*, (2) *fasciculus lenticularis*, (3) *fasciculus thalamicus*, (4) *fasciculus subthalamicus*, and (5) *descending fibres*. These were described and illustrated (7.130) with the subthalamus (p. 1005). Main destinations are: (1) the *thalamus*, mainly the *nucleus ventralis anterior*, with smaller contributions to the nuclei ventralis intermedius and centromedianus; (2) the *subthalamic nucleus* and other subthalamic centres, including the zona incerta, entopeduncular nucleus and nucleus of the prerubral field; (3) the *substantia nigra*; (4) the *red nucleus*; (5) the *midbrain reticular formation*; (6) the *inferior olivary nucleus*. Illustration 7.197 summarizes some of the main connections of the basal nuclei based on an analysis by Webster (1975).



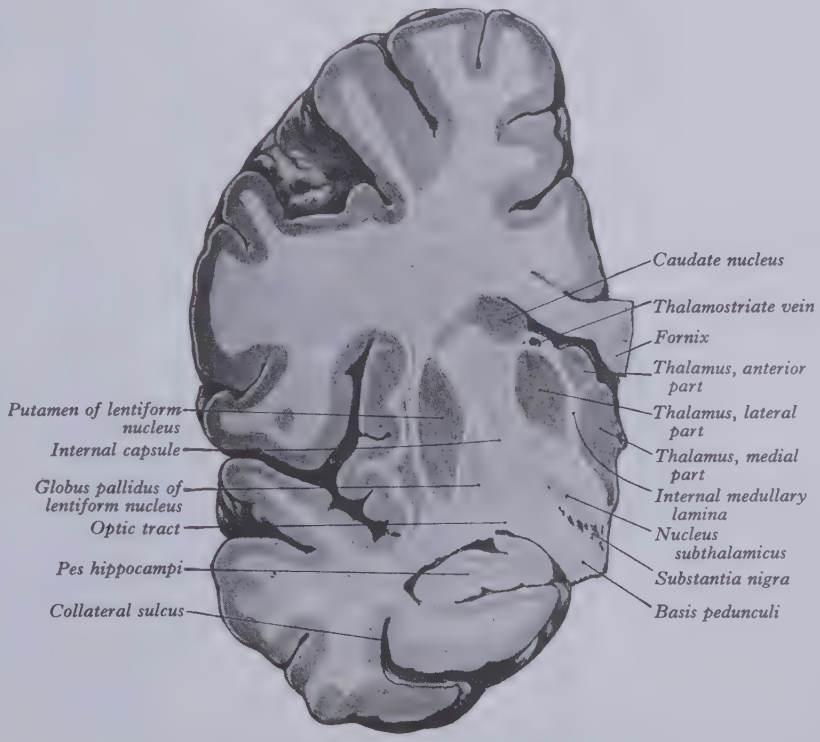
The following points need emphasis. The external pallidal segment projects to the internal, where most pallidofugal fibres start. Afferents to the subthalamic nucleus, however, arise mainly in the external segment. A *pallidohypothalamic tract* has long appeared in accounts of the corpus striatum; studies using newer degeneration techniques yield no evidence of such a connection. The tract so-designated pursues an aberrant course around the column of the fornix, most fibres, however, rejoining the main pallidal outflow.

SUMMARY AND FUNCTIONAL STUDIES

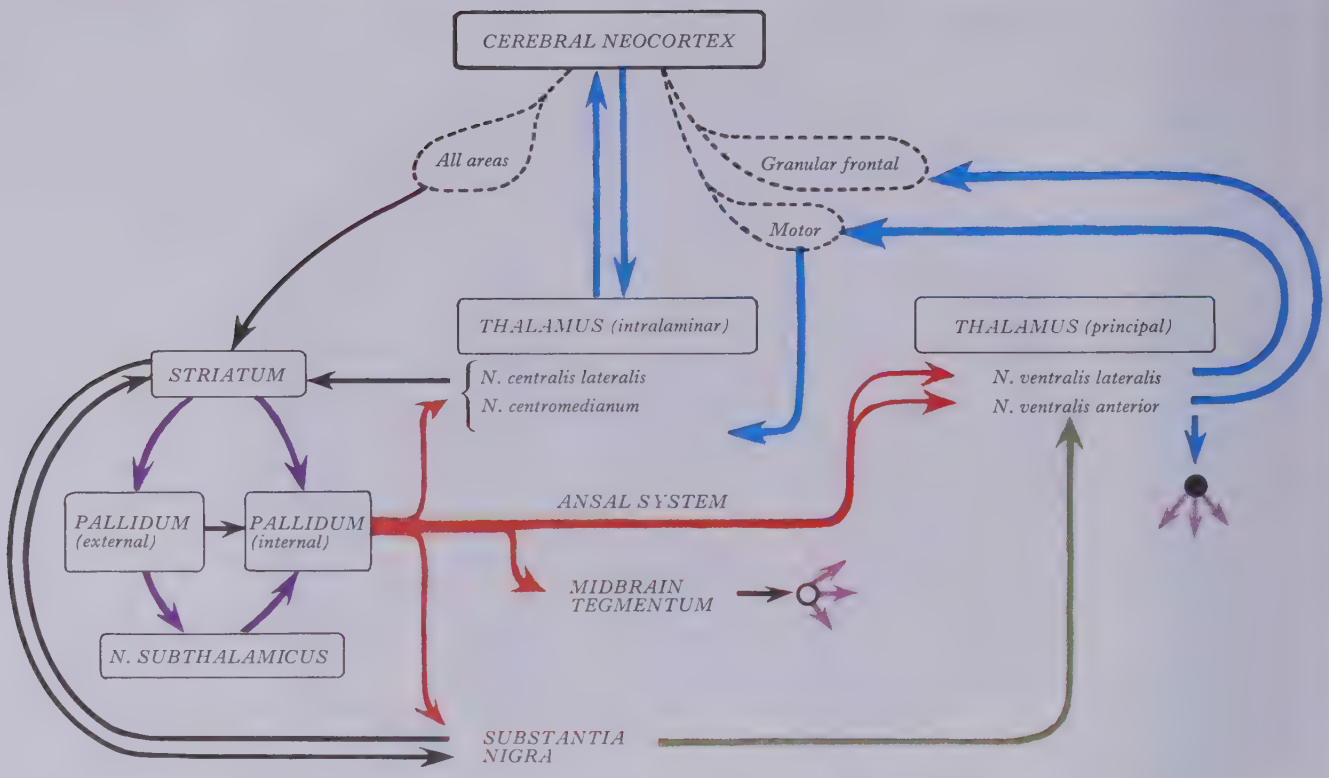
The corpus striatum and associated regions have exceedingly complex interconnections but the details and our understanding of their functions remain elementary. Broadly, information *converges* to the corpus striatum from most of the cerebral cortex, thalamus, subthalamus and some brain-stem centres. 'Processed' information then *diverges* to the thalamus, subthalamus and various brain-stem centres (vide supra).

The main striatal outflow, as part of the 'extrapyramidal motor system', was long considered to *descend* through various polysynaptic paths to the lower motor centres. While reticulospinal and rubrospinal tracts undoubtedly carry information partly from the corpus striatum, it is clear that the major striatal outflow is to the thalamic *nucleus ventralis anterior* (p. 1003) where, after integration with other channels, *ascending* paths radiate to the *motor and premotor cortex* (areas 4 and 6). Large reciprocal connections with the *subthalamic nucleus* and *substantia nigra* also exist.

Many organic nervous diseases have long been known to affect, variably, different parts of the corpus striatum, their associated nuclei and tracts. These exhibit, in different forms and combinations, the following elements: (1) *disturbances of muscle 'tone'*, i.e. resistance to stretch, which is sometimes reduced; more commonly *rigidity* is present; (2) *loss of automatic associated movements* such as arm-swinging, facial expressions, etc.; (3) *unwanted movements*, uncontrollable and purposeless, which may be *choreiform*, *athetoid* or *ballistic* (p. 1006), or *tremor* due to alternating contractions of opposing muscles; tremor is usually 'static', i.e. when the limb is at rest, but occasionally *intention tremor* occurs, as in some forms of cerebellar dysfunction (p. 978). Attempts to link various combinations with disease in specific locations have had limited success and experimentation has been largely uninformative.



7.195 Posterior aspect of a coronal section through the anterior cornua of the lateral ventricles.

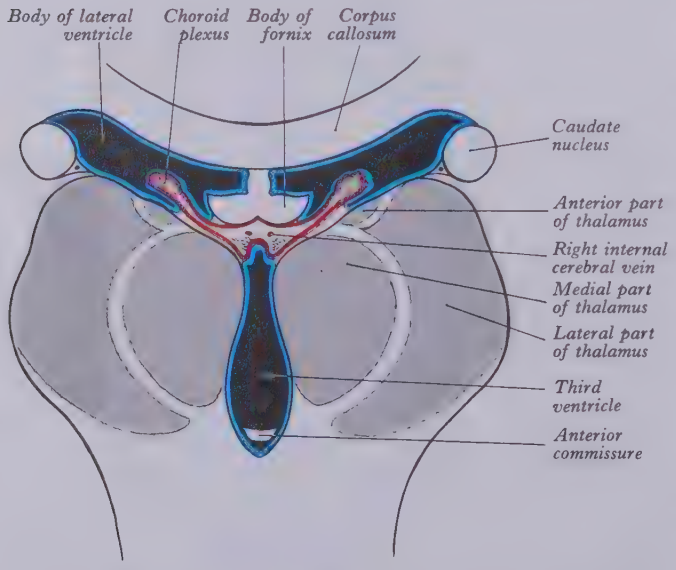


Removal of the putamen, caudate nucleus or globus pallidus often causes little obvious motor change, provided the lesions do not affect adjacent structures. Complete bilateral ablation of the globus pallidus in monkeys, however, results in poverty of movement and reduction in manipulative skills.

Rapid stimulation of the caudate nucleus in unanaesthetized animals sometimes elicits movements of the head and limbs, with some indications of a somatotopic nuclear pattern. Low-frequency or chemical stimulation at different sites in the corpus striatum usually inhibits motor responses; it may induce long periods of immobility, inhibition of cortically induced movements and 'arrest reactions' in unanaesthetized animals. Confirmation has been obtained by 'unit' recording from the motor cortex and ventrolateral thalamus: inhibition of unit activity followed caudate stimulation. Inhibition of the responses established by learning processes follows caudate nuclear stimulation.

Surgical ablation of the globus pallidus or ventrolateral thalamus has been performed, often with some success, to diminish contralateral rigidity and tremor. Thalamic ablations seem more effective in the relief of tremor, while pallidal lesions have greater effect in reducing rigidity. In addition to their therapeutic value, such manoeuvres provide material for examination and also allow electro-physiological recording. Most interesting has been the identification of neurons in the ventrolateral thalamus in cases of Parkinsonian tremor, which display rhythmical discharge of impulses, their frequency corresponding to the tremor (Guiot et al 1962, Guiot et al 1964, Jasper 1966, Bates 1969). Similar phenomena have been induced by placing brainstem lesions in monkeys. Intensive study, anatomical, physiological, behavioural and pharmacological, was and is in progress attempting to discover a causal mechanism for this rhythmic neuronal discharge. The demonstration of an *inhibitory dopaminergic nigrostriate pathway*, probably involved in some cases of Parkinsonian tremor (Calne 1970), was highly interesting. Of the various mechanisms initially proposed, it was considered most likely that normal striatal function depends on a balance between the inhibitory afferents just mentioned and cholinergic excitatory afferents. Reduced activity in the inhibitory path leads to excessive excitatory output from the pallidum, leading to oscillating bursts of activity in ventrolateral thalamic neurons which, through their cortical radiations, may generate rhythmical activity in various corticofugal tracts to the lower motor centres. This implied earlier

7.196 Anterior aspect of a coronal section through the right cerebral hemisphere.



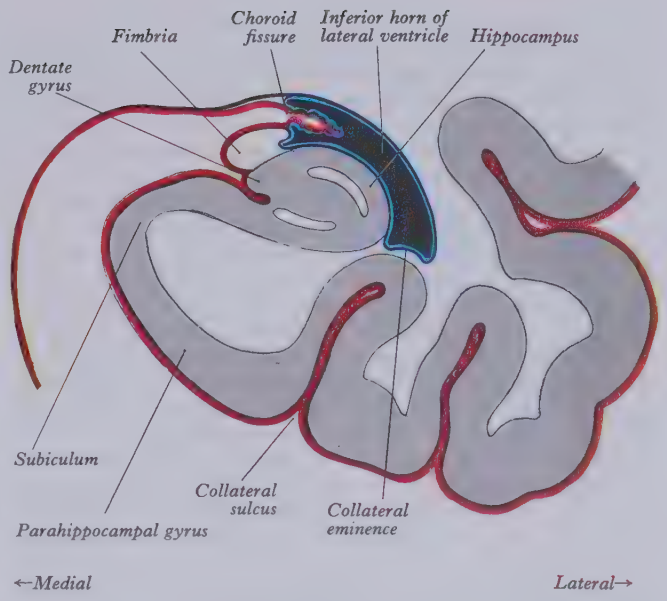
7.197 A scheme of the principal connections of the basal nuclei. At the points indicated the dorsal thalamic nucleus ventralis anterior projects on to several subcortical regions including the thalamic nucleus ventralis lateralis. The midbrain tegmentum probably establishes polysynaptic relationships with the spinal cord grey matter and the thalamic intralaminar nuclei. Colour has been used to assist visualization of the individual pathways. See text for further comment. Based on data summarized by K Webster (1975) of the Dept. of Anatomy, King's College, University of London, by permission of the author.

that dopamine is a normal striatal neurotransmitter. A body of evidence shows that dopamine levels in the striatum are reduced in many cases of Parkinsonism, paralleled by the encouraging clinical responses to replacement therapy in many patients given L-dopa, a precursor of dopamine. The foregoing account is now outdated, but retained for historical reasons. See Nieuwenhuys (1985) for bibliography and review of the complex chemical architecture of the neostriatum (17 neuromediators).

Despite this rapid progress in clinicopharmacological matters, the striatal role in normal behaviour remains conjectural, except for the established view that the corpus callosum is involved in motor control, with emphasis displaced from a descending path to cortical control by the striatum. (For a review of the structure and function of basal nuclei and an extensive bibliography consult Webster 1975.)

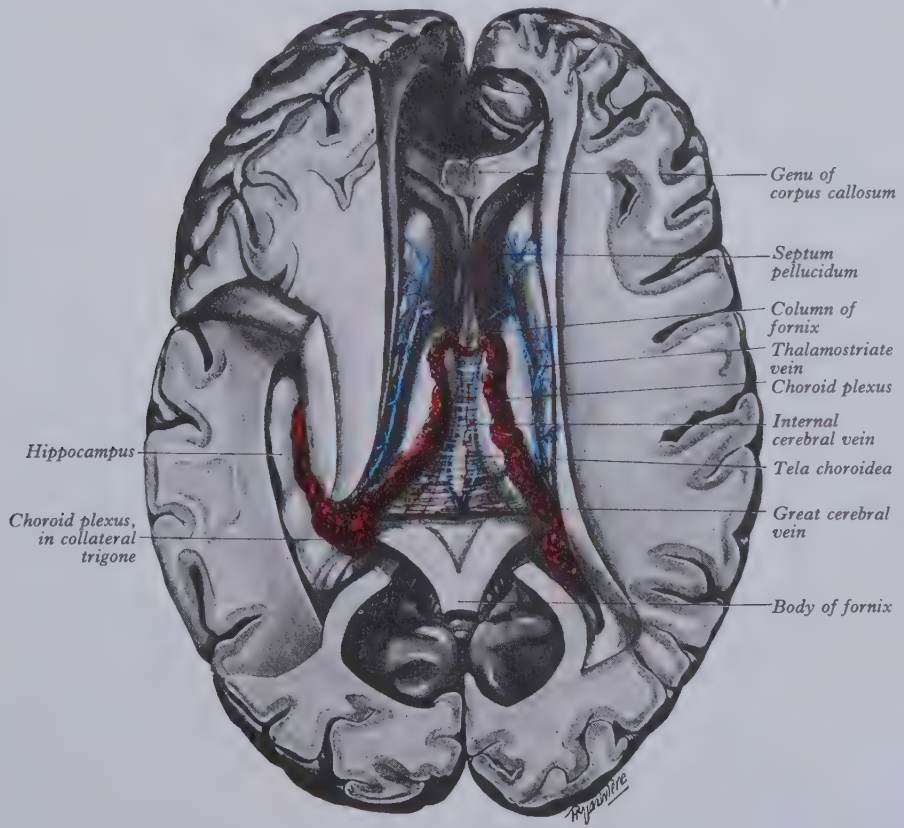
The claustrum is a thin sheet of grey matter co-extensive with the insula and putamen, from which it is separated by the external capsule. Thickest below and in front, it becomes continuous here with the anterior perforated substance, amygdala, and prepiriform cortex. It is regarded by some as belonging to the corpus striatum, by others as a detached part of the insular cortex; but detailed studies suggest that it may have at least two structurally and functionally distinct zones, the '*insular*' *claustrum* and the '*temporal*' or '*prepiriform*' *claustrum*. In experimental animals the insular part has been shown to have reciprocal, topically organized *corticoclaustral* and *claustrocortical* connections with many regions of the neocortex. Its connections and functional significance are unknown in the human brain.

The external capsule, a thin layer of white matter interposed between the lentiform nucleus and claustrum, derives its fibres from the insula's frontoparietal operculum; crossing lateral to the lentiform nucleus, these turn medially below it and the ansa lenticularis. Their subthalamic connections are uncertain. Some fibres of the anterior commissure are believed to traverse the external capsule.



7.198 Diagram of a coronal section through the lateral and third ventricles. The pia mater of the tela choroidea is shown in red and the ependyma in blue.

The Choroid Plexus of the Lateral Ventricle

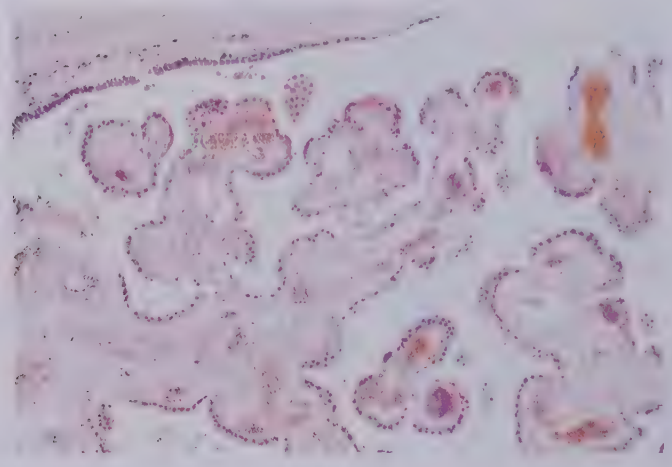


Projecting into the lateral ventricle at its medial side is a highly vascularized fringe of pia mater and ependyma (7.198, 199, 200), the choroid plexus of the lateral ventricle, part of a larger structure, the *tela choroidea*, described below. Its pial basis is invaginated during development (p. 189) along a linear region of the medial hemispheric wall where no nervous tissue develops; hence the pia directly contacts the ventricular *ependyma*, the two tissues

being fused to form the choroid plexus, which otherwise consists chiefly of small blood vessels, capillaries and nerve fibres. It extends anteriorly to the interventricular foramen, where it is continuous across the third ventricle with the plexus of the opposite ventricle. From the foramen it passes posteriorly in contact with the thalamus (7.144) curving round its posterior end into the ventricle's inferior cornu and reaching the pes hippocampi (7.185). When the plexus is torn away from its hemisphere, the line of invagination becomes the *choroid fissure*. Through the central part of the ventricle the fissure is between the fornix superiorly and the thalamus inferiorly (7.198) and in the inferior cornu between the stria terminalis above and the fimbria below (7.199). The fissure is the first groove to appear on the surface of the cerebrum (p. 189); in coronal sections of the brain at eight weeks the choroid fissure is already in contact with the lateral margin of the ependymal roof of the third ventricle and its overlying vascular pia mater. At this stage, before development of the commissures and expansion of the lamina terminalis, one pial layer extends over the third ventricle. The corpus callosum and body of the fornix expand posteriorly above the choroid fissure, carrying a layer of pia on their inferior surface, which overlies the third ventricular pial layer, and fusing with it to form the central part of the tela choroidea; the lateral extensions of this, also double layered, invaginate the choroidal fissures and form choroid plexuses in the lateral ventricles. Posteriorly the two pial layers separate, the inferior (original) layer following the ventricular roof to the pineal gland and tectum, the superior cleaving to the corpus callosum and passing round the splenium to the superior callosal surface.

As described above, two layers of pia mater fuse to form the *tela choroidea of the third ventricle* (as usually termed, though the choroid plexuses of the *lateral* ventricles are extensions of it). From above it is triangular, with a rounded apex between the interventricular foramina, often indented by the anterior columns of the fornix (7.200). Its lateral edges are irregular containing choroid vascular fringes. At the posterior, basal angles of the tela these fringes continue and curve on into the inferior cornua, while centrally the pial layers depart from each other here as already detailed. When the tela choroidea is removed a transverse slit is left between the splenium and the junction of the ventricular roof with the tectum, the *transverse fissure* (not a cerebral fissure in the ordinary sense, for cortex is not involved). It marks the posterior limit of the *extracerebral space* enclosed by the posterior extensions of the corpus callosum above the third ventricle; in this, enclosed between the two layers of pia mater, are the roots of the choroid plexuses of the third ventricle (p. 1019) and of the lateral ventricles.

7.199 Diagram of a coronal section through the inferior cornu of the lateral ventricle. The pia mater is shown in red and the ependyma in blue.



7.200 The tela choroidea of the third ventricle and the choroid plexus of the lateral ventricle.

The microscopic structure of a choroid plexus is essentially as follows. The visible irregular fringes are covered by microscopic *folds* and *villous processes*, each containing afferent and efferent vessels (fine arteries, arterioles, venules and fine veins), and an intervening *capillary plexus*, with supporting connective tissue, and nerve fibres. Villi and folds show varying degrees of complexity (7.201); sections demonstrate the large surface area created, estimated to be at least 200 cm^2 (Voetmann 1949), ignoring the *microvilli* which electron microscopy shows on the ventricular aspects of ependymal cells (Maxwell & Pease 1956). Ependymal microvilli are not as regular in size and distribution as microvilli in some sites, e.g. the small intestine (p. 30), some having bulbous ends and rather more akin to those in the epithelium of the proximal renal tubules; as in these, the basal aspects of the ependymal cells present invaginations, though to a lesser extent (Pappas & Tennyson 1962). Scott et al 1974 have reported a preliminary scanning electron microscopic study of human fetal and infant choroid plexus, largely confirming the above remarks. These appearances with an absence of secretory granules, unspecialized Golgi apparatus and other features, suggest water transport rather than secretion. However, physiological studies (Davson 1970) show that the cerebrospinal fluid, largely produced by the choroid plexuses, is not a mere filtrate. Ultrastructural studies have shown that some ependymal cells have *cilia*, tight junctions and a distinct *basement membrane* separating them from the adjacent capillaries (Wislocki & Ladman 1958), the latter being sometimes fenestrated. Experiments (Brightman & Reese 1969) with protein peroxidase as a tracer showed that, while capillary endothelium was readily permeable to the tracer, its passage was blocked by tight junctions between the choroidal ependymal cells. All these findings are related to the concept of a *blood–brain barrier* (pp. 895, 1092). (For further comments on the structure and possible functional roles of general ependymal cells and specialized varieties, e.g., tanycytes, cells clothing circumventricular organs, choroid plexuses and more recent reviews see p. 894, 1005, 1453.)

The *stroma* of choroidal villi, derived from the pia mater of the tela choroidea, consists of pial fibroblasts but few, if any, collagen fibres. The cells are much flattened and do not form complete sheets between the ependyma and capillary endothelium. Nerve fibres appear to be absent from villi but in their larger stems the connective tissue is greater and myelinated and non-myelinated nerve fibres have been identified (Clark 1934, Cooper 1958); their functional significance is uncertain but the non-myelinated fibres are considered vasomotor postganglionic sympathetic elements; others may be from the vagus and glossopharyngeal nerves. Few studies of the nerves of choroid plexuses have been reported. However, histochemical studies (Lindvall et al 1977) have revealed cholinergic nerve fibres in association with the vessels and epithelium of all choroid plexuses in various mammals, including baboons.

The *blood supply* of choroid plexuses in the tela choroidea is from the anterior choroidal branch of the internal carotid and choroidal branches of the posterior cerebral artery (pp. 748, 754), the former usually a single vessel, the latter three to five in number (Millen & Woollam 1953). The two sets anastomose to some extent. Capillaries drain into a rich venous plexus, served by a single choroidal vein leaving the tela choroidea, commencing near each basal (posterolateral) angle of the tela. This region corresponds to the frontier between territories of anterior and posterior choroidal arteries and here also (on each side) a solitary so-called 'glomus' (p. 693) is situated, near the free edge of the choroid plexus; many tributaries of the choroidal vein converge towards it; nothing appears to be known regarding its significance in the plexus.

7.201 A section of part of the choroid plexus of the lateral ventricle, stained with haematoxylin and eosin. Note the ependyma lining the ventricular wall above and covering the loose connective tissue cores of the processes of the plexus, which contain numerous small blood vessels, including many capillaries. A calcareous deposit (dark blue) is present in one process. Owing to the complexity of the ramification of the processes, several appear as disconnected islands of tissue.

Cerebral Dimensions

The human brain has often been weighed and measured and compared in volume, weight, relation to total body weight and proportionate size of its main divisions with those in brains of many other vertebrates. Even without quantification, comparisons permit some generalizations regarding the relation between brain size and various abilities in mankind and other animals. But even metrical data, where available and reliable, are merely estimates of the bulk of nervous tissue, taking little account of the degrees of organization or even proportions of particular elements, such as nerve cells, nerve fibres, neuroglia and vascular tissue. Such details must obviously be considered if valid comparisons are to be made. Hence, no more than crude deductions are to be expected from data of this kind. The available measurements are usually dependent on small series in any particular species, even sometimes upon a single example. Hence allowance for individual variation can scarcely be made, whether due to sex, age or nutritional state, or indeed any factors which may influence brain size or its relation to body size and weight; and it is particularly this ratio which is the focus of most attention. Even in respect of mankind, for whom much more adequate observations are recorded, the effects of such factors are often overlooked.

An 'average' human male adult's brain is said to weigh about 1450 g and that of his female counterpart about 100 g less; but such figures are not useful without the corresponding ranges: of the order of 1240–1680 in males and 1130–1510 in females. Proportionately males and females differ less in brain weight than in total body weight. Even the ranges quoted would exclude numbers of famous people whose brain weights were outside such extremes, in both directions! (Consult Blinkov & Glezer 1968, for examples and much other data.) Different ranges for races have been stated but the differences between their means are not generally significant, when the much greater variation in body weight is taken into consideration. Chrzanowska et al (1973, 1975), in a study of 1670 human brains (896 male and 774 female, ranging from 20 to 89 years in age), found the average difference between the sexes to be 130–150 g, stating that brain weight is positively correlated with height and recording progressive diminution in brain weight, in both sexes, from 30 to 40 years onwards. They computed a loss in weight of one-ninth in brains of both sexes by the ninetieth year.

Before maturity, human brains vary markedly in weight and ratio to total body weight (Purpura & Schade 1964), showing throughout growth, however, the relatively outstanding development which characterizes adults. Unlike other mammals, such as rodents, in which maximal growth rate may be pre- or postnatal, the cerebral growth spurt in mankind and primates in general is *perinatal*, in late fetal development and the first extra-uterine year, during which the brain at least doubles in weight (Dogson 1962), reaching about 90% of its final weight by the sixth year. Most of this increase is due to myelination rather than any increase in nerve cells; for this reason alone comparison of growing human brains, on the basis of weight, with the brains of adults

or of other species, is pointless where correlation with ability is the criterion.

The human brain is obviously large, absolutely and relatively, but surpassed in both respects by those of other mammals. Dolphins, elephants (4000–5000 g) and whales (6800 g is recorded for the blue whale, *Balaenoptera musculus*) have heavier brains but this is offset by brain:body weight ratios of about 1:600 in elephants and about 1:850 in large whales. However, in dolphins the ratio is approximately 1:40, somewhat 'better' than the human average of about 1:50. In some small mammals, such as mice, the ratio may be as low as 1:35, while in smaller primates ratios of 1:12 have been estimated (squirrel monkey). Among primates man occupies an almost average position in brain:body weight ratio, only the larger apes and monkeys falling much below him in this detail. In absolute size of brain, of course, he much surpasses any other primate; a male gorilla (Schultze 1969) may have a cranial capacity of 412–752 cm^3, well below the human range (1200–1500 cm^3). The largest gorilloid brain recorded weighed 750 g (Holloway 1968), distinctly less than the human range. Extremely small brain weights are recorded in microcephalic idiots; but what is more significant is that brain weights in dwarfs which were *below* the average upper limit for gorillas were nevertheless recorded in humans possessing at least elementary speech; and symbolic abstractions of language are often correlated with a large absolute size of the human cerebrum. This view has been questioned (Lenneberg 1964); while a certain, as yet indefinable, minimal size of brain might be associated with the extraordinary potentialities of mankind in cerebration, it is clear that the data so far noted scarcely illuminate this problem.

As said above, measurements of brain size and brain-to-body weight ratio afford no indication of cerebral organization; nor do they allow for the density of packing or total numbers of nerve cells in any particular brain. While it is said that this density does not vary greatly in mammalian brains when calculated for the whole organ, estimates of this kind were, until quite recently, comparatively few and much subject to error. The figures for samples of the cerebral cortex are subject to similar strictures; it is of interest to note here that a cubic millimetre has been estimated to contain 142 000 cells in mice, 21 500 in macaques and merely 10 500 in mankind. But the area of the human cerebral cortex (p. 1043) is at least twelve times greater than that of macaques, which may nevertheless have a brain-to-body weight ratio similar to man's. However, two separate quantitative investigations are importantly related to these findings; firstly concerning neocortical *surface area* and secondly the distribution of neuronal populations in cortices of different *thickness*. As noted elsewhere (p. 1043) surface area estimates have been surprisingly few, some earlier figures roughly corresponding but a pilot study (employing elementary cartography on published plates in an atlas) resulted in a much higher figure (almost four times greater). Clearly, with these gross differences in such an obvious parameter as surface area, much more extensive investigation with improved techniques is urgently required. The figures for neurons per cubic millimetre of cortex in different species are interesting but become powerfully illuminated when the *total number* of neurons in a column of standard pial surface area and extending through the *full thickness of the* cortex are compared. With the exception of visual area 17, *all other areas*, irrespective of cortical thickness and species of mammal, have virtually identical neuronal numbers (about 66% pyramidal and 33% stellate). Area 17 has a population about 2·5 times greater. In these numerical respects their cortices are uniform or homogeneous, see Rockel et al (1980), Powell (1981), Powell & Hendrickson (1981), and p. 1043.

Another approach to the problems of comparison of mammalian and especially primate brains (Tilney & Riley 1928) is to estimate the weights of the main divisions such as the cerebrum, cerebellum, midbrain, medulla oblongata, olfactory bulb, neocortex, paleocortex, archicortex, corpus striatum and other features, expressing some of these quantities as indices. (As an example of a more recent such study consult Stephan et al 1970.) Large numbers of species of insectivores and primates have been thus compared; though in many species only one sample has been measured, interesting comparisons are possible. It is easy to appreciate, without metrical data, that in the human brain olfactory structures are small, absolutely and relatively, that the cerebrum-pons-cerebellum complex is markedly developed or that the human cerebral cortex is very extensive; but quantitative assessment is much more valuable. In comparing man and gorilla, e.g. ratio by weight of their medullae oblongatae is approximately 9:6:7, though the gorilla weighs at least twice as much as the man. The ratios for the mesencephalon, cerebellum and diencephalon are roughly 2:1, but the human telencephalon is three times as heavy as the gorilloid. The gorilla's olfactory bulb is almost three times the size of man's, while the latter's hippocampus is nearly two and a half times as heavy as the gorilla's. Incidentally the ratio of olfactory bulb to hippocampus in the gorilla is hence about 1:15 and in man 1:90, an interesting commentary on the status of the hippocampus as part of the 'rhinencephalon' (p. 1029). Legait et al (1973) have made some volumetric comparisons of the hypothalamus and hypophysis relative to the total brain volume in a large series of mammals (principally rodents). They observed a constant brain:hypothalamic ratio but some variation between the comparative volumes of hypothalamus and hypophysis, particularly for the anterior lobe of the latter (adenohypophysis).

Space does not permit further exploration of such data and it must be said that, although such considerations may have marked significance in evolutionary comparisons between man and other mammals (particularly sub-human primates) they do not provide any clear definition of what is responsible in man's brain for his enormous complexity of behaviour. Perhaps it is rather in this and his consequently ever more complex culture, that the essence of humanity can best be defined. It is noteworthy that in assessing the human paleontological record the accent has gradually passed from comparison of cranial capacities to that of cultures. The Australopithecinae, with brains little if at all larger than those of gorillas, may leave us in doubt; but in *Homo habilis*, with, it is true, a larger but still very modest cranial capacity, doubts evaporate as to his humanity and perhaps most of all because of his ability, as revealed in surviving artefacts. In more recent ancestors also and again not merely because of increasing *hominoid* brain size (in which *Homo neanderthalensis* even surpassed us, yet is now extinct) but even more because of the increasing evidence of their *human* culture are we convinced of a close relationship to ourselves. Their abilities, which from such simple beginnings have led to the great achievement and communication of practical and abstract creation in our own era, are no more likely than our own to be explicable in terms of gross cerebral mensuration. (For discussions of the significance of brain size consult Tobias 1970, 1971, Jerison 1970, Van Valen 1974.)

Blood Vessels of the Brain

The arterial supply of the brain (pp. 743, 750) is derived from the **internal carotid** and **vertebral arteries** which lie in the subarachnoid space (p. 1089). The vertebral and basilar arteries give branches to the spinal cord, brain stem and cerebellum, the basilar artery ending at the upper border of the pons by dividing into two posterior cerebral arteries. The internal carotid artery divides at its end into **anterior** and **middle cerebral arteries**; the anterior are interconnected by the **anterior communicating artery**. Just before its end the internal carotid artery connects via the **posterior communicating artery** with the **posterior cerebral artery**, completing a vascular circle, the **circulus arteriosus**, around the interpeduncular fossa (**6**.84). The dimensions of vessels forming the circulus arteriosus (circle of Willis) were studied in 100 fixed brains from cadavers by Kamath (1981). The greatest variation in length was found in the anterior communicating artery and in diameter in the posterior communicating artery. Abnormal narrowing of vessels was commoner on

the right than on the left, the posterior cerebral artery being particularly affected. In keeping with the dominance of the left hemisphere, it was found that this appeared to have the better blood supply, all arteries except the posterior communicating being of larger mean diameter on the left. It should be appreciated that although the circulus arteriosus offers a potential shunt in abnormal conditions, such as during an occlusion or spasm, in normal circumstances it is not an equalizer and distributor of blood from different sources. For details of collateral circulation following blockage of the main feeders of this circle, see Fields et al (1965) and Gillilan (1974). From the circulus arteriosus, or vessels near it, **central branches** arise to supply the interior of the cerebral hemisphere and the thalamus. These vessels form six principal groups: (1) *the anteromedial group*, from the anterior cerebral and anterior communicating arteries (p. 747); (2) *the posteromedial group*, from the posterior cerebral and posterior communicating arteries; (3 and 4) the right and left *anterolateral groups*, from the middle cerebral arteries; (5 and 6) right and left *posterolateral groups*, from the posterior cerebral arteries. (For details consult Kaplan & Ford 1966.) Lang & Brunher (1978) have described a recurrent central ramus, often double, arising from the anterior cerebral artery beyond the origin of its anteromedial group of central rami and returning to join these; they name this vessel *arteria recurrens anterior*.

The entire blood supply of the **cerebral cortex**, described in detail by Duvernoy et al (1981), comes from **cortical branches** of the anterior, middle and posterior cerebral arteries, which reach the cortex in the pia mater. They divide in its substance, have branches penetrating the cortex perpendicularly and are divisible into long and short rami (Von Bonin 1950). The **long** and **medullary arteries** traverse the cortex and penetrate the subjacent white matter for 3 or 4 cm (Lewis 1957) without communicating and thus form many small independent systems. **Deep medullary vessels** extending from central branches to the cortex have been described but these are recurrent branches of the long or medullary vessels (Lewis 1957). The **short arteries** are confined to the cortex, forming with the long vessels a compact network in the middle zone of the grey matter, the outer and inner zones being sparingly supplied. Lazorthes et al (1968) and de Reuck (1972) have described the differences in angio-architecture in iso- and allocortical areas, the former being more elaborate with arterioles ending in different strata. Vessels of the cortex are not so strictly 'terminal' as those in the white matter or central system (Sunderland 1938) but, although adjacent vessels anastomose on the surface of the brain, they become end arteries as soon as they enter it. Even superficial anastomoses occur in general only between microscopic branches of the cerebral arteries; there is little evidence that they can provide a vicarious circulation after the occlusion of larger vessels. Owing to the cellularity of the grey matter, its blood supply is more copious than that of white.

The *lateral surface* of the hemisphere is mainly supplied by the *middle cerebral artery*; a strip next to the superomedial border as far back as the parieto-occipital sulcus is supplied by the *anterior cerebral artery*; the occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) is supplied by the *posterior cerebral artery* (**6**.82, 83). *Medial* and *inferior surfaces* are supplied by the *anterior*, *middle* and *posterior* cerebral arteries, the area supplied by the anterior extending almost to the parieto-occipital sulcus and including the medial part of the orbital surface. (For detailed distribution of the anterior cerebral artery in 53 hemispheres and 300 angiograms consult Farnarier et al 1977.) The rest of this surface and the temporal pole are supplied by the middle cerebral artery. The remaining medial and inferior surface is supplied by the posterior cerebral artery (**6**.82, 83). The junctional zone near the occipital pole between the territories of the middle and posterior cerebral arteries corresponds to the striate cortex concerned with the macula. The phenomenon known clinically as '*sparing of the macula*' may be due to the collateral circulation of blood from branches of the middle cerebral artery into those of the posterior, when the latter vessel is blocked. The middle cerebral artery may itself supply the macular area (Smith & Richardson 1966).

Most of the *corpus striatum* and *internal capsule* is supplied by the medial and lateral striate rami of the middle cerebral artery's central branches, the rest being supplied by central branches of the anterior cerebral artery. A ramus of the middle cerebral is Charcot's 'artery of cerebral haemorrhage' (p. 748).

The *choroid plexuses* of the *third* and *lateral ventricles* are supplied by branches of the internal carotid and posterior cerebral arteries.

Finer details of the vessels of some parts of the diencephalic region have been well explored, particularly in relation to the hypophysis cerebri and related hypothalamic nuclei (p. 1008, Haymaker et al 1969). Detailed studies of the vascularization of the lamina terminalis (Duvernoy et al 1969) and of the posterior wall of the third ventricle (Plets 1969) have been reported. The arterial supply to the lamina is from the anterior cerebral arteries and their communicating vessel and is described as supplying a superficial pial capillary plexus which drains into a second, deeper plexus of sinusoidal capillaries, with loops or vortices which drain in turn into the hypothalamic veins. The significance of these arrangements is unknown. The main artery to the posterior parts of the third ventricle is the medial branch of the posterior choroidal artery; this supplies the posterior commissure, habenular region, pineal gland and medial parts of the thalamus, including the pulvinar. The *thalamus* is supplied chiefly by branches of the posterior communicating, posterior cerebral and basilar arteries; their pattern of branches and varying details of angio-architecture in the different thalamic nuclei, have been described in extenso in human brains, with a critique of literature by Plets et al (1970) and Percheron (1977). The latter has denied the often noted thalamic supply by the anterior choroidal artery, deriving almost the entire thalamic supply from branches of the posterior cerebral and basilar arteries (p. 748).

The vessels supplying the *brain stem* have been described in detail by Duvernoy (1978). The *midbrain* is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels entering on their medial and lateral sides; the medial vessels enter the medial side of the crus and also supply the superomedial part of the tegmentum, including the oculomotor nucleus, lateral vessels supplying the lateral part of the crus and the tegmentum. The colliculi are supplied by three vessels on each side from the posterior cerebral and superior cerebellar arteries. An additional supply to the crura, the colliculi and their peduncles comes from the posterolateral group of central branches of the posterior cerebral artery.

The *pons* is supplied by the basilar artery and the anterior inferior and superior cerebellar arteries. Direct branches of the basilar enter along the basilar sulcus; branches also enter along the trigeminal, abducent, facial and vestibulocochlear nerves and nervus intermedius. There is also a supply from the pial plexus.

The *medulla oblongata* is supplied by the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries. Some branches enter along the anterior median fissure and the posterior median sulcus. Other vessels enter along radicles of the last four cranial nerves to supply the central substance. There is also a supply via a pial plexus from the same main arteries.

The *cerebellum* is supplied by three pairs of cerebellar arteries which, like the cerebral, form superficial anastomoses. Their internal distribution has not been much explored but anastomoses between deeper, medullary branches, as distinct from cortical, have been postulated (Gomes 1969). The anatomy and development of the cerebellar arteries have been reviewed by Gillilan (1974). According to Kielbasinski (1976) the vermis is supplied by one or both inferior cerebellar arteries. The vascularization of the human cerebellar cortex has been investigated in detail by Duvernoy (1983).

The *choroid plexus of the fourth ventricle* is supplied by the posterior inferior cerebellar arteries.

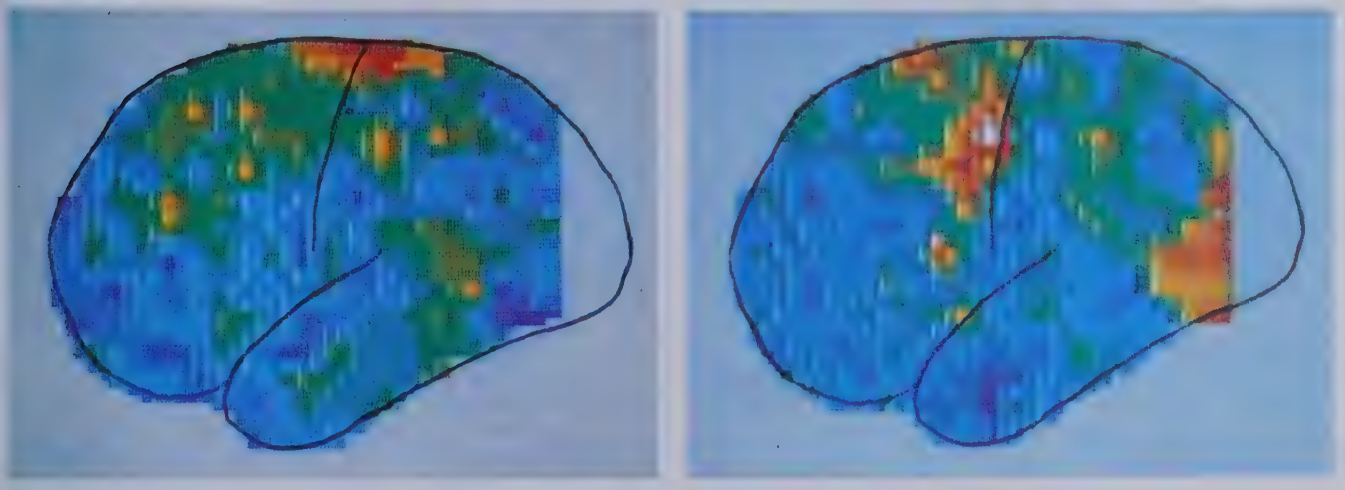
The blood supplies of the optic chiasma, tract and radiation are of marked clinical interest. The chiasma is supplied in part by the anterior cerebral arteries but its median zone depends upon rami from the internal carotids reaching it via the stalk of the hypophysis cerebri. Anterior choroidal and posterior communicating arteries supply the optic tract, while the optic radiation receives blood through deep branches of the middle and posterior cerebral arteries. For further details consult Abbie (1938), Bergland & Ray (1969).

Cerebral Blood Flow and Functional Localization

That the levels of activity, metabolism and blood flow fluctuate in close correspondence has long been known. Though the mechanisms of selective control of blood flow to different regions were then obscure, Schmidt & Hendrix (1937), using thermocouples, demonstrated a marked increase in flow through the visual cortex (in cats), during localized retinal illumination. Subsequent years brought many confirmatory experiments, not only in the visual pathway. In recent years, an increasing range of radio-isotopes and the advent of scanning cameras have stimulated an upsurge of interest in cerebral blood-flow depending upon a new, non-invasive technique, potentially able to localize intracranial pathological states which modify the blood-flow pattern, e.g. neoplasms, post-traumatic loci, intracranial abscess, cerebral infarction and so forth (Maisey 1978). Some observers soon realized the potential of the technique in monitoring fluctuating levels of blood flow (and of functional activity) in different regions of, e.g. the cerebral cortex during a wide range of activities (Lassen et al 1978). An isotope of xenon (xenon 133) dissolved in sterile saline is injected into a carotid artery and the subject's head is scanned (during the arrival and 'washout' of the isotope) by a gamma-ray camera, which carries 254 scintillation detectors each collimated to scan about 1 cm^2 of the cortical surface. Results from this roster of detectors, processed in a digital computer, are displayed on a cathode colour screen. The colour of each *pixel* or square denotes a range of blood flow rate, shown through the subjacent cortex. The mean flow rate is shown in green, down to 20% below the mean are shades of blue, and up to 20% above the mean are through orange to shades of red. Illustration 7.202A,B shows two examples of the results. Already hundreds of apparently normal hemispheres have been scanned during many activities ranging from uncomplicated voluntary movements or the sensory stimulation of various modalities, to complex activities such as reading aloud and problem-solving. Broadly, the functional areas mapped by traditional means have been confirmed. There will doubtless be refinement of this fascinating technique, with advantage to both clinician and researchers into cerebral activities.

The venous drainage of the brain (pp. 798–805) can be divided into veins receiving from the cerebrum and from the cerebellar-brain stem arena. The veins are thin-walled, devoid of valves and most of them cross the subarachnoid space to join the dural venous sinuses.

The veins of the cerebrum are either external or internal. **External cerebral veins** are grouped as three sets: the *superior* draining forwards into the superior sagittal sinus; the *inferior* draining principally into the transverse and cavernous sinuses; and the *middle* which are subdivided into superficial and deep. The *superficial middle cerebral vein* drains most of the lateral surface of the hemisphere, following the lateral sulcus to end in the cavernous sinus. The *deep middle cerebral vein* drains the insular region and joins the *anterior cerebral* and *striate veins* to form a *basal vein*. Regions drained by the anterior cerebral and striate veins correspond approximately to those supplied by the anterior cerebral artery and the central branches entering the anterior perforated substance. These striate veins have been described in detail by Rosa & Borzone (1973). The basal veins pass back alongside the interpeduncular fossa and midbrain, receive tributaries from this vicinity and join the *great cerebral vein*.



The two **internal cerebral veins** are formed near the interventricular foramina by union of the *thalamostriate* and *choroidal veins* draining the choroid plexuses of the third and lateral ventricles. They travel back parallel to one another between the layers of the tela choroidea and unite to form the great cerebral vein, which enters the straight sinus.

The veins of the *midbrain* join the basal or great cerebral veins. *Pontine* veins drain into the basal vein, cerebellar veins, the petrosal sinuses, transverse sinus or the venous plexus of the foramen ovale. Veins of the *medulla oblongata* drain into the veins of the spinal cord, the adjacent dural venous sinuses or along the last four cranial nerves via radicular veins to the inferior petrosal sinus or superior bulb of the jugular vein. For systematic accounts of the superficial veins of the brain stem consult Tournade et al (1972) and Duvernoy (1975).

The **veins of the cerebellum** drain mainly into sinuses adjacent to them or, from the superior surface, to the great cerebral vein.

Nerves

Though the *innervation* of the intercranial arteries (including those supplying the brain) remains obscure, a considerable supply of postganglionic sympathetic fibres accompany the carotid and

7.202 Patterns of presumed relative levels of neuronal activity in different regions of the cerebral cortex as revealed by measurement of regional blood-flow. A. shows the pattern which accompanies movement of the contralateral foot; B. shows a pattern which accompanies activity of the eyes engaged in a pursuit movement. The colour scales indicate the percentage flow rate above or below the mean (dark green). Radioactive xenon scan pictures supplied by N A Lassen, D H Ingvar and E Skinhoj, Bispebjerg Hospital, Copenhagen (see text).

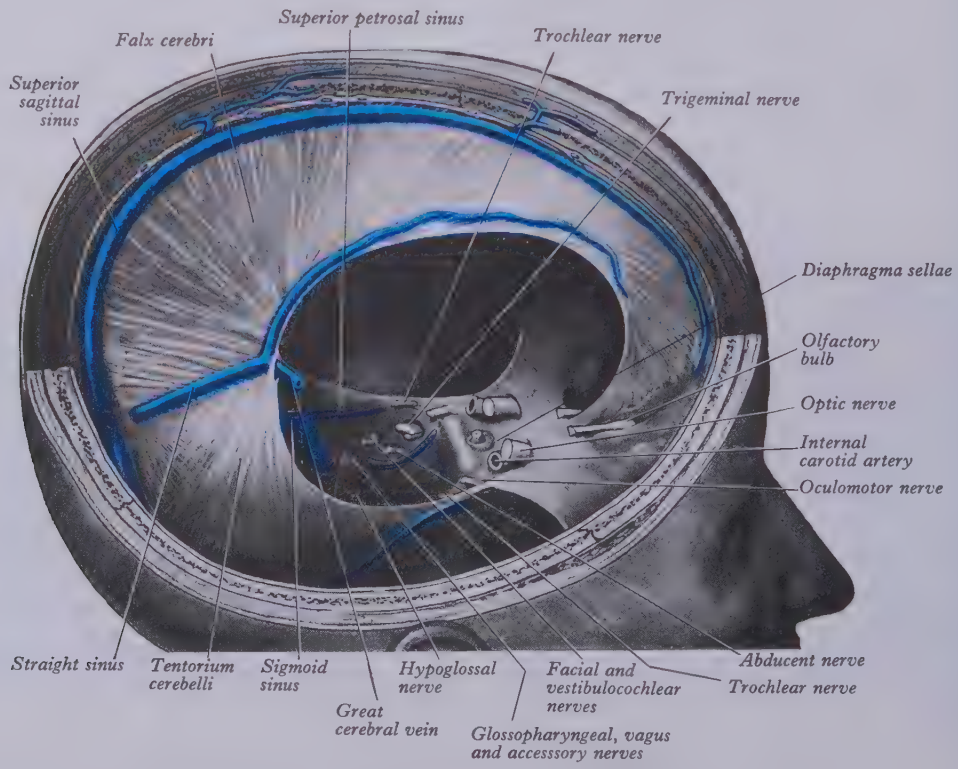
vertebral arterial trees and some myelinated fibres accompany them. A parasympathetic supply is doubtful (Nelson & Rennels 1970, Purves 1972).

There are *no lymphatics* in the central nervous system. The subarachnoid space is prolonged along the olfactory nerves, providing a route between this space and tissue spaces in the nasal mucoperiosteum. The so-called perivascular spaces around cerebral vessels are controversial (p. 1092). Electron microscopy confirms the extension of pial elements around vessels into the brain in various mammals, e.g. rat (Samarasinghe 1965) and cat (Jones 1970). In the latter study the arachnoid 'space' around small arterioles entering the cortex appeared to contain collagen bundles, pial cells and possibly macrophages, but these do not form a complete sheath; in large areas the basal laminae of the brain and vessel are apposed. The 'space' does not extend around the capillaries, where the two basal laminae fuse. These observations indicate that the perivascular spaces are not continuous with the perineuronal spaces.

THE MENINGES

The brain and the spinal cord are enveloped, from without inwards, by three membranes (meninges): the dura mater, the arachnoid mater and the pia mater.

THE DURA MATER



The dura mater, a thick, dense, inelastic membrane, is the most external of the meninges. *Cerebral dura mater*, enclosing the brain, differs in some features from *spinal dura mater*, surrounding the spinal cord and will be described separately. They are continuous with each other at the foramen magnum

The cerebral dura mater lines the cranial cavity. It is said to be composed of two layers, an *inner* or *meningeal* and an *outer* or *endosteal*, but these are united, except where they separate to enclose the venous sinuses draining blood from the brain (p. 799). It adheres to the internal surfaces of the cranial bones, sending blood vessels and fibrous processes into them, adhesion being firmest at the sutures, the cranial base and around the foramen magnum. The vessels and fibrous processes are torn across when the dura mater is detached from the bones, its outer surface then becoming rough and fibrillated; the inner surface is smooth. The endosteal layer is continuous through the cranial sutures and foramina with the pericranium and through the superior orbital fissure with the orbital periosteum. The meningeal layer provides tubular sheaths for the cranial nerves as they traverse the cranial foramina; these sheaths fuse with the epineurium as the nerves emerge from the skull. The sheath of the optic nerve is continuous with the ocular sclera (p. 1181).

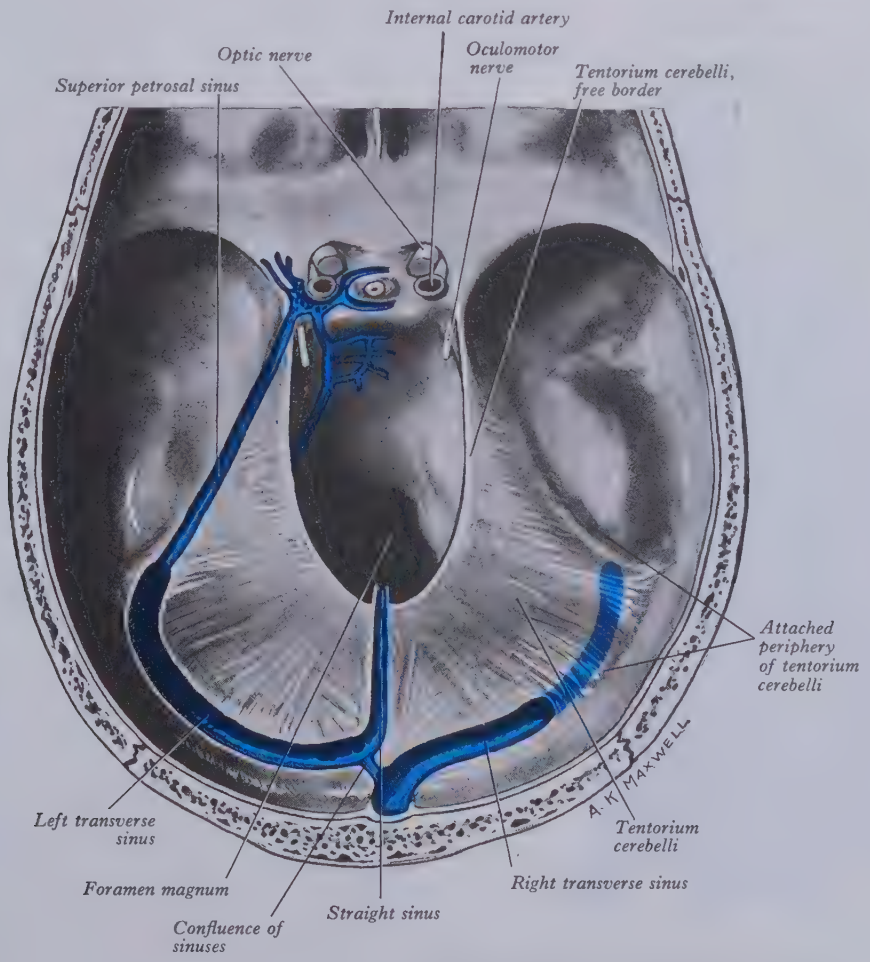
The meningeal layer is folded inwards as four septa that partially divide the cranial cavity into freely communicating spaces in which the subdivisions of the brain are lodged.

(1) *The falx cerebri* (7.203A) is a strong, crescentic, process of dura mater descending vertically in the longitudinal fissure between the cerebral hemispheres. It is narrow in front, where it is fixed to the crista galli, and broad behind, where it blends in the midline with the tentorium cerebelli; the anterior part is thin and frequently perforated by numerous apertures. Its convex upper margin is attached to the internal cranial surface on each side of the median plane, as far back as the internal occipital protuberance; the superior sagittal sinus (p. 800) runs along this margin in a cranial groove, to both banks of which the falx is attached. Its lower edge is free and concave and contains the inferior sagittal sinus. The straight sinus runs along its attachment to the tentorium cerebelli.

(2) *The tentorium cerebelli* (7.203A,B) is a crescentic, 'tented' lamina of dura mater covering the cerebellum and supporting the

7.203A The cerebral dura mater and its reflexions, exposed by the removal of a part of the right half of the skull and brain.

cerebral occipital lobes. Its concave, anterior edge is free and between it and the dorsum sellae of the sphenoid bone is a large *tentorial incisure*, occupied by the midbrain and the anterior part of the superior aspect of the cerebellar vermis. Its convex outer limit is attached: (*a*) posteriorly, to the lips of the transverse sulci of the occipital bone and the postero-inferior angles of the parietal bones, where it contains the transverse sinuses; (*b*) laterally, to the superior borders of the petrous temporal bones, where it encloses the superior petrosal sinuses. Near the apex of the petrous temporal bone, the lower layer of the tentorium is evaginated anterolaterally under the superior petrosal sinus, forming a recess between the endosteal and meningeal layers in the middle cranial fossa. This recess is the *trigeminal cave* containing the trigeminal roots and ganglion (its posterior part being a little more extensive below the ganglion than above it). The evaginated meningeal layer fuses in front with the anterior part of the ganglion. At the apex of the petrous temporal bone the free border and attached periphery of the tentorium cross each other (7.203B); the anterior ends of the free border are fixed to the anterior clinoid processes and the attached periphery to the posterior clinoid processes. For details of the comparative anatomy and phylogeny of the tentorium cerebelli see Klintworth (1968).

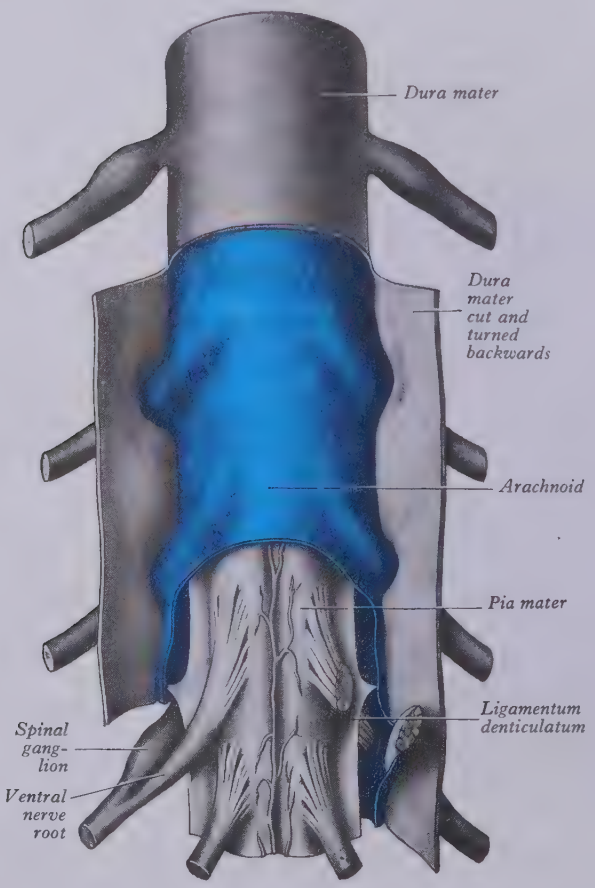


(3) *The falx cerebelli*, a small, crescentic fold of dura mater, is below the tentorium cerebelli, projecting forwards into the posterior cerebellar notch. Its base, directed upwards, is attached to the posterior part of the inferior surface of the tentorium cerebelli in the median plane; its posterior margin, attached to the internal occipital crest, contains the occipital sinus; its apex frequently divides into two small folds, which disappear at the sides of the foramen magnum. Hasan & Das found the falx cerebelli double in 76 of 100 cadavers.

(4) *The diaphragm sellae* (7.203B) is a small, circular, horizontal fold of dura mater, forming a roof to the sella turcica, almost completely covering the hypophysis; a small, central, opening in it transmits the infundibulum.

The arrangement of the dura mater in the central part of the middle cranial fossa is complex (7.203B). The rim of the tentorial incisure converges on the attached periphery, crossing it near the apex of the petrous temporal bone and continuing forwards as a ridge on the dura mater, to attach to the anterior clinoid process. This ridge marks the junction of the roof and lateral wall of the cavernous sinus (7.203A,B). The attached periphery of the tentorium cerebelli follows the superior border of the petrous temporal bone and, crossing under the free border, continues forwards to the posterior clinoid process as a rounded, indefinite ridge on the dura mater. An angular interval thus exists between the anterior parts of the attached periphery and the free border (7.203B); in this interval the dura mater is part of the roof of the cavernous sinus and is pierced in front by the oculomotor and behind by the trochlear nerves, which remain in contact with the dura mater after piercing it and proceed antero-inferiorly into the lateral wall of the cavernous sinus (**6**.155–157).

In the middle cranial fossa, anteromedially, the dura mater ascends as the lateral wall of the cavernous sinus. Reaching the ridge produced by the anterior continuation of the free border of the tentorium, it turns medially, as the roof of the cavernous sinus, and is here pierced by the internal carotid artery (7.203A,B). Medially, the roof of the sinus is continuous with the upper layer of the diaphragma sellae. At or just below the opening in the diaphragma for the infundibulum, the dura mater, arachnoid and pia mater blend with each other and with the capsule of the hypophysis (p. 1451); within the sella turcica it is impossible to differentiate the meninges, and the subdural and subarachnoid spaces are obliterated (**6**.155).



Apart from its function as periosteum, the dura mater probably exerts a steadying influence, through the tentorium and falx, upon

7.203B The superior aspect of the tentorium cerebelli.

the movement of the brain in the cranial cavity; but this is a speculation. As noted, the venous sinuses are enclosed in its thickness and some are in the margins of the dural partitions. The junction of the great cerebral vein and straight sinus is a critical point in the venous drainage of the brain; if the relation between these two channels is much altered for more than short periods of time, as may occur when 'space-occupying' lesions above the tentorium cause the descent of the brain relative to the tentorium, obstruction of the great cerebral vein may ensue, with sequelae of venous back-pressure, oedema of the choroid plexuses and overproduction of cerebrospinal fluid.

The structure of the dura mater is basically fibrous, white collagen fibres predominating, with some elastic fibres. The collagen fibres are densely arranged in laminae, in which they often lie parallel in fascicles with wide angles between them in adjacent laminae, producing a latticed appearance easy to see in the tentorium cerebelli. As has been noted, the cerebral dura mater is described as having two layers, *endosteal* and *meningeal*, a description owing more, perhaps, to dural separation where venous sinuses occur and splitting at the foramen magnum and optic canals, than to any marked histological differences. Smaller branches of meningeal vessels are largely in the endosteal layer, since they are (despite their name) primarily periosteal. Fibroblasts occur throughout the dura mater but osteoblasts are confined to the endosteal layer. Elastic fibres separate the laminae of collagen fibres, which are also more extensively separated by lacunar spaces considered by some to be continuous with the subdural space (vide infra); these spaces are mainly confined to the meningeal dura mater. Several features thus distinguish the external and internal layers of the dura but there is no discontinuity indicating a distinct bilaminar nature. At all cranial foramina the endosteal element is continuous with the external periosteum, and with the sutural membranes, until the sutures close; at these locations it is more strongly attached but elsewhere it is more easily detached from the cranial bones. The meningeal element is continuous with the dural sheaths of the spinal cord and optic nerves. At other foramina it is 'pierced' by the nerve or vessel, but is more accurately described as becoming continuous with the perineurium or adventitial sheaths. Though apposed to the arachnoid mater internally, the dura mater is easily separated from it, as exemplified by the occurrence of subdural haemorrhages between them. Although contrary views have been expressed there is little doubt that a layer of flattened 'mesothelial' cells exists on the internal aspect of the dura and that fluid, though a mere capillary film, usually marks this zone of potential separation. Rascol & Izard (1974) have described a 'neurothelium' in this zone, its cells arranged in several irregular layers, with abundant intercellular spaces devoid of collagen fibres; the cells display tonofilaments and desmosomes. They consider that this fragile epithelium is easily torn apart to produce a 'subdural space'. (The structure of the subjacent arachnoid is described on p. 1089.)

7.204 A part of the spinal cord exposed from the ventral aspect, showing its meningeal coverings.

The arteries of the cerebral dura mater are numerous. In the anterior cranial fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries and a branch from the middle meningeal. In the middle fossa are: the middle and accessory meningeal branches of the maxillary artery; a branch of the ascending pharyngeal entering by the foramen lacerum; branches of the internal carotid; and a recurrent branch from the lacrimal artery. In the posterior fossa are: the meningeal branches of the occipital artery (one entering the skull by the jugular foramen, another by the mastoid foramen); the posterior meningeal branches of the vertebral artery; and occasional twigs from the ascending pharyngeal which enter by the jugular foramen and hypoglossal canal. The meningeal arteries are chiefly distributed to bone, in contrast to those in the spinal dura mater, and are therefore unsuitably named; only very fine branches are distributed to the cranial dura mater itself.

The veins returning blood from the cranial dura mater are described on pp. 798–805.

The nerves of the cerebral dura mater have been much investigated over a long period (von Luschka 1850, Arnold 1851, Hovelacque 1927, Siwe 1931, Penfield & McNaughton 1940, Kimmel 1961a, b). The most authentic sources of dural innervation are the *trigeminal nerve*, including its ganglion and three divisions, the first three *cervical spinal nerves* and the *cervical sympathetic* trunk. Less well-established meningeal branches have been described from the vagus and hypoglossal nerves and possibly the facial and glossopharyngeal (but vide infra).

In the *anterior cranial fossa* are meningeal branches of the anterior and posterior ethmoidal nerves and anterior filaments of the meningeal rami of the maxillary (*nervus meningeus medius*) and mandibular (*nervus spinosus*) trigeminal divisions. *Nervi meningeus medius et spinosus* are, however, largely distributed to the dura of the *middle cranial fossa*, which also receives filaments from the trigeminal ganglion. A recurrent *tentorial nerve* (a branch of the ophthalmic division) supplies the *tentorium cerebelli*. The dura in the *posterior cranial fossa* is innervated by ascending meningeal branches of the upper cervical nerves which enter it through the anterior part of the foramen magnum (second and third cervical) and through the hypoglossal canal and jugular foramen (first and second cervical nerves). Meningeal branches from the vagus and hypoglossal and possibly other cranial nerves may exist, but strong evidence shows that nerves so described are usually recurrent filaments from the cervical nerves which run in the sheaths of cranial nerves (Kimmel 1961a, b).

All the meningeal nerves contain a postganglionic sympathetic component, either from the superior cervical sympathetic ganglion or by communication with its perivascular intracranial extensions. These components are probably vasomotor; experiments have shown that they exert a vasoconstrictor action on pial vessels (see p. 1085 for cerebral blood flow).

Various dural receptor terminals, including simple end-bulbs and Meissner's and Pacinian corpuscles, have been described in various mammals; as little recent information is available concerning man, the roles of the sensory and autonomic supply to the cerebral dura mater remaining uncertain.

The spinal dura mater (7.204, 208) is a loose sheath, representing only the inner (meningeal) layer of the cranial dura mater; the outer (endosteal) layer is represented by the

periosteum of the vertebral canal, which is separated from the spinal dura mater by an *extradural (epidural) space*. Spinal dura mater is attached to the edge of the foramen magnum and to the posterior surfaces of the second and third cervical vertebral bodies and also by fibrous slips to the posterior longitudinal ligament, especially towards the caudal end of the vertebral canal. A midline fold is occasionally present (Parkin & Harrison 1985). The subdural space ends at the lower border of the second sacral vertebra; below this, the dura mater invests the spinal filum terminale, descending to the back of the coccyx to blend with the periosteum. The spinal dura mater has tubular prolongations around the spinal roots and nerves as they traverse the intervertebral foramina (7.208). These prolongations are short in the upper vertebral column but gradually become longer with the increasing obliquity of the spinal roots (7.81). Dural sheaths of spinal nerves fuse with their epineuria in or slightly beyond the intervertebral foramina; this continuity may act as a slight check on movements of the nerves when affected by bodily movement. At the cervical level, where the nerves are short and vertebral movement greatest, their sheaths are bound strongly to the periosteum of the adjacent transverse processes (Sunderland 1974).

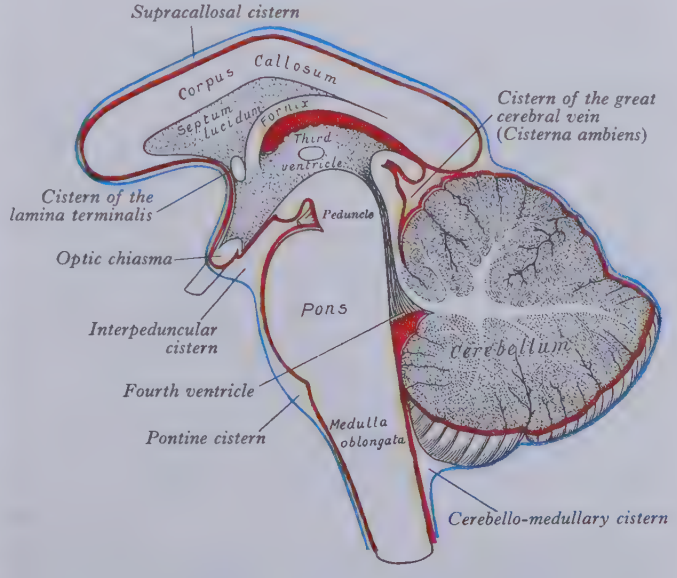
The extradural (epidural) space, lying between the spinal dura mater and the periosteum and ligaments within the vertebral canal, contains loose connective tissue, fat and a venous plexus. In the lumbar region, the dura mater is apposed to the walls of the vertebral canal, being attached to them by connective tissue in a manner permitting displacement of the dural sac during spinal movement and venous engorgement; fat is deposited posteriorly in recesses between the ligamenta flava (Parkin & Harrison 1985). The connective tissue extends for a short distance through the intervertebral foramina along the spinal nerves. Dyes or other fluids injected into it at sacral level can spread up to the cranial base; local anaesthetics injected near a spinal nerve just outside its intervertebral foramen may spread up or down to affect the adjacent spinal nerves or pass to the opposite side. In each case spread is through the extradural space. (For the nerve supply of the spinal dura mater, see p. 1125.)

The subdural space between the dura and arachnoid maters is a potential space containing a film of serous fluid between the surfaces of the apposed membranes. Apparently it does not connect with the subarachnoid space, but continues a short distance along the cranial and spinal nerves, communicating with their lymph spaces. Around the optic nerves it is continued as far as the back of the eyeballs. The functional significance of the subdural space remains controversial; possible connections with venous channels or with hypothetical lymph spaces in the dura mater have been claimed and disclaimed (Hoffmann & Thiel 1956). Electron microscopy shows no cells of an epithelial type in the dura mater, except at its arachnoid surface. The dural lacunae may in fact be artefacts; the evidence refutes any passage of significant amounts of fluid from the dura into the subdural or subarachnoid spaces (Kaplan & Ford 1966), but lymphatic drainage from the spinal extradural adipose tissue, possibly including the spinal dura, has been established (Millen & Woollam 1962).

THE ARACHNOID MATER

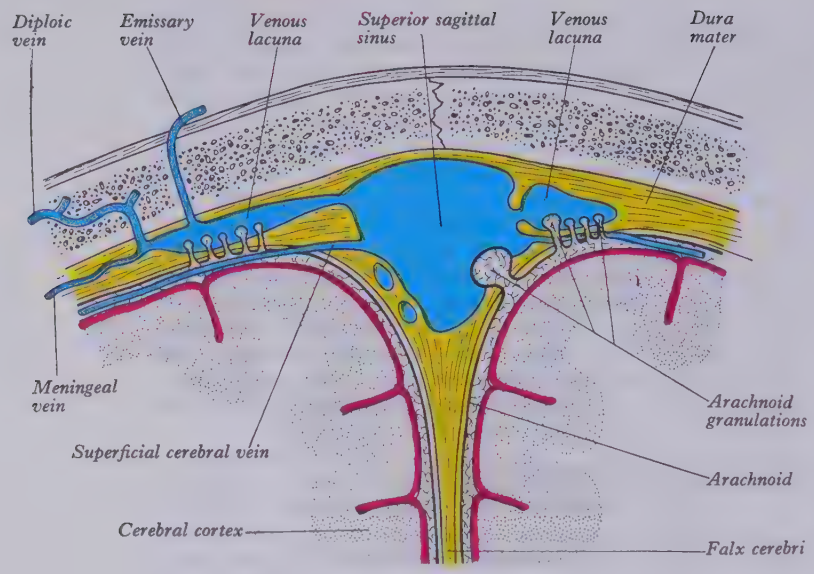
The arachnoid, a delicate membrane enveloping the brain and spinal cord, lies between the pial and dural meninges, separated from the dura mater by the *subdural space*, which is traversed by isolated trabeculae, most numerous on the posterior surface of the spinal cord; it is separated from the pia mater by the *subarachnoid space*, which is filled with cerebrospinal fluid. The arachnoid surrounds the beginnings of the cranial and spinal nerves, enclosing them as far as their exits from the skull and vertebral canal.

The *cerebral part of the arachnoid* invests the brain loosely and does not enter the sulci or fissures, with the exception of the longitudinal fissure. On the upper surface of the brain it is thin and virtually transparent, but it is thicker on the basal aspect of the brain and is centrally slightly opaque where it extends between the temporal lobes in front of the pons, leaving a large space between it and the pia mater. It fuses with the other meninges in the hypophysial fossa.



The *spinal part of the arachnoid* (7.204, 208) is a thin, delicate tubular investment for the spinal cord, continuous above with the cerebral arachnoid; below, it widens around the cauda equina and ends at the level of the lower border of the second sacral vertebra. (For structure of the pia-arachnoid see p. 1091.)

The subarachnoid space, between the arachnoid and pial meninges, contains cerebrospinal fluid and the larger blood vessels of the central nervous system and is traversed by delicate connective tissue trabeculae, connecting the arachnoid and pia; these two layers come into contact on the summits of the cerebral gyri; but where the arachnoid bridges the sulci, angular spaces are left, filled by subarachnoid trabecular tissue. Wherever the brain and cranium are not closely adapted, the arachnoid is separated from the pia by wide intervals, named *subarachnoid cisterns*, which are continuous with each other through the general subarachnoid space of which they are merely dilatations. Subarachnoid trabeculae are here scant or absent.



The Subarachnoid Cisterns (7.205)

The *cerebello-medullary cistern* (*cisterna magna*) (7.205) is formed by the arachnoid bridging the interval between the medulla oblongata and the inferior cerebellar surface. It is triangular in sagittal section and is continuous below with the subarachnoid space of the spinal cord. The *pontine cistern* (7.205) is an extensive space ventral to the pons; it contains the basilar artery and below is continuous with the spinal subarachnoid space, behind with the cerebello-medullary cistern and, rostral to the pons, with the interpeduncular cistern. As the arachnoid crosses between the two temporal lobes it is separated from the cerebral peduncles and structures in the interpeduncular fossa by the *interpeduncular cistern*, containing the circulus arteriosus; anteriorly this cistern continues rostral to the optic chiasma and over the surface of the corpus callosum, where the arachnoid stretches between the cerebral hemispheres below the free edge of the falx cerebri, leaving a space containing the anterior cerebral arteries. The *cistern of the lateral fossa* contains the middle cerebral artery and is formed by the arachnoid bridging the lateral sulcus. The *cistern of the great cerebral vein* (*cisterna ambiens* or *superior cistern*) occupies the interval between the splenium and the superior cerebellar surface; it contains the great cerebral vein and the pineal gland. It is a widely used neurosurgical landmark.

Smaller cisternae have been described, including the *prechiasmatic* and *postchiasmatic cisterns* related to the optic chiasma, the *cistern of the lamina terminalis* and the *supracallosal cistern*, all of which are here included as extensions of the interpeduncular cistern and which contain the anterior cerebral arteries.

7.206 A coronal section through the vertex of the skull to show the arrangement of the veins and the meninges of the brain and arachnoid granulations.

The subarachnoid space connects with the ventricles of the brain by three openings: the *median aperture* (p. 979) in the median plane in the inferior part of the roof of the fourth ventricle and the two *lateral apertures* at the ends of that ventricle's lateral recesses (p. 979), behind the upper roots of the glossopharyngeal nerves. There is no communication between the subdural and subarachnoid spaces. Communications exist between tissue spaces in the nasal mucous membrane and the subarachnoid space through channels present along the course of the olfactory nerves.

The spinal subarachnoid space is relatively wide, being largest in the lower part of the vertebral canal, where the arachnoid encloses the cauda equina. Continuous above with the cranial subarachnoid space, it ends below at the level of the lower border of the second sacral vertebra. It is partially divided by the subarachnoid septum and the ligamentum denticulatum, described later (p. 1091).

The arachnoid granulations (7.206, 207) are small elevations, usually occurring in clusters near the superior sagittal, transverse and some other sinuses. They protrude into the sagittal sinus and its venous lacunae (7.207). They are visible at the age of eighteen months and are widely disseminated at three years, increasing in number and size as age advances. They cause pressure atrophy of bone, producing pits on the internal cranial aspect. Arachnoid granulations are macroscopic enlargements, or distensions, of minute projections of the arachnoid mater, termed *arachnoid villi*, normally numerous in the young. The growth and structure of arachnoid villi and granulations have been extensively studied (Le Gros Clark 1920). Each villus is a diverticulum of the subarachnoid space, penetrating into the dura mater, and covered by a layer of flat cells with large nuclei and lightly staining cytoplasm. The subarachnoid space within the granulation has a reticulum of fine fibrous tissue, usually denser peripherally than in the granulation's interior; in advanced age it frequently contains calcareous nodules. At the summit of a villus, mesothelial cells proliferate to form a cap which penetrates the dura mater and fuses with the endothelium of the sinus into which it projects (7.206), pulling out a little stalk of arachnoid with a diverticulum of the subarachnoid space. Except where fused with endothelium, the villus is surrounded by subdural space and dura mater, the latter, covered by a layer of mesothelium, being invaginated into the sinus by the protrusion of the granulation. Fluid injected into the subarachnoid space passes into the granulations and villi and thence into the venous sinuses of the dura by osmosis.

The cerebrospinal fluid (Davson 1970) is a clear, slightly alkaline fluid, with a specific gravity of about 1·007, containing in solution inorganic salts like those in plasma and traces of protein and glucose. It is secreted into the ventricles of the brain by the choroid plexuses and into the subarachnoid space by plexuses in the fourth ventricle's lateral recesses (p. 979). From the ventricles it escapes through the apertures of the fourth ventricle into the cerebello-medullary and pontine cisterns of the subarachnoid space. Intracranially the fluid ascends through the tentorial incisure, spreading over the inferior cerebral surface and ascending over the superolateral aspects of each hemisphere to reach the arachnoid villi of the superior sagittal sinus, there re-entering the bloodstream. There is probably little active flow at spinal level, diffusion and alterations of posture serving to maintain its composition constant throughout the subarachnoid space. Experiments in cats (Howarth & Cooper 1949) suggests that spinal cerebrospinal fluid may return locally to the venous system

7.207A Relations of the pia and arachnoid maters to the dura, brain and vessels, according to Hutchings & Weller (1986) and Alcolado et al (1988). Note the subpial space. Provided by R Weller, Department of Pathology, Southampton University.

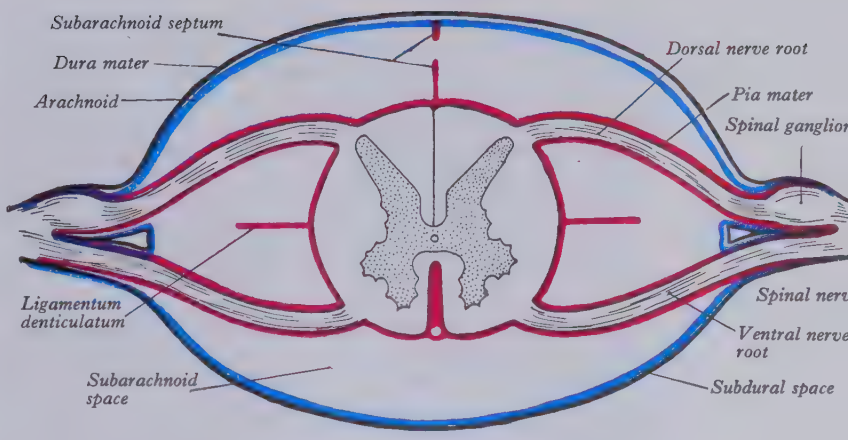
through the vertebral venous plexuses, intervertebral veins and the posterior intercostal and upper lumbar veins into the azygos and hemiazygos veins. The fluid supports the brain and spinal cord and maintains a uniform pressure around them. A brain weighing 1500 g in air weighs 50 g in cerebrospinal fluid, through which the total weight of the system is distributed to the meningeal parieties and their external supports. The circulation of cerebrospinal fluid and the function of the arachnoid villi were classically explored by Weed (1920, 1938). Electron microscopy suggests that there is open communication between the subarachnoid space and the lumen of the superior sagittal sinus by fine endothelial tubules traversing the arachnoid granulations (in sheep). A valvular action has been proposed in these structures but this drainage, even if confirmed, does not exclude filtration (Jayatilaka 1965).

Applied Anatomy. Central nervous diseases often alter the cells which normally occur in cerebrospinal fluid or the concentration of its chemical constitutents. Interference with circulation is indicated by variations in subarachnoid pressure. Specimens of cerebrospinal fluid are obtained by *lumbar puncture*, through the interval between the third and fourth (or fourth and fifth) lumbar laminae or spines. A needle is inserted at the intersection of the intertubercular plane and posterior median line, passed obliquely up and forwards above the upper border of a spine and through or alongside the supraspinous and interspinous ligaments into the vertebral canal. The dura mater and arachnoid are punctured, admitting the needle's tip into the subarachnoid space *below* the end of the spinal cord (7.57). The fluid escapes at the rate of about one drop per second, but when under increased pressure it escapes as a jet. The introduction of a large needle, such as a trocar, between the vertebral laminae is difficult except at lumbar levels. In any case, the introduction of its point accurately enough to withdraw fluid into the narrow subarachnoid space surrounding the spinal cord would be extremely difficult, apart from the danger to the cord itself; but it is primarily the *ease* with which fluid can be tapped from the large subarachnoid space *caudal* to the spinal cord which determines the choice of *lumbar* puncture.



THE PIA MATER

The pia mater closely envelops the brain and spinal cord; it is a vascular membrane, a plexus of minute blood vessels held together by fine loose connective tissue.

The *cerebral pia mater* invests the whole surface of the brain, dipping between cerebral gyri and cerebellar laminae, and is invaginated to form the tela choroidea of the third ventricle and the choroid plexuses of the lateral and third ventricles (pp. 1019, 1080); as it passes over the roof of the fourth ventricle it forms the tela choroidea and choroid plexuses (p. 979). On the cerebral hemispheres it provides a multitude of sheaths around minute vessels which enter the cortex perpendicularly; on the cerebellum it is more delicate, the vessels from its deep surface are shorter and its relations to the cortex less intimate. Recent work by Hutchings & Weller (1986) and Alcolado et al. (1988) defines a subpial space continuous with perivascular spaces around arachnoid vessels (see 7.207A,B).

The *spinal pia mater* (7.204, 208) is firmer and less vascular, but like the cerebral pia it consists of an external '*epi-pia*' containing larger vessels and an internal '*pia-glia*' or '*pia-intima*' in contact with nervous tissue (vide infra). Between the two are some vessels and clefts connecting with the subarachnoid space and a number of blood vessels. It is intimately adherent to the spinal cord. It enters the anterior median fissure, lining its walls with an intervening open meshwork of fine fibrous strands (7.208). A longitudinal fibrous band, the *linea splendens*, extends along the anterior midline. *Ligamenta denticulata* are on each side and a *subarachnoid septum* is posterior (7.208). Beyond the conus medullaris the pia mater continues as the *filum terminale* (p. 922). The pia mater ensheaths the cranial and spinal nerves, blending with their other membranous investments.

The *ligamentum denticulatum* (7.204, 208), a narrow, fibrous sheet situated on each side of the spinal cord between the ventral and dorsal spinal roots, has a medial border continuous with the spinal pia mater, its lateral border having a series of triangular

7.208 A transverse section through the spinal cord and its membranes. Black = dura mater, blue = arachnoid mater, red = pia mater.

processes, their apices fixed at intervals to the dura mater. There are usually 21 processes on each side; the first crosses behind the vertebral artery where it pierces the dura mater and is separated by the artery from the first cervical ventral root; it is attached to the dura mater above the rim of the foramen magnum, just behind the hypoglossal nerve; the spinal accessory nerve ascends on its posterior aspect (7.85). The last process is between the exits of the twelfth thoracic and first lumbar spinal nerves and is a narrow oblique band descending laterally from the conus medullaris (7.204). Changes in the form and position of the denticulate ligaments during spinal movements have been demonstrated by cineradiography (Epstein 1966).

The *subarachnoid septum* is a median, interrupted, fibrous sheet connecting the arachnoid to the pia mater opposite the posterior median sulcus (7.208). Incomplete and cribriform in the cervical region, it is a more complete partition at thoracic levels.

The Microscopic Structure of the Leptomeninges

The ultrastructures of the arachnoid and pial meninges are better described together (Winckler 1960); they have a common phylogenetic history, develop embryonically in continuity and preserve this intimate relation in their final differentiation, and indeed, are frequently regarded as a *pia-arachnoid*. They will, however, be described here successively, because they have slight differences. (For review see Hutchins & Weller 1986, Albacado et al 1988.)

The structure of arachnoid mater, like that of the pia, is essentially that of loose, irregular connective tissue. Both *leptomeninges*, like the dura mater (*pachymeninx*), are regarded as generally mesodermal, though the innermost region of pia mater is neurectodermal (Millen & Woollam 1961). In the most primitive vertebrates all three are an undifferentiated *meninx primitiva* but in tetrapods a thick external pachymeninx and more delicate internal leptomeninx are differentiated; in mammals and birds this difference is accentuated. All three meninges develop in mesenchyme around the central nervous system, with the proviso mentioned above.

The *arachnoid mater* consists of collagen, elastin and reticulin fibres, with flat cells usually considered to be mesothelial. On both its dural and internal aspects, cells with long cytoplasmic processes and cytoplasm paler than in the dural fibrocytes, form several layers with a subjacent basement membrane. Tight junctions occur between some of these cells (Nelson et al 1961); collagen fibres are generally interspersed among them and elastic fibres may also appear between the layers. The fibres of the arachnoid are finer than those of the dura mater. Fine *trabeculae* of arachnoid tissue extend across the *subarachnoid space*. These are usually considered to have a covering of 'mesothelial' cells lying over collagen fibres within which are reticulin fibres surrounding numerous small vessels traversing the trabeculae to reach the pia mater and central nervous system. The trabeculae vary much in size and distribution; most are fine strands and are most numerous in the intracranial subarachnoid space but largely absent where this is

dilated to form cisternae (p. 1089); they are scarcely evident in the human spinal region. Descriptions of the trabeculae are usually illustrated from other mammals and may convey a misleading impression of their development in humans. Intertrabecular spaces are usually large and are described as coalescing to form a single continuous subarachnoid space; but in the human arrangement large stretches of the space are completely free from trabeculae. Crossing the subarachnoid space the arachnoid trabeculae fuse with the pia mater, which itself is divisible into two layers (vide infra), the external being a vascularized connective tissue stratum covered by mesothelium bounding the space on its inner, cerebral (or spinal) aspect; some regard this as arachnoid tissue, considering only an avascular layer of collagen and other fibres and accompanying cells next to the nervous tissue as the true pia, the subarachnoid space being regarded as existing *within* the arachnoid mater. Others prefer to think of the two leptomeninges as being conjoined as one membrane, the pia-arachnoid.

The arachnoid mater is little vascularized and often described as avascular; but it does support large numbers of small vessels and accompanying nerves which traverse the trabeculae to reach the pia mater. Its mesotheliocytes, and particularly their intercellular tight junctions and the basal lamina, are a barrier to the free diffusion of colloidal substances between the subarachnoid and subdural spaces, the central nervous system and its non-capillary vessels. Return of cerebrospinal fluid is thus largely, if not entirely, limited to the arachnoid villi (p. 1090), where this permeability barrier is modified and possibly circumvented by minute valvular canaliculi. The barrier is also absent where the craniospinal nerves traverse the fused sleeves of the pia, arachnoid and perineurium. At these locations cerebrospinal fluid can diffuse through the arachnoid tissue into the adjacent lymphatics.

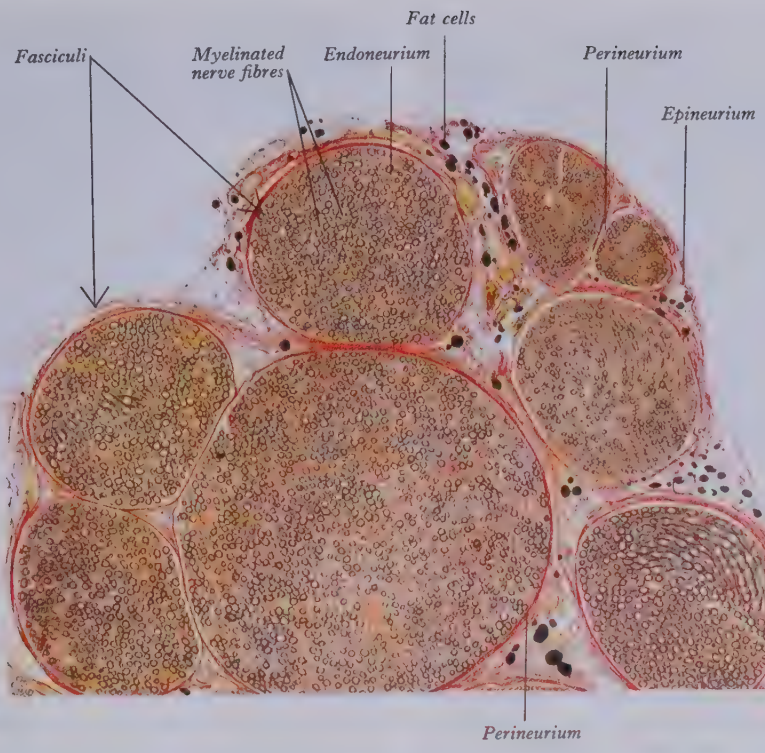
The structure of the pia mater is also that of loose connective tissue, containing collagen, elastin and reticulin fibres with flat 'mesotheliocytes' like those of the arachnoid; the cells are considered to be fibrocytic elements by some, especially where they form several layers interleaved with reticulin fibres, next to the central nervous system. Here the innermost cells are apposed to convoluted basal lamina, which lies between them and the subjacent end-feet of astrocytes. This relationship is so close that the internal stratum of the pia, with the basement membrane and glial processes, are sometimes combined as '*pia-glia*' or *pia-intima*, to differentiate it from the rest of the membrane, the '*epi-pia*', which is the pial stratum regarded as arachnoid by some, as noted before. Sleeves of pia and arachnoid, with intervening extensions of subarachnoid space, enter the central nervous system around the blood vessels, forming perivascular 'cuffs', the subject of so many past polemics.

The pia mater contains large numbers of small blood vessels and their vasomotor nerve supplies. On the spinal surface the more external connective tissue layer of the pia, the epi-pia, is more developed than on the cerebral surface, where it is not easily identified. In this stratum vessels are suspended by trabeculae of pial tissue which blend with arachnoid trabeculae where these occur. Thus many pial vessels project above the surface as they ramify in their pia-arachnoid suspension and are partially surrounded by subarachnoid space. Where they enter the central nervous system, as noted above, prolongations of the space and the two leptomeninges accompany each vessel as far as its capillaries, which are *not* separated from nervous tissue by the 'pia–glial' barrier. Current views deny any significant interchange of fluid between the perivascular extensions of the subarachnoid space and nervous tissue or blood, nor is drainage through them considered likely. It is suggested that these minute fluid-filled spaces merely accommodate to pulsatile variation in the calibre of the vessels which they surround.

The coverings of central nervous capillaries resemble those in the choroid plexuses (p. 1082) in the complete absence of connective tissue elements. The neuronal compartment is separated from blood only by vascular endothelium, the astrocytic end-feet and their joint basal lamina. The individual contribution of these to the *blood–brain barrier* is uncertain in mankind; however, abundant experimental evidence shows this to be the major and (apart from the contributions of the choroid plexuses to the cerebrospinal fluid) probably the exclusive site of entry of fluid and solutes into central nervous tissue. Arachnoid villi thus provide the main exit for cerebrospinal fluid, the drainage of extracellular fluid from the nervous tissue being partly back into the pre-venous ends of capillaries and perhaps partly through the ependyma into the ventricular system. Experiments in mice, using horseradish peroxidase as a tracer, have shed some light on the blood–brain barrier (Brightman et al 1970). In most of the sites examined endotheliocytes are impermeable to large molecules and have very effective occluding (tight) junctions between them, features which prevent passage of tracer. Similar junctions exist between the modified ependymal cells of choroid plexuses. The degree to which these findings apply to other sites has been the subject of much research (see also p. 894).

Apart from their functions in the production, circulation and reabsorption of cerebrospinal fluid, the meninges also collectively provide mechanical support to the central nervous system, especially in the buoyant effect of the contained cerebrospinal fluid. Like connective tissues elsewhere they also provide vital routes of access for vessels and at least a mechanical barrier to infection.

THE PERIPHERAL NERVOUS SYSTEM



The peripheral nervous system comprises the afferent or centripetal nerve fibres connecting receptors to the central nervous system and efferent, centrifugal nerve fibres connecting the central nervous system to the effector apparatus. In mankind these are grouped into 12 pairs of cranial nerves issuing from the brain and 31 pairs of spinal nerves. The sympathetic trunks, ganglia and splanchnic nerves are part of this system but will be described in a separate section (pp. 1154–1169).

In the most primitive vertebrates the spinal cord has a series of ventral motor nerve roots, arising from a ventral (anterior) grey column, and a series of dorsal sensory nerve roots, connected to the dorsal (posterior) grey column. The ventral and dorsal roots do not unite or coincide exactly in position; a ventral root is segmental and distributed to the myotome corresponding to its neuromere of origin while dorsal roots are intersegmental, running in the intersegmental connective tissue to their cutaneous distribution. In most fishes and all higher vertebrates the corresponding ventral and dorsal roots unite to form individual spinal nerves, whose arrangement therefore follows a very primitive pattern, with relatively little modification during evolution.

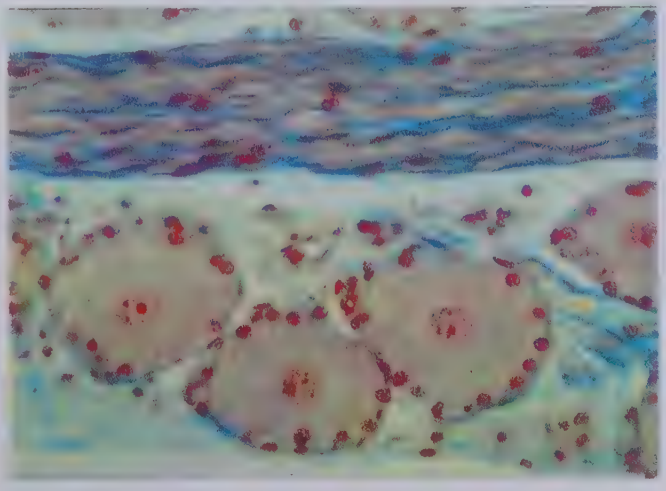
The arrangement of the cranial nerves, on the other hand, has been profoundly modified. The development and adaptations of the branchial system and suppression of segments during elaborate changes in the head region are largely responsible for this transmutation. In the brain, the corresponding ventral and dorsal nerves *never* fuse, though adjoining ventral *or* dorsal nerves sometimes do. Owing to the disappearance of some myotomes, the corresponding ventral nerves are suppressed; and dorsal nerves, originally sensory to the skin of the head and the mucous membrane of the mouth and pharynx, acquire motor fibres which they distribute to the musculature arising in the branchial region (p. 172). With growth and modification of the brain and elaboration of the head, the cutaneous areas are transferred from one nerve to a neighbour, altering the functions of the individual dorsal nerves.

The incorporation of some precervical segments into the head leads to the fusion of corresponding ventral nerves; the hypoglossal nerve, so formed, is thus added to the cranial series.

The cerebrospinal nerves, as described in detail elsewhere (p. 896), contain numerous nerve fibres collected into bundles,

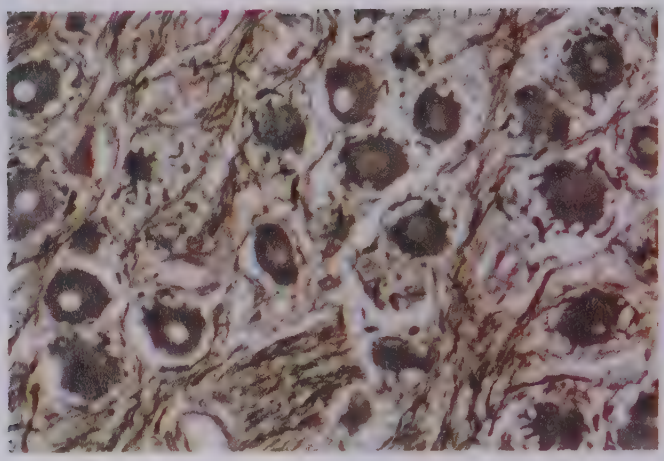
7.209 Transverse section of a peripheral nerve (cat). Stained with osmic acid and van Gieson's technique. Note the nerve fasciculi, the epi-, peri- and endoneurial connective tissue sheaths and the regional variations in the calibre of the myelinated nerve fibres. Magnification *c.* × 55.

and enclosed in connective tissue sheaths (7.209); a small bundle is termed a *fasciculus*. Each fasciculus is surrounded by a connective tissue sheath, the *perineurium*. Individual nerve fibres are held together and supported by a connective tissue *endoneurium*, continuous with septa from the perineurium. The collagen fibres of the endoneurium are longitudinally orientated and bundles are sometimes invaginated into the Schwann cells (lemmocytes) of non-myelinated nerve fibres (Gamble & Eames 1964). A small nerve may be a single fasciculus; but nerves usually contain several fasciculi held together by a connective tissue investment, the *epineurium*. Cerebrospinal nerves contain myelinated and non-myelinated nerve fibres in proportions varying with their functional roles.



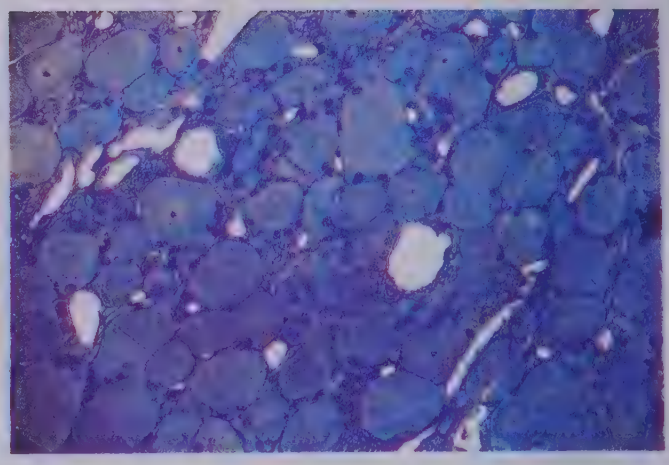
The blood vessels supplying a nerve end in a capillary plexus whose members pierce the perineurium and run largely parallel with the fibres, connected by short transverse vessels, to form narrow, oblong meshes, as in muscle. Small non-myelinated vasomotor nerve fibres accompany the larger, and break up into fibrils forming networks around them. Myelinated *nervi nervorum* run in the epineurium, their fibres ending in oval or bulbous corpuscles (p. 913).

Cerebrospinal nerve fibres pursue uninterrupted courses from the centre to the periphery but single fibres or groups may leave one fasciculus to join another, often at acute angles. Nerves divide into branches, frequently communicating with the branches of nearby nerves, forming *plexuses*. Such a plexus is formed by the ventral rami of spinal nerves, e.g. cervical, brachial, lumbar and sacral plexuses; terminal fasciculi may form peripheral plexuses. In forming a plexus, the component nerves divide, join and again subdivide, often in such a complex manner that individual fasciculi are intricately interwoven. Each branch leaving a plexus may hence contain filaments from more than one or even all the 'roots' of the plexus. In smaller plexuses in the periphery there is free interchange of fibres. Through this interchange, every nerve leaving a plexus gains more extensive connections with the spinal cord.



The origin of a nerve is a phrase usually implying its site of exit from or entry into the central nervous system. This is sometimes called its *superficial origin*, its *deep origin* being the assembly of nerve cells from which its peripheral axons come, or to which they proceed. The superficial origin may be single or by one or several 'roots'. *Efferent nerve fibres* are the peripheral axons of neurons with somata in the central grey matter; *afferent nerve fibres* spring from neurons with somata in special sense organs (e.g. the retina) or in the sensory ganglia of cerebrospinal nerves. Having entered the central nervous system afferent nerve fibres branch and send their terminals to synapse with specific neurons within it.

The peripheral terminations of sensory nerves are described on pp. 906–916 and those of motor nerves on pp. 904–906.



Ganglia are aggregations of neuronal somata associated with some peripheral nerves, occurring in the dorsal roots of spinal

7.210 A typical field in a dorsal spinal nerve root ganglion. Note the characteristic juxtaposition of large ovoid nerve cell somata and the fascicles of myelinated and non-myelinated nerve fibres. Note also the nuclei of the capsular (satellite) cells which surround each nerve cell. Grübler's stain; material provided by Lyn Gregson, Dept. of Anatomy, Guy's Hospital Medical School, London.

nerves and the sensory roots of the trigeminal, facial, glossopharyngeal, vagal and vestibulocochlear cranial nerves. They also occur in autonomic nerves (p. 1157). They vary in form and size, each ganglion being invested by a smooth, firm capsule of fibrous connective tissue continuous with the perineurium and sending numerous fibrous processes into the ganglion.

Each ganglion contains neurons and their fibres and, in some instances, fibres from cells located elsewhere which pass through or terminate in it. Their structure is considered in greater detail on p. 1123. In *spinal ganglia* the neurons are large, unipolar and grouped at the periphery (7.210); in autonomic ganglia they are multipolar and more uniformly scattered (7.211, 212). Each spinal ganglionic neuron has a nucleated capsule (7.236) continuous with the Schwann cells of its fibres. Larger neurons in the spinal ganglia (7.210) are irregularly spherical, with a single dendro-axonal process passing towards the centre of the ganglion and dividing like a T; one neurite (the axon) enters the spinal cord, while the other (the dendrite) passes to the periphery (vide infra). Near its origin the process is coiled into a form termed a *glomerulus* (p. 888). The smaller neurons, which are more numerous, give rise to fine non-myelinated fibres in peripheral nerves and their spinal roots, each having a thin dendro-axonal process which does not form a glomerulus, instead passing straight to its bifurcation. The peripheral division of the initial process of a unipolar ganglion cell resembles an axon in every respect, but it functions as an elongated dendrite. However, all neurites in peripheral nerves, afferent or efferent, are generally termed axons.

The somata of afferent neurons in primitive invertebrates, such as *Hydra*, lie in the ectoderm, with superficial dendritic processes projecting from them; but in all vertebrates they are close to the central nervous system, their peripheral processes being presumably elongated homologues of the short 'dendrites' of primitive neurons. Primary olfactory neurons retain this primitive position (p. 1173). In the sensory ganglia of the cranial nerves, neurons are unipolar, but in vestibulocochlear ganglia they remain bipolar.

THE CRANIAL NERVES

The craniocaudal sequence of cranial nerves is as follows:

1 Olfactory	5 Trigeminal	9 Glossopharyngeal
2 Optic	6 Abducent	10 Vagal
3 Oculomotor	7 Facial	11 Accessory
4 Trochlear	8 Vestibulocochlear	12 Hypoglossal

These nerves are continuous with the brain, traversing the foramina in the cranial base. The **motor** or **efferent** fibres of cranial nerves arise from groups of neurons in the brain which are their *nuclei of origin*. They are connected with the cerebral cortex by corticonuclear fibres which arise from neurons of cortical motor areas, descending chiefly in the genicular part of the internal capsule to the brain stem, where many but not all decussate and end by arborizing around the neurons of origin of the motor cranial nerves. The **sensory** or **afferent** cranial nerves arise (except for one instance, see p. 1095) from neurons situated outside the brain, grouped to form ganglia or sited in peripheral sensory organs such as the nose and eye. Their processes enter the brain and end around neurons grouped to form their *nuclei of termination*, fibres from the cells of which usually cross before ascending to connect indirectly with the cerebral cortex. Of course, the pathways involved are usually more complex but not different in principle.

Fibres of most cranial nerves begin to myelinate about the fourteenth week in utero, but not until the twenty-second week i.u. in the sensory part of the trigeminal nerve and cochlear division of the vestibulocochlear, and even later in the optic nerve.

The Olfactory Nerves

The olfactory nerves serving the sense of smell (7.213) have their cells of origin in the olfactory mucosa in the nasal cavity; this olfactory region comprises the mucosa of the superior nasal concha and the opposite part of the nasal septum. The nerve fibres originate as the central or deep processes of the olfactory cells (7.150) and collect into bundles which cross in various directions, forming a plexiform network in the mucosa, finally forming about 20 branches, which traverse the cribriform plate in lateral and medial groups and end in the glomeruli of the olfactory bulb (7.150). Each branch has a sheath consisting of dura mater and pia-arachnoid, the former continuing into the nasal periosteum, the latter into the perineural sheaths of the nerve bundles. Tissue spaces in these sheaths connect with those in the nasal mucous membrane and with the subarachnoid space.

The olfactory nerves are non-myelinated and are bundles of fine axons enfolded within Schwann cells. They are unique in the peripheral origin of their neurons in ectoderm, where they remain throughout life in all vertebrates.

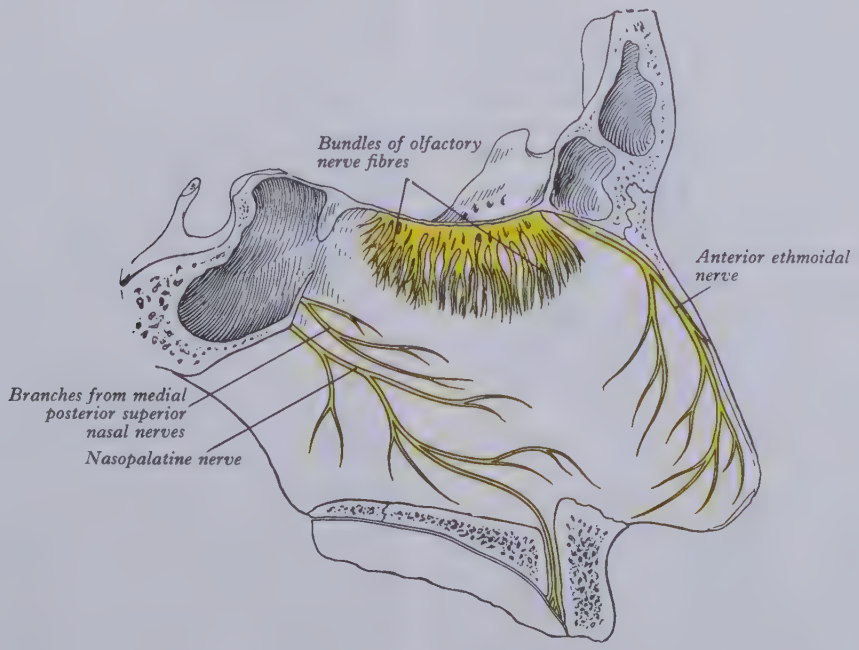
Applied Anatomy. In severe head injuries involving the anterior cranial fossa the olfactory bulb may be separated from the

olfactory nerves or the nerves may be torn, producing *anosmia*, loss of olfaction. Fractures may involve the meninges, admitting cerebrospinal fluid into the nose. Such injuries also open up avenues for infection from the nasal cavity. The extensions of the subarachnoid space around bundles of olfactory nerve fibres, sometimes regarded as a lymphatic drainage, may favour the spread of infection into the cranial cavity. Evidence for this route of infection is equivocal.

Associated with the olfactory nerves are two small **nervi terminales** (Pearson 1941). These were discovered in lower vertebrates but they exist in the human embryo and adult, consisting mainly of non-myelinated nerve fibres with small groups of bipolar and multipolar neurons. Each nerve lies medial to an olfactory tract and its branches traverse the cribriform plate to be distributed to the nasal mucosa. The nerve is connected to the brain near the anterior perforated substance and septal areas; in some animals its fibres reach the lamina terminalis, in others the hypothalamic region. Peripherally it passes to the mucosa of the nasal cavity (see p. 1176). Ganglion cells have been associated with the nerve by Pearson (1941) and others and ganglia have been observed in mice by Gruneberg (1973), who did not, however, equate them with the ganglion cells which are scattered along the human terminal nerve. The connections and significance of the latter '*ganglion terminale*' are unknown. Bojsen-Møller (1975) considered the nerve to be entirely sensory and recent evidence suggests a role in pheromonal detection in some mammals. The **vomeronasal nerve**, with which the nervus terminalis is frequently confused, is probably absent in adults (p. 1029).

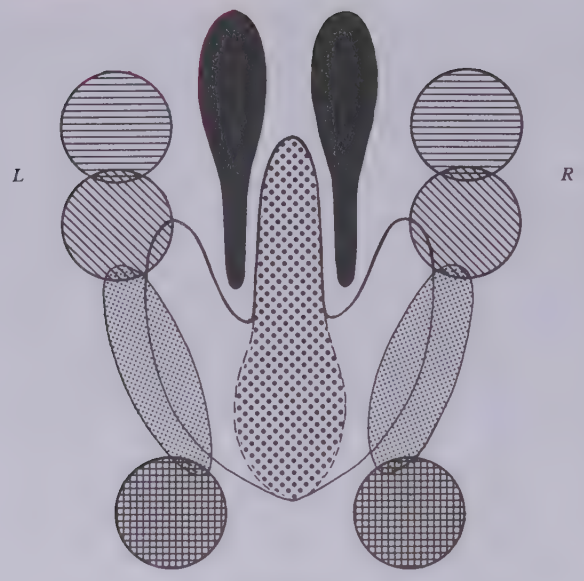
The detailed structure and central connections of the olfactory bulb are described on pp. 1028–1033 and the structure of the olfactory mucosa on p. 1173.

The Optic Nerve



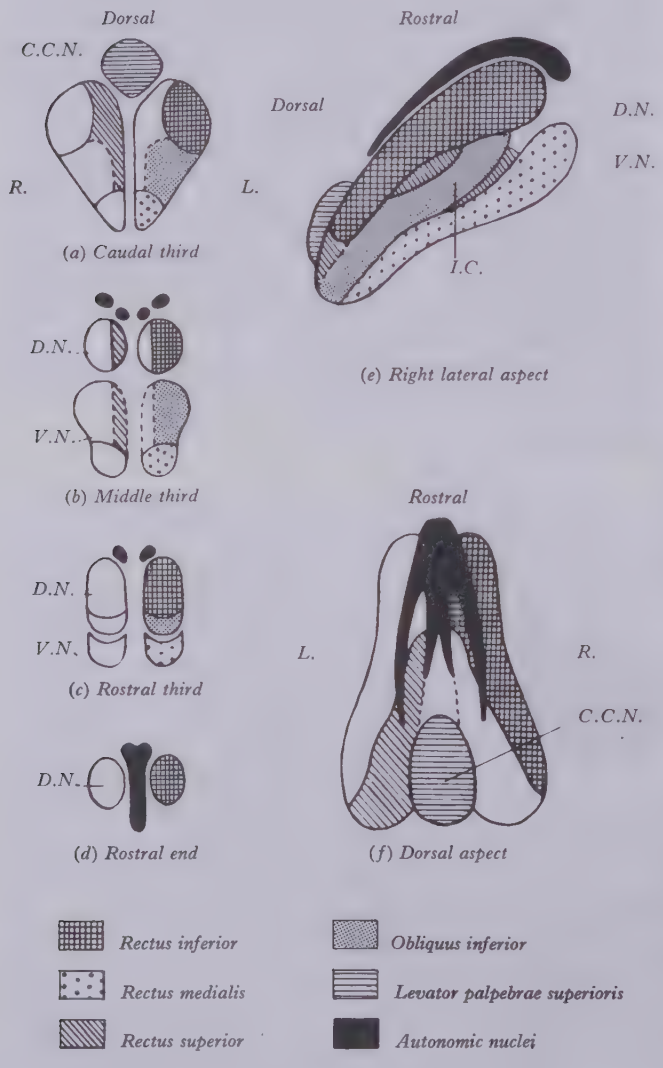
The optic nerve, mediating vision, is distributed to the eyeball. Most of its fibres are afferent, originating in retinal ganglionic neurons (p. 1202), but some may be efferent, their origin uncertain. Developmentally, the optic nerves and retinae are outgrowths of the brain (p. 201), their fibres are covered by oligodendrocytes, not Schwann cells (p. 893). Optic nerve fibres form the internal layer (*stratum opticum*) of the retina, being the axons of cells in its ganglionic layer; they converge on the optic disc, pierce the outer layers of the retina, the choroid coat, and lamina cribrosa near the posterior pole of the eyeball, about 3 or 4 mm nasal to its centre. As they traverse the lamina cribrosa they develop myelin sheaths and run in fascicles collecting to form the optic nerve. This nerve is about 4 cm long and is directed posteromedially through the back of the orbital cavity, where it runs through the optic canal into the cranial cavity to join the optic chiasma. Its intraorbital part, about 25 mm long, has a slightly sinuous course, the nerve being about 6 mm longer than the distance between the optic canal and the eyeball. Posteriorly it is surrounded by the four recti and separated from them anteriorly by fat, in which the ciliary vessels and nerves are embedded. The ciliary ganglion lies between the optic nerve and the lateral rectus. The nerve is pierced inferomedially about 12 mm behind the eyeball by the central retinal artery and vein, which pass along the centre of the nerve to the optic disc. In the optic canal, which is about 5 mm long, the nerve lies superomedial to the ophthalmic artery and is separated medially from the sphenoidal and posterior ethmoidal sinuses by a thin osseous lamina; anterior to the canal the nasociliary nerve and ophthalmic artery run forward and medially, crossing above the optic nerve, whilst a branch from the inferior division of the oculomotor nerve passes below it to the medial rectus (7.225).

The intracranial part of the optic nerve, which is about 10 mm long, runs posteromedially from the optic canal to the optic chiasma. The posterior parts of the olfactory tract and gyrus rectus and, near the chiasma, the anterior cerebral artery are above the nerve, the internal carotid artery being lateral to it.



The optic nerve is enclosed in three sheaths continuous with the meninges (7.309, 310) and prolonged to the eyeball. The outer *sheath*, from the dura mater, is thick and fibrous, blending with the sclera. The *intermediate sheath* from the arachnoid mater is thin, separated from the outer by the subdural space and from the inner by the subarachnoid space. The inner *sheath* from the pia mater is vascular and closely invests the nerve. From its deep surface septa enter the nerve, dividing and reuniting to enclose, as seen in transverse sections, polygonal areas which are occupied by fascicles of fibres, about 1000 fascicles in all. The inner sheath also invests the central vessels of the retina as far as the optic disc.

The ultrastructure of the optic meninges resembles that of meninges elsewhere (Anderson & Hoyt 1969) but the amount of collagen fibres in the pia and arachnoid is greater than in the intracranial leptomeninges. As elsewhere the subarachnoid space is lined completely by epitheliocytes of the pia-arachnoid, resembling fibroblasts and forming multilaminar membranes of 'mesothelium' or 'meningothelium'.



Near the eye the macular fibres (*papillo-macular bundle*) are lateral in the nerve, but they gradually become medial and just

anterior to the chiasma lie close to the medial margin. Fibres from the upper and lower retinal areas are, respectively, above and below; the fibres from the temporal quadrants are lateral, and those from the nasal quadrants medial.

Counts of optic nerve fibres in man (Oppel 1963, Kupfer et al 1967) show that there are about 1200 000 myelinated axons, about 92% being about 1 μm in diameter, the rest varying from 2 to 10 μm. About 53% cross in the chiasma. Most end in the lateral geniculate body but some pass to the pretectal nucleus, superior colliculus and hypothalamic nuclei (p. 1009). A small number are efferent but of unknown origin. Such centrifugal fibres reaching the retina have attracted much interest in birds, where they arise from the *isthmo-optic nucleus*, which lies dorsolaterally at the junction of the mid- and hindbrain (Cowan & Clarke 1976).

The optic nerve is supplied with arterial blood by the plexus in its pial sheath and by direct intraneural branches. The pial plexus is supplied by a superior hypophysial and the ophthalmic artery intracranially, by recurrent ophthalmic branches in the optic canal and by posterior ciliary arteries and the extraneural part of the central retinal artery in the orbit. Intraneural branches are from the central artery but their actual contribution to the nerve is probably small (Belmonte 1968, Francois & Neetens 1969). The rich supply of the optic papilla and lamina cribrosa has been emphasized (Henkind & Levitsky 1969). Venous drainage is by the central retinal vein (p. 1204, and Steele & Blunt 1956).

The optic chiasma (p. 1014) and the **optic tract** (p. 1015) have been described elsewhere.

Applied Anatomy. The optic nerve is liable to neuritis or atrophy in some central nervous conditions and its anatomy may partly explain this predisposition. (1) From its development and structure the optic nerve is a prolongation of brain substance, rather than a cranial nerve. (2) It has sheaths from the three cerebral meninges, separated by spaces connecting with the subdural and subarachnoid spaces. The pial sheath sends a process into the nerve and enters intimately into its structure. Thus infection of the meninges or the brain readily extends to the nerve. *Optic neuritis* or *papilloedema*, often a sequela of intracranial neoplasm, is probably caused by increased pressure due to excess fluid in the general subarachnoid space, which extends as far as the lamina cribrosa (p. 1181).

The Oculomotor Nerve

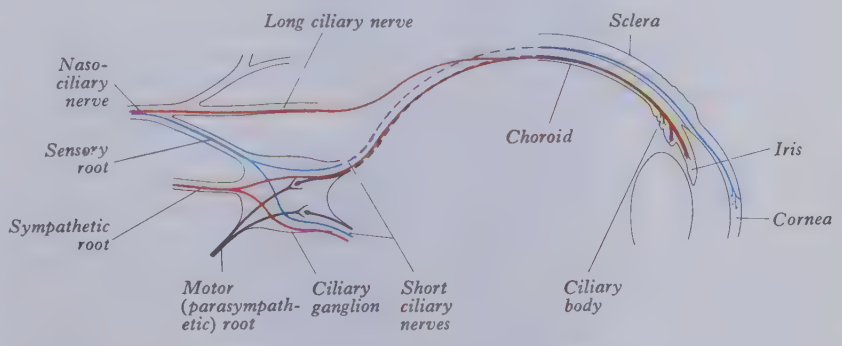
The oculomotor nerve (**6**.151, 152, **7**.139, 152, 216, 226) supplies all the extraocular muscles except the obliquus superior and rectus lateralis; it also supplies, through the ciliary ganglion, the sphincter pupillae and ciliaris. It contains about 24 000 axons. Its fibres arise from a *complex of nuclei* in the grey matter, ventral to the cranial part of the cerebral aqueduct and extending rostrally for a short distance into the floor of the third ventricle. From this region its fibres pass forwards through the tegmentum, red nucleus and the medial part of the substantia nigra, curving with a lateral convexity to emerge from the sulcus on the medial side of the cerebral peduncle (**7**.86, 87, 118). Peripherally the nerve contains afferent fibres from neurons in the trigeminal ganglion, considered proprioceptive (Bortolami et al 1977, Manni et al 1978). Small neurons, varying in number in different species, occur in the oculomotor nerve; these are usually regarded as ectopic proprioceptive neurons, perhaps displaced from the trigeminal ganglion (Tozer 1912, Bortolami et al 1977).

The nuclear complex from which its efferent fibres arise consists of several paired groups of large multipolar neurons, identifiable in most mammals, with paired masses of smaller multipolar neurons, not so easily identified but well developed in primates and other mammals and the source of the parasympathetic outflow in the oculomotor nerves. On each side the large-celled mass is divided into **dorsolateral**, **intermediate** and **ventromedial nuclei** (7.214), extended in columnar form almost in the long axis of the midbrain (Crosby & Henderson 1948, Warwick 1950); these sub-nuclei are identifiable in early fetal life in man (Pearson 1944). Experiments in monkeys show that they are motor pools of the *rectus inferior*, *obliquus inferior* and *rectus medialis*, in dorsoventral order (7.214). Dorsal to the right and left

large-celled masses and level with their caudal extremities, is a median nucleus of similar large neurons, the **caudal central nucleus**, which appears to be the conjoined motor pool of the *levatores* of the upper eyelids (Warwick 1950, 1953). Dorsal to the main oculomotor nuclei are the **accessory** or **autonomic nuclei** (of Edinger and Westphal), composed of smaller multipolar neurons, whose axons travel in the oculomotor nerve to relay in the ciliary ganglion (Warwick 1954); these are largest rostrally, fusing together to arch ventrally over the main oculomotor nuclei (7.214); in their caudal, paired parts these autonomic columns have a tendency to further splitting in man and other primates. Sugimoto et al (1978), using the retrograde horseradish peroxidase technique, suggest that many oculomotor parasympathetic neurons may be sited near but outside these nuclei.

Though a median group of larger motor neurons has been a standard feature of oculomotor topography for decades, this 'central nucleus of Perlia' is most variable in mammals, even in the same species. The function of convergence was early ascribed to it on inadequate and fallacious evidence. Its development in primates is not commensurate with its supposed function, nor is it possible to equate its size with binocular vision (Le Gros Clark 1926). It is often unidentifiable in the human midbrain (Tsuchida 1906, Crosby & Woodburne 1943). There are always a few scattered large motor neurons between the right and left oculomotor masses but these never constitute a clear nucleus, like the caudal central nucleus; in any case, they appear to innervate the superior, not the medial, rectus (Warwick 1955).

Other views of the arrangement of the motor pools of the extraocular muscles have been advanced (Brouwer 1918, Szentágothai 1942, Bender & Weinstein 1943), all suggesting a rostrocaudal pattern rather than the dorsoventral scheme described here; but in both forms of organization, though different in other ways, there is agreement that the issuing oculomotor fibres, somatic and autonomic, are almost completely ipsilateral; at the most, some axons from the median raphe and the caudal central nucleus may cross to the opposite oculomotor nerve to innervate the rectus superior and levator palpebrae superioris; extensive oculomotor decussation, a usual tenet of textbook accounts, is not supported by the experimental studies quoted here, almost all of which were carried out in primates. A more recent study, carried out in cats (Tarlov 1972, 1975), describes longitudinal motor pools for individual muscles but arranged differently from those in monkeys (Warwick 1955). Tarlov has also defined a projection (p. 1112) to the oculomotor from the medial and superior vestibular nuclei, terminals from both providing a partly bilateral and overlapping distribution in some oculomotor 'pools' and suggesting excitatory and inhibitory roles; certain physiological data tend to support this (High et al 1971).



For a discussion of the claims that other nuclei contribute to the oculomotor nerve consult Warwick (1953).

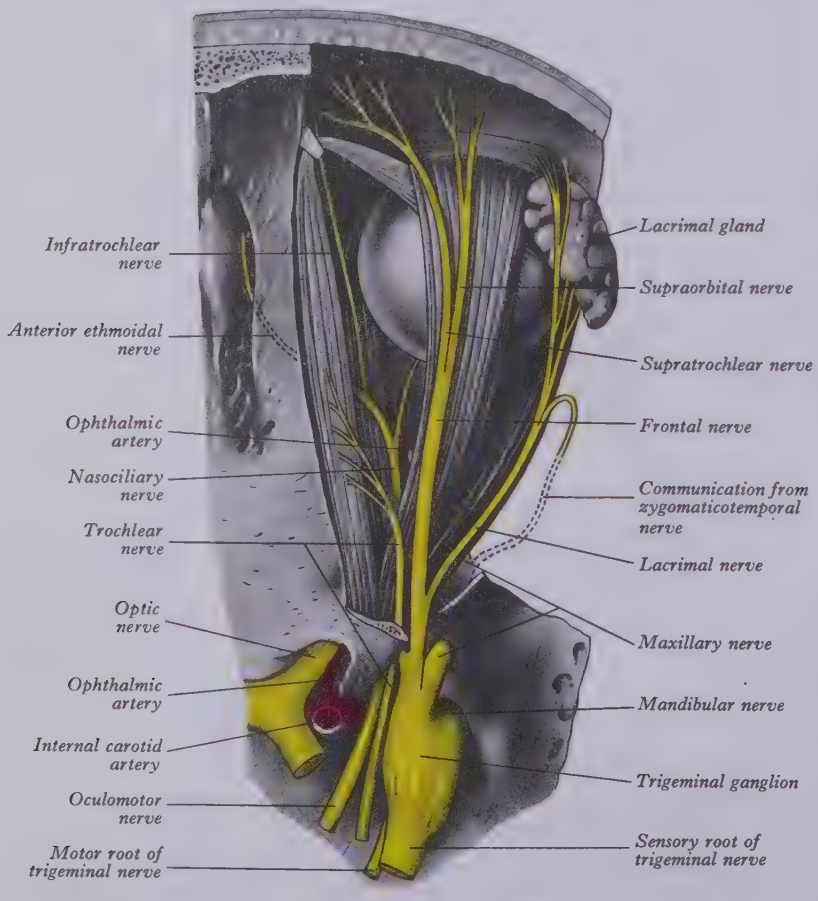
Connections of the oculomotor nuclei include fibres from: (1) *both* corticonuclear tracts, some leaving at oculomotor level, some (aberrant fibres) at a higher level and thereafter descending in the medial lemniscus; they either end on oculomotor neurons or are linked to them via interneurons; (2) the medial longitudinal fasciculus, connecting nuclei of the third, fourth, sixth and eighth cranial nerves (p. 985); (3) the tectobulbar tract, connecting to the visual cortex through the superior colliculus; (4) the bilateral pretectal nuclei for the light reflex. Horseradish peroxidase studies indicate a reciprocal connection between oculomotor and abducent nuclei (Graybiel & Hartwig 1974, Maciewicz et al 1975). Such internuclear connections are expected from the results of experimental stimulation of or damage to the medial longitudinal fasciculus and clinicopathological data of internuclear ophthalmoplegia. These connections are part of the control of horizontal eye movements. (For discussion consult Bender 1964, Highstein 1977. See also p. 1122.) Other experiments using the horseradish peroxidase technique suggest that many neurons in the accessory oculomotor nuclei project to the cerebellum and spinal cord (Sugimoto et al 1978).

Course. As it emerges from the brain the nerve lies in the subarachnoid space covered by the pia mater. It passes between the superior cerebellar and posterior cerebral arteries (6.81A), runs forwards in the interpeduncular cistern lateral to the posterior communicating artery, perforates the arachnoid in the triangular interval between the free and attached borders of the tentorium cerebelli and pierces the inner dural layer lateral to the posterior clinoid process to traverse the roof and, anteriorly, descend into the lateral wall of the cavernous sinus, where it lies above the trochlear nerve (6.156). Here it receives one or two filaments from the internal carotid sympathetic plexus and connects with the ophthalmic division of the trigeminal. It divides into superior and inferior rami, which enter the orbit by the superior orbital fissure within the anulus tendineus communis, with the nasociliary nerve between them (7.218, 329).

The smaller *superior ramus* ascends on the lateral side of the optic nerve, supplying the rectus superior and levator palpebrae superioris. The *inferior ramus* divides into three branches: one passing under the optic nerve to the rectus medialis, another to the rectus inferior, the third and longest passing forwards between the rectus inferior and lateralis to the obliquus inferior. The branches enter the muscles on their ocular surfaces, except that to the obliquus inferior, which enters its posterior border. From the nerve to obliquus inferior a short (sometimes double or treble) branch passes to the lower part of the ciliary ganglion as its *motor, parasympathetic root*. It contains finely myelinated fibres from the accessory oculomotor nucleus, which synapse with the ganglionic neurons, whose postganglionic fibres pass in the short ciliary nerves to the sphincter pupillae and ciliaris (pp. 1188, 1194).

The ciliary ganglion (7.215, 218) is a small, flat reddish-grey ganglion about the size of a large pin's head, situated near the orbital apex in loose fat between the optic nerve and the rectus lateralis, usually lateral to the ophthalmic artery. It is a peripheral parasympathetic ganglion. Its neurons, which are multipolar, are larger than in typical autonomic ganglia; a very small number of more typical neurons are also present (Warwick 1954). Its *connections* or *roots* (7.215) enter or leave it posteriorly. Only its parasympathetic function is basic and sympathetic and sensory fibres merely pass through (or are absent in some mammals). The *parasympathetic root*, derived from the nerve to the inferior oblique, consists of preganglionic fibres from the accessory (Edinger–Westphal) nuclei (7.139), which relay in the ganglion, the postganglionic fibres travelling in the short ciliary nerves to the sphincter pupillae and ciliaris. More than 95% of these fibres supply the ciliaris, which is much the larger muscle in volume (Warwick 1954); hence this motor pathway is more concerned with accommodation than with the light reflex. The *sympathetic root* is a branch from the internal carotid plexus, passing direct to the ganglion or joining the sensory root to reach it indirectly; it consists of postganglionic fibres from the superior cervical ganglion, which traverse the ganglion without synapsing, to emerge into the short ciliary nerves. They are distributed to blood vessels of the eyeball but may include axons supplying the dilatator pupillae when these do not follow their usual course in the ophthalmic, nasociliary and long ciliary nerves. The *sensory root* is a *ramus communicans* of the nasociliary nerve, containing sensory fibres from the eyeball which reach the ganglion in short ciliary

7.215 The ciliary ganglion, with its roots and branches of distribution. Red = sympathetic fibres, heavy black = parasympathetic fibres, blue = sensory (cerebrospinal) fibres. Alternative pathways are given for the sympathetic fibres to the dilatator pupillae. A schematic sagittal section is shown of the upper lateral quadrant of the eyeball but the retina has not been included.



nerves and traverse it without synapsing. The ramus leaves the ganglion posteriorly and runs back to join the nasociliary nerve near its orbital entry.

The *branches* of the ganglion are eight to ten delicate filaments which emerge anteriorly in two bundles, the lower being larger, termed *short ciliary nerves*. The postganglionic parasympathetic fibres in them are myelinated. With the ciliary arteries they run sinuously forwards, above and below the optic nerve, dividing into 15–20 branches which pierce the sclera around the optic nerve and run in small grooves on the internal scleral surface. They contain motor and sensory fibres, the former distributed to sphincter pupillae and ciliaris and to choroidal and iridial blood vessels. The existence of proprioceptive fibres in the oculomotor nerve can no longer be doubted, since stretch endings occur in the extraocular muscles (p. 1122). How far such fibres travel in the nerve, and their central terminations, remain unsettled (p. 1099). The blood supply of the ciliary ganglion, investigated in man by Eliscova (1973), is from small rami of muscular, posterior ciliary and central retinal arteries.

Applied Anatomy. Complete severance of the oculomotor nerve leads to: (1) ptosis, due to paralysis of the levator palpebrae superioris; (2) lateral strabismus, due to the unopposed action of the rectus lateralis and obliquus superior; (3) pupillo-dilatation, because the sphincter pupillae is paralysed; (4) loss of accommodation and of the light reflex, the sphincter pupillae and ciliaris being paralysed; (5) prominence of the eyeball (proptosis) due to muscular relaxation; (6) diplopia, the false image being the higher. Lesions may be partial, with, e.g. a dilated and fixed pupil, with ptosis but no other signs. Irritation of the nerve causes spasm in the muscles supplied by it, e.g. medial strabismus from spasm of the medial rectus, accommodation for near objects only from spasm in the ciliaris or a contracted pupil from spasm in the sphincter pupillae.

The Trochlear Nerve

The trochlear nerve (7.216, 218), the thinnest cranial nerve, supplies the ocular superior oblique muscle. It contains about 3400 fibres (Björkman & Wohlfart 1936) but in fetuses the number is greater, as in other cranial nerves. According to Mustafa & Gamble (1979), the adult human nerve contains about 2400 fibres, fetal counts being 4000 (at CR length 9·2 cm), 6000 (at CR length 10 cm) and 3200 (at CR length 24 cm). Many fibres therefore degenerate after an initial increase. The orbital part of the nerve contains more fibres than its stem, a disparity also observed in fetal trochlear nerves.

1098 7.216 The nerves of the right orbit: superior aspect.

The trochlear nucleus lies in the floor of the cerebral aqueduct, level with the upper part of the inferior colliculus (7.86, 87, 117), and is in line with the ventromedial part of the oculomotor nucleus, in the position of the somatic efferent column. The medial longitudinal fasciculus is ventral to it. The oculomotor and trochlear nuclei often overlap slightly but can be distinguished by the smaller size of the trochlear neurons.

Connections. The nucleus receives fibres from: (1) *both* corticonuclear tracts, probably in a manner similar to the oculomotor nucleus (p. 1097); (2) the medial longitudinal fasciculus, connecting nuclei of the third, fourth, sixth and eighth cranial nerves (p. 985); (3) the tectobulbar tract, by which impulses arrive from the visual cortex through the superior colliculus (pp. 986, 1122). Tarlov & Tarlov (1975) have described, in cats, GABA-transmitting terminals of axons from the superior vestibular nucleus in the trochlear nucleus, regarding them as inhibitory.

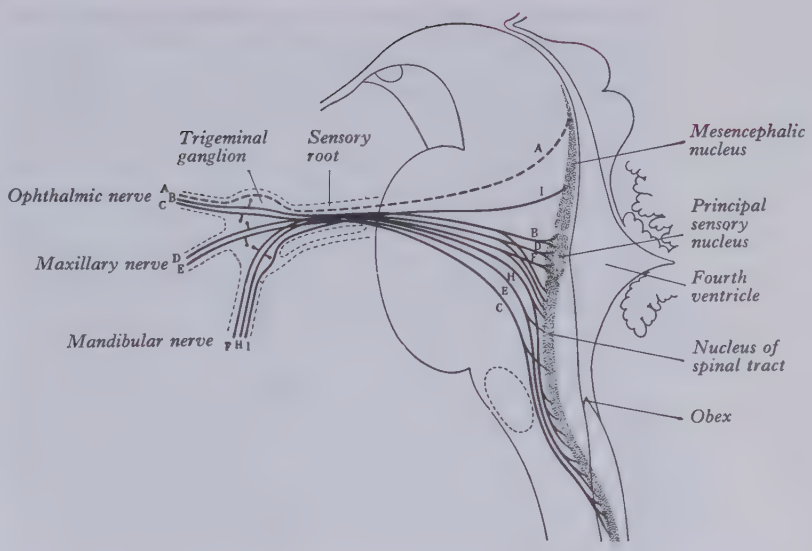
Course. After leaving its nucleus the trochlear nerve pursues an unusual course (p. 983), at first descending laterally through the tegmentum and turning posteriorly round the central grey matter into the anterior medullary velum. Here it decussates with its fellow, crossing the midline to emerge from the velum at the side of the frenulum veli, below the inferior colliculus (7.116). It is the only cranial nerve to emerge dorsally from the brain stem.

The nerve crosses to the lateral side of the superior cerebellar peduncle and winds round the cerebral peduncle just above the pons, between the posterior cerebral and superior cerebellar arteries, appearing between the upper pontine border and the temporal lobe. It pierces the inner dural stratum below the free edge of the tentorium cerebelli, just behind the posterior clinoid process, and then passes forwards in the lateral wall of the cavernous sinus, below the oculomotor nerve and above the ophthalmic division of the trigeminal (6.155). Here it is adherent to the tentorial branch of the ophthalmic nerve, which lies below it. Near the anterior end of the sinus it crosses the oculomotor nerve, entering the orbit by the superior orbital fissure above the annular tendon and medial to the frontal nerve (7.216). In the orbit it inclines medially, above the origin of the levator palpebrae superioris, to enter the orbital surface of the obliquus superior (7.218).

In the lateral wall of the cavernous sinus the nerve communicates with the ophthalmic division of the trigeminal and with the internal carotid sympathetic plexus. In the superior orbital fissure it occasionally sends a branch to the lacrimal nerve. Though an exchange of fibres in the cavernous sinus has been denied (Sunderland & Hughes 1946), subsequent fibre analysis in human material (Zaki 1960) suggests that a substantial component of large nerve fibres, possibly proprioceptive, exists in the trochlear nerve *distal* to the sinus; this part contains 3500 fibres but only 2400 proximal to the sinus. Though it is sometimes assumed, as in the oculomotor nerve, that proprioceptive fibres (from the superior oblique) enter the brain stem in the trochlear nerve, Manni et al (1970) suggest that these leave the nerve peripherally to join the ophthalmic division of the trigeminal.

Applied Anatomy. Interruption of the trochlear nerve paralyses the superior oblique, limiting inferolateral ocular movement; the affected eye rotates medially, producing *diplopia*. Single vision prevails as long as the eyes move above the horizontal; diplopia occurs on looking downwards. To counteract this the sufferer holds his head forwards and inclined to the other side.

The Trigeminal Nerve



The trigeminal, the largest cranial nerve, is the sensory supply to the face, the greater part of the scalp, the teeth, the oral and nasal cavities and the motor supply to the masticatory and some other muscles. It also contains proprioceptive nerve fibres from the

masticatory and probably the extraocular muscles. It has three divisions: ophthalmic, maxillary and mandibular. Baumel (1974) has reviewed the functions of the widespread peripheral connections between the trigeminal and facial nerves. Despite the voluminous literature on this topic, uncertainties still exist; however, the preponderant view is that fibres joining the trigeminal from the facial are afferent and arise largely from the facial musculature. The trigeminal nerve emerges from the ventral surface of the pons, near its upper border, as a large sensory and a small motor root, the latter lying anteromedial to the former.

Fibres in the *sensory root* are mainly axons of cells in the **trigeminal** (*semilunar*) **ganglion**, which (7.216–219) occupies a recess (*trigeminal cave*) in the dura mater covering the trigeminal impression near the apex of the petrous temporal bone (p. 397). The ganglion lies at a depth of 4·5–5 cm from the lateral surface of the head at the posterior end of the zygomatic arch; it is crescentic, with its convexity directed anterolateral and on its surface interlacing nerve fascicles are visible. *Medial* to it are the internal carotid artery and the posterior part of the cavernous sinus; *inferior* are the motor root of the nerve, the greater (superficial) petrosal nerve, the apex of the petrous temporal bone and the foramen lacerum. It receives filaments from the internal carotid sympathetic plexus and supplies twigs to the tentorium cerebelli.

The neurites of unipolar cells in the trigeminal ganglion divide into peripheral and central branches, the former being grouped to form the *ophthalmic* and *maxillary* nerves and the sensory part of the *mandibular*. The central branches constitute the fibres of the sensory root, leaving the ganglion's concave margin to run posteromedially under the superior petrosal sinus and tentorium cerebelli to enter the pons. Some fibres from proprioceptor endings in the masticatory muscles traverse the ganglion uninterruptedly to pass to the mesencephalic nucleus of the trigeminal (p. 983). Some sensory fibres from the extraocular muscles may do likewise but electrophysiological observations (Manni et al 1970) indicate that most if not all of such proprioceptive axons have somata in the trigeminal ganglion (p. 1098).

On entering the pons, the fibres of the sensory root run dorsomedially towards the **principal sensory nucleus** situated at this level (7.96); before reaching the nucleus about 50% of the fibres divide into ascending and descending branches, the others ascending or descending without division. The descending fibres, predominantly finely myelinated or non-myelinated, form the **spinal tract of the trigeminal nerve** which reaches the upper cervical spinal cord; as it descends, terminals and collaterals are given off to synapse with neurons in the **spinal trigeminal nucleus** (7.86, 88–90, 91, 94, 217), which contains small and intermediate neurons and is continuous with the substantia gelatinosa of the spinal cord. The tract embraces the nucleus dorsolaterally; in the lower medulla oblongata it is superficial and lies under the tuberculum cinereum. The fibres which synapse in the nucleus are concerned mostly (but not entirely) with pain and thermal sensibility. Experiments show that: (1) the ophthalmic fibres are ventral in the tract and descend to the lower limit of the first cervical spinal segment; (2) the maxillary fibres are central and do not extend below the medulla oblongata; (3) mandibular fibres are dorsal in the tract and do not extend much below the mid-medullary level (7.217). This evidence is confirmed by the clinical results of section of the spinal tract (Smyth 1939, Brodal 1947, Falconer 1949) in cases of severe trigeminal neuralgia; section 4 mm below the obex renders the ophthalmic and maxillary areas analgesic but tactile sensibility, apart from the abolition of 'tickle', is much less affected; to include the mandibular area, section must be made at the level of the obex. By such a section, analgesia is extended to the mucosa of the tonsillar sinus, the posterior lingual third and adjoining parts of the pharyngeal wall (glossopharyngeal nerve) and the cutaneous area supplied by the auricular branch of the vagus. The fibres concerned must, therefore, join the trigeminal spinal tract and end in its nucleus. As a result of such operations the laminar representation in the tract has also been confirmed. A small group of sensory neurons associated with the glossopharyngeal nerve but related to the spinal tract of the trigeminal, has been described (Bossy 1968). Other afferents reach the spinal nucleus from the sensory root of the facial nerve and the dorsal roots of the upper cervical nerves;

7.217 The nuclei receiving the primary afferent fibres of the trigeminal nerve: A. proprioceptive fibres from ocular muscles; B. tactile and pressure fibres from opthalmic areas; C. pain and temperature fibres from the ophthalmic area; D. tactile and pressure fibres from the maxillary area; E. pain and temperature fibres from the maxillary area; F. tactile and pressure fibres from the mandibular area; H. pain and temperature fibres from the mandibular area; I. proprioceptive fibres from the muscles of mastication. Proprioceptive fibres are believed to occur in all three divisions of the trigeminal nerve.

descending fibres from the sensorimotor cortex also pass to it (p. 1122).

It is appropriate to divide the spinal trigeminal nucleus into three levels: *the nucleus oralis* (most rostral, adjoining the principal sensory nucleus), the *nucleus interpolaris* and *nucleus caudalis* (the most caudal part, continuous with the dorsal grey column). They differ in structure and to some extent in their connections. The nucleus caudalis resembles in its neuronal pattern the dorsal grey column, the nuclei interpolaris and oralis being devoid of neurons 'equivalent' to those in the substantia gelatinosa. All levels receive afferents from the whole trigeminal sensory field but all C fibres are believed to end in the caudal nucleus and its neurons alone respond to noxious stimuli; furthermore, its projection is to the contralateral ventroposterior thalamic nucleus, as is that of the nucleus oralis; in contrast, the nucleus interpolaris projects to the anterior lobe of the cerebellum.

Some ascending trigeminal fibres, many of them heavily myelinated, synapse around the small neurons in the principal sensory nucleus, which lies lateral to the motor nucleus and medial to the middle cerebellar peduncle; it is continuous inferiorly with the spinal nucleus (7.86, 217) and is considered to be mainly concerned with tactile stimuli.

Other ascending fibres enter the **mesencephalic nucleus**, a column of *unipolar* cells, whose peripheral branches may convey proprioceptive impulses from the masticatory muscles; it is also stated (Corbin & Harrison 1940, Pearson 1949) that similar impulses reach it from the teeth and from the facial and ocular muscles (7.86, 117, 195, 196). Its neurons are unique in being the only primary sensory neurons with somata in the central nervous system (Johnston 1909). If, however, the primary proprioceptive neurons of extraocular muscles are in fact situated in their motor nerves or in the trigeminal ganglion (pp. 1098, 1122), some mesencephalic trigeminal neurons may be 'secondary' in status. Small multipolar cells, possibly interneurons, occur near the unipolar neurons.

Connections. Most fibres arising in the trigeminal sensory nuclei cross the midline to ascend in the trigeminal lemniscus (p. 983) to the thalamic nucleus ventralis posterior medialis (p. 1002), relaying to the cortical postcentral gyrus (areas 3, 1 and 2, p. 1056). Some, however, ascend to the same nucleus of the ipsilateral thalamus. Collateral branches of primary and

secondary afferent trigeminal neurons probably reach many other central regions, such as the other cranial nerve nuclei, the reticular formation, cerebellum, tectum, subthalamus, hypothalamus, etc., but details have not been established in human brains (Humphrey 1969, Webster 1977, Nieuwenhuys et al 1988, p. 1122.)

Nerve fibres ascending to the mesencephalic nucleus may give collaterals to the motor trigeminal nucleus and cerebellum, the 'axons' being, of course, morphologically dendrites. The true axons of mesencephalic neurons possibly descend in part to the principal trigeminal sensory nucleus. Electrophysiological evidence suggests that the mesencephalic nucleus is modulated during masticatory reflexes by connections with the vagus nerve but anatomical confirmation of this is lacking (Manni et al 1977).

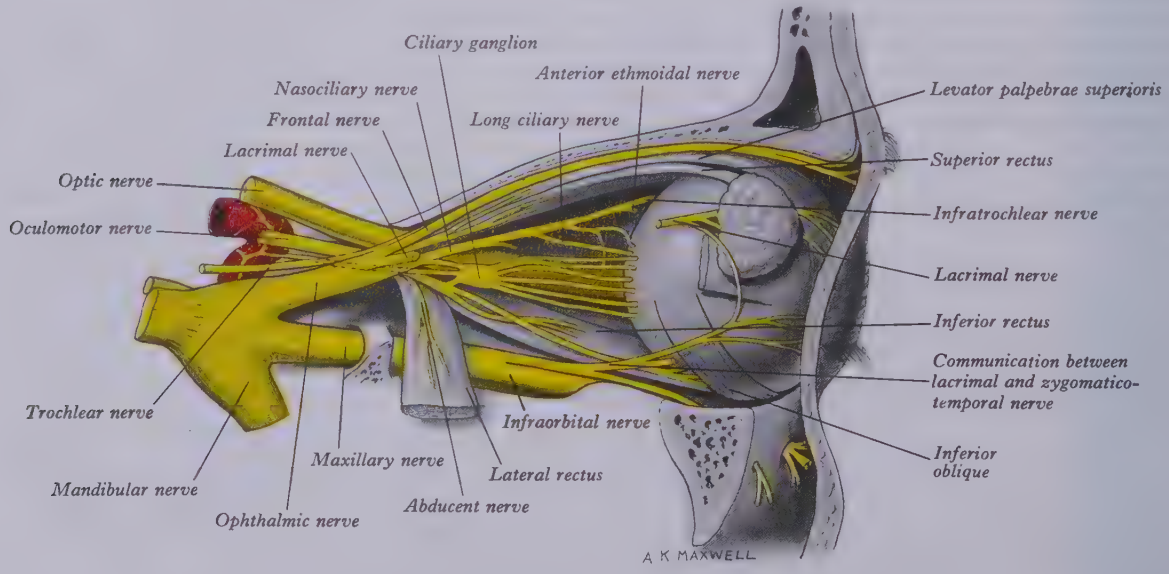
The motor nucleus of the trigeminal nerve is ovoid, with characteristic large multipolar cells interspersed with smaller multipolar cells. It lies in the upper pons medial to the principal sensory nucleus, separated from it by fibres of the trigeminal nerve. It occupies the position of the branchial (special visceral) efferent column (7.86, 87, 96) and consists of a number of relatively discrete sub-nuclei whose axons innervate individual muscles (Szentágothai 1949).

Connections. The motor nucleus receives fibres from *both* corticonuclear tracts; these fibres leave the tracts at the nuclear level or higher in the pons (aberrant corticospinal fibres), descending in the medial lemniscus. They may end on motor neurons or interneurons. The motor nucleus receives afferents from the sensory nuclei, including some possibly from the mesencephalic nucleus, forming monosynaptic reflex arcs for proprioceptive control of the masticatory muscles. It also receives afferents from the reticular formation, red nucleus and tectum, the medial longitudinal fasciculus and possibly from the locus ceruleus, by which salivary secretion and mastication may be correlated.

THE OPHTHALMIC NERVE

The ophthalmic nerve (7.216, 219, 224), the superior and smallest trigeminal division, is wholly sensory. It supplies the eyeball, lacrimal gland and conjuctiva, part of the nasal mucosa and the skin of the nose, eyelids, forehead and part of the scalp. It arises from the anteromedial end of the trigeminal ganglion as a flat band, about 2·5 cm long, passing forwards in the cavernous sinus in its lateral wall, below the oculomotor and trochlear nerves (6.155); just before entering the orbit by the superior orbital fissure it divides into *lacrimal*, *frontal* and *nasociliary* branches.

The ophthalmic nerve is joined by filaments from the internal carotid sympathetic plexus and communicates with the oculomotor, trochlear and abducent nerves, thus forming routes by which proprioceptive fibres in these nerves may possibly enter the trigeminal. It has a recurrent meningeal branch (*tentorial nerve*), which crosses below and adheres to the trochlear nerve and is distributed to the tentorium cerebelli (p. 1088).



The lacrimal nerve (7.216), the smallest of the main ophthalmic branches, sometimes receives a filament from the trochlear nerve. The lacrimal nerve enters the orbit through the lateral part of the superior orbital fissure (7.219) and runs along the upper border of the rectus lateralis with the lacrimal artery, receiving a twig from the zygomaticotemporal branch of the maxillary nerve, often said to contain lacrimal secretomotor fibres (p. 1155). Entering the lacrimal gland, it supplies it and the adjoining conjunctiva. It then pierces the orbital septum and ends in the upper eyelid, joining filaments of the facial nerve. It is occasionally absent, being replaced by the zygomaticotemporal nerve; when this is absent it is replaced by a branch of the lacrimal nerve.

The frontal nerve (7.216, 218), the largest branch of the ophthalmic division, enters the orbit by the superior orbital fissure (7.216) above the annular tendon and proceeds between the levator palpebrae superioris and the periosteum, dividing about midway between the apex and base of the orbit into a small supratrochlear and a large supraorbital branch.

The *supratrochlear nerve* runs anteromedially, passing above the trochlea, and supplies a descending filament to the infratrochlear branch of the nasociliary nerve. It then emerges between the trochlea and the supraorbital foramen, curving up on the forehead close to the bone with the supratrochlear artery and supplying the conjunctiva and the skin of the upper eyelid; it then ascends beneath the corrugator and the frontal belly of occipitofrontalis, dividing into branches which pierce these muscles to supply the skin of the lower forehead near the midline.

The *supraorbital nerve* proceeds between the levator palpebrae superioris and the orbital roof and traverses the supraorbital notch or foramen, supplying palpebral filaments to the upper eyelid and conjunctiva. It ascends on the forehead with the supraorbital artery, dividing into a smaller medial and a lateral branch, which supply the skin of the scalp nearly as far back as the lambdoid suture. These branches are at first deep to the frontal belly of the occipitofrontalis; the medial branch perforates it, while the lateral pierces the epicranial aponeurosis. The main nerve and both branches supply small rami to the mucosa of the frontal sinus and to the pericranium; some enter the sinus by foramina in the floor of the supraorbital notch.

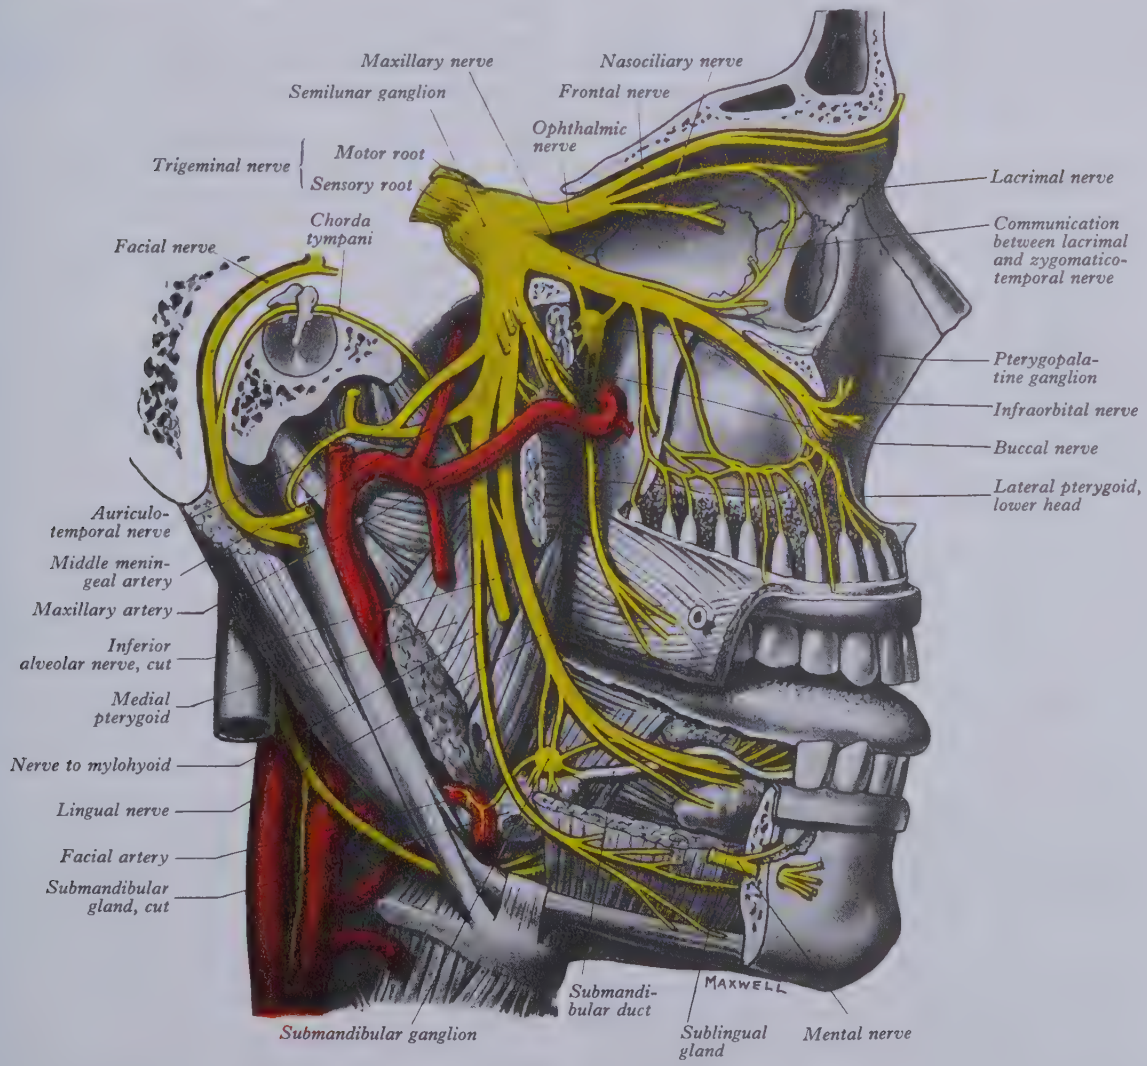
The nasociliary nerve (7.216, 218), intermediate in size between frontal and lacrimal, is more deeply placed in the orbit, which it enters through the annular tendon between the two rami of the oculomotor nerve (7.218). It crosses the optic nerve with

7.218 The nerves of the right orbit and the ciliary ganglion: lateral aspect.

the ophthalmic artery and runs obliquely below the rectus superior and obliquus superior to the medial orbital wall. Here, as the *anterior ethmoidal nerve*, it traverses the anterior ethmoidal foramen and canal, enters the cranial cavity and runs forwards in a groove on the upper surface of the cribriform plate beneath the dura mater; it descends through a slit lateral to the crista galli into the nasal cavity, where it occupies a groove on the internal surface of the nasal bone. It supplies two *internal nasal branches*: a medial to the anterior septal mucosa and a lateral to the anterior part of the lateral nasal wall. It emerges, as the *external nasal nerve*, at the lower border of the nasal bone, descending under the transverse part of the nasalis to supply the skin of the nasal ala, apex and vestibule.

The nasociliary nerve connects with the ciliary ganglion and has long ciliary, infratrochlear and posterior ethmoidal branches.

The *ramus communicans* to the ganglion (p. 1097, 7.215) usually joins the nerve as it enters the orbit lateral to the optic nerve, emerging from the ganglion's posterosuperior angle (7.215); it is sometimes joined by a filament from the internal carotid sympathetic plexus or from the superior oculomotor ramus.



Two or three *long ciliary nerves* branch from the nasociliary as it crosses the optic nerve. They accompany the short ciliary nerves to pierce the sclera near the attachment of the optic nerve. Running forwards between sclera and choroid, they supply the ciliary body, iris and cornea and usually contain the sympathetic fibres for the dilatator pupillae (p. 1194), these being postganglionic fibres from neurons in the superior cervical ganglion. In view of the susceptibility of the corneal epithelium to damage, the corneal distribution of the long ciliary nerves is of great importance.

The *infratrochlear nerve* branches from the nasociliary near the anterior ethmoidal foramen; running forwards along the medial orbital wall above the rectus medialis it is joined, near the trochlea, by a small branch from the supratrochlear nerve. It leaves the orbit below the trochlea, supplying the skin of the eyelids and the side of the nose above the medial canthus, the conjunctiva, lacrimal sac and lacrimal caruncle.

The *posterior ethmoidal nerve* leaves the orbit by the posterior ethmoidal foramen and supplies the ethmoidal and sphenoidal sinuses.

THE MAXILLARY NERVE

The maxillary nerve (7.218, 219), the intermediate division of the trigeminal, is wholly sensory; it leaves the trigeminal ganglion between the ophthalmic and mandibular divisions as a flat plexiform band which passes horizontally forwards, low in the lateral wall of the cavernous sinus (6.155), to traverse the foramen rotundum, where it becomes more cylindrical and compact. Crossing the upper part of the pterygopalatine fossa, it inclines laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla and enters the orbit through the inferior orbital fissure, as the **infraorbital nerve**. Traversing the infraorbital groove and

7.219 The right ophthalmic, maxillary and mandibular nerves and the submandibular and pterygopalatine ganglia. Note that the zygomatic and superior alveolar nerves are not labelled in this diagram.

canal in the orbital floor, it appears on the face through the infraorbital foramen, under the cover of levator labii superioris, and divides into branches which distribute to the nasal ala and lower eyelid and to the skin and mucous membrane of the cheek and upper lip; these rami communicate with the facial nerve.

Since the mouth is regarded as having evolved from a pair of fused visceral clefts, the maxillary nerve can be described as the pretrematic and the mandibular nerve as the post-trematic branch of the trigeminal nerve. In the early fetus the maxillary nerve primarily supplies structures of the maxillary process but later extends into the adjoining frontonasal process (p. 149 and 7.224).

The branches of the maxillary nerve can be divided into four groups corresponding to their origins, as follows:

In the cranial cavity:	Meningeal
In the pterygopalatine fossa:	Ganglionic, Zygomatic, Posterior superior alveolar
In the infraorbital canal:	Middle superior alveolar, Anterior superior alveolar
On the face:	Palpebral, Nasal, Superior labial

The meningeal nerve or *nervus meningeus medius* (Kimmel 1961a, b) leaves the maxillary nerve near the foramen rotundum; it receives a ramus from the internal carotid sympathetic plexus and accompanies the frontal branch of the middle meningeal artery to supply the dura mater in the middle cranial fossa. Its anterior twigs just reach the anterior fossa.

Two ganglionic branches connect the maxillary nerve to the pterygopalatine (sphenopalatine) ganglion situated just below it in the pterygopalatine fossa (7.219). They contain lacrimal secretomotor fibres (vide infra) and sensory fibres from the orbital periosteum and the mucosae of the nose, palate and pharynx (p. 1328).

The zygomatic nerve (7.219) starts in the pterygopalatine fossa, enters the orbit through the inferior orbital fissure, runs along its lateral wall and divides into two branches, zygomaticotemporal and zygomaticofacial.

The *zygomaticotemporal nerve* passes along the orbit's inferolateral angle, supplies a ramus to the lacrimal nerve (p. 1100), traverses a canal in the zygomatic bone into the temporal fossa, ascends between the bone and temporalis and pierces the temporal fascia about 2 cm above the zygomatic arch, to supply the skin of the temple. It communicates with the facial and auriculotemporal nerves. As it pierces the temporal fascia it sends a slender twig between its two layers towards the lateral angle of the eye. The lacrimal ramus conveys parasympathetic postganglionic fibres from the pterygopalatine ganglion to the lacrimal gland.

The *zygomaticofacial nerve* also traverses the inferolateral angle of the orbit, emerging on the face through a foramen in the zygomatic bone; perforating the orbicularis oculi, it supplies the skin on the prominence of the cheek. It forms a plexus with zygomatic branches of the facial nerve and palpebral branches of the maxillary nerve. Occasionally it is absent. Ruskell (1974) has (in primates) described an *orbitociliary* branch, which leaves the maxillary nerve in the pterygopalatine fossa, to traverse the inferior orbital fissure and reach the eyeball through the ciliary ganglion or retro-orbital plexus (p. 1103); dissections in 25 monkeys, with degeneration experiments, established this course and suggested a predominantly sensory role for its fibres.

The superior alveolar (dental) nerves (7.219) arise from the maxillary nerve in the pterygopalatine fossa or in the infraorbital groove (canal). They are the posterior, middle and anterior superior alveolar nerves. **The posterior superior alveolar (dental) nerve** leaves the maxillary in the pterygopalatine fossa and runs antero-inferiorly to pierce the infratemporal surface of the maxilla (p. 1305), descending under the mucosa of the maxillary sinus. After supplying the sinus the nerve divides into small branches which link up as the molar part of the *superior dental plexus* supplying twigs to the molar teeth. It also supplies a branch to the upper gum and the adjoining part of the cheek.

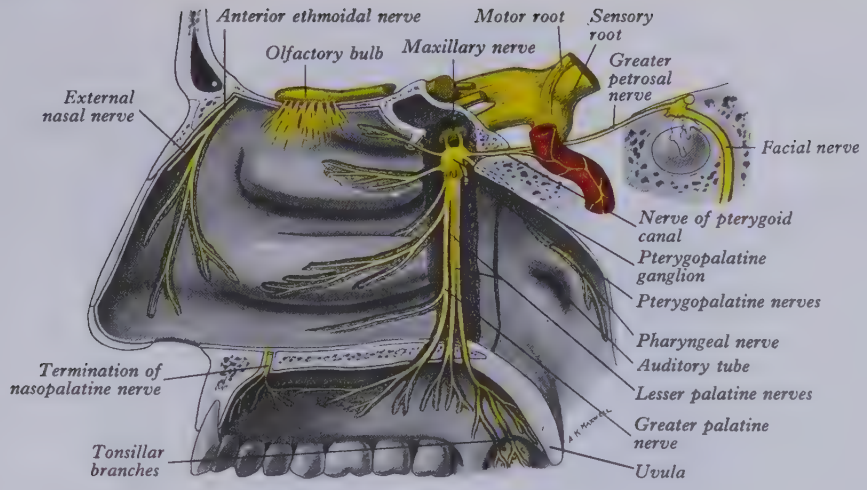
The middle superior alveolar (dental) nerve arises from the infraorbital nerve as it runs in the infraorbital groove, and runs down and forwards in the lateral wall of the maxillary sinus. Like the posterior, it ends in small branches which link up with the superior dental plexus, supplying small rami to the upper premolar teeth. This nerve is variable: it may be duplicated or triplicated or absent (Wood Jones 1939, Fitzgerald 1956, Pacini & Gremigri 1975).

The anterior superior alveolar (dental) nerve (7.219) leaves the lateral side of the infraorbital nerve near the midpoint of its canal and traverses the canalis sinuosus (p. 1304) in the anterior wall of the maxillary sinus. Curving first under the infraorbital foramen, it passes medially towards the nose, turns downwards and divides into branches supplying the incisor and canine teeth. It assists in the formation of the superior dental plexus and gives off a *nasal branch*, which passes through a minute canal in the lateral wall of the inferior meatus to supply the mucous membrane of the anterior area of the lateral wall (as high as the opening of the maxillary sinus) and the floor of the nasal cavity, communicating with the nasal branches of the pterygopalatine ganglion. Finally it emerges near the root of the anterior nasal spine to supply the adjoining part of the nasal septum.

The palpebral branches ascend deep to the orbicularis oculi, piercing the muscle to supply the skin in the lower eyelid and join with the facial and zygomaticofacial nerves near the lateral canthus.

Nasal branches supply the skin of the side of the nose and of the movable part of the nasal septum, joining the external nasal branch of the anterior ethmoidal nerve.

Superior labial branches, large and numerous, descend behind the levator labii superioris, to supply the skin of the anterior part of the cheek, upper lip, oral mucosa and labial glands, and are joined by branches from the facial nerve to form the *infraorbital plexus*.



The pterygopalatine (sphenopalatine) ganglion (7.219, 221), the largest of the peripheral parasympathetic ganglia, is placed deeply in the pterygopalatine fossa, near the sphenopalatine foramen and anterior to the pterygoid canal, It is flattened, reddish-grey and lies just below the maxillary nerve as it crosses the fossa. Though *connected functionally with the facial nerve*, it is so closely related to the maxillary nerve in position that it may conveniently be described here.

Its *motor* or *parasympathetic root* is the *nerve of the pterygoid canal* (p. 1110). Entering the ganglion posteriorly, its fibres probably arise from a special lacrimatory nucleus in the lower pons, emerging in the sensory root of the facial nerve (*nervus intermedius*) to run in its greater petrosal branch (p. 1110), which unites with the deep petrosal nerve (7.221) to form the nerve of the pterygoid canal. These preganglionic fibres relay in the pterygopalatine ganglion, the postganglionic fibres following a complicated course to their destination; leaving the ganglion in one of its branches, they join the maxillary nerve and pass into its zygomatic branch and thence probably into the zygomaticotemporal nerve, leaving it in its communicating ramus to reach the lacrimal nerve (p. 1100). Thus they supply secretomotor fibres to the gland (vide infra). Secretomotor fibres (of uncertain origin) for the palatine, pharyngeal and nasal glands are also believed to follow a similar route to the ganglion, where they are relayed, the postganglionic fibres running in the palatine and nasal branches (7.221).

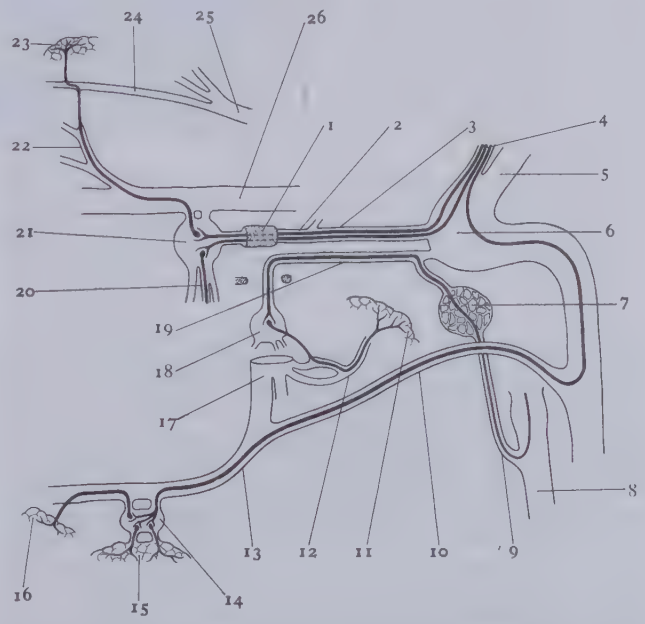
The *sympathetic root* is also incorporated in the nerve of the pterygoid canal. Its postganglionic fibres arise in the superior cervical ganglion and travel via the internal carotid plexus and deep petrosal nerve.

The *branches* which appear to arise from the pterygopalatine ganglion (7.220) are largely derived from the maxillary nerve and, though intimately related to the ganglion, do *not* synapse in it. They include the orbital, palatine, nasal and the pharyngeal branches.

The *orbital branches* are two or three fine rami which enter the orbit by the inferior orbital fissure and are distributed to the periosteum and orbitalis muscle; some fibres traverse the posterior ethmoidal foramen to supply the sphenoidal and ethmoidal sinuses. The fibres supplying the orbitalis are from the

7.220 The right pterygopalatine ganglion and its branches.

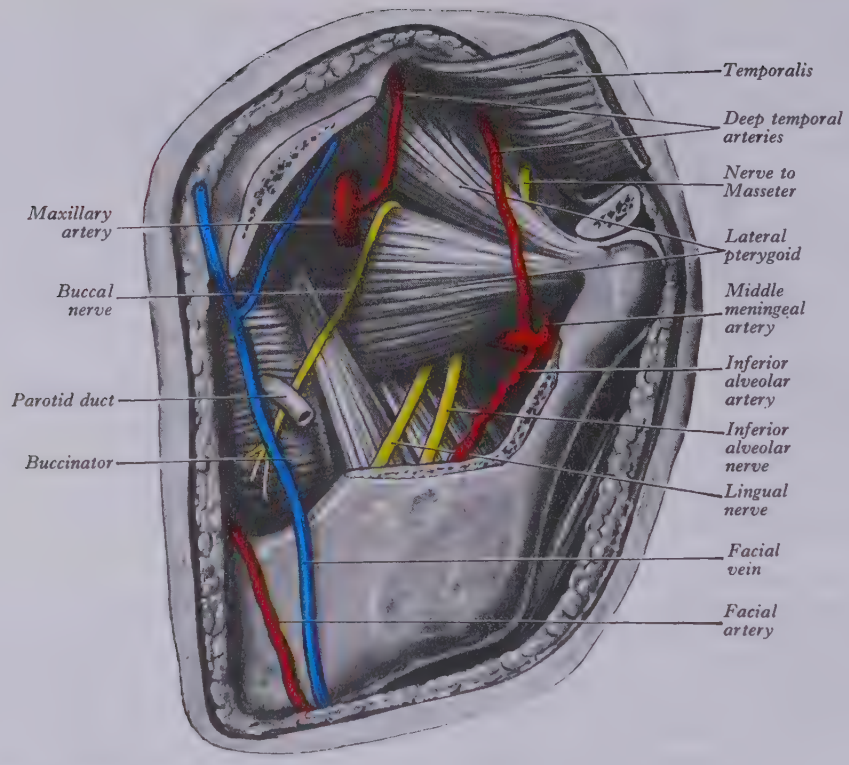
sympathetic root. Experiments in monkeys and dissections of human material suggest that the orbital rami form, with branches of the internal carotid sympathetic nerve, a *'retro-orbital' plexus* (Ruskell 1970, 1971) said to supply parasympathetic and sympathetic branches to orbital structures, including the lacrimal gland (p. 1155).



The *palatine nerves* (7.220) are distributed to the roof of the mouth, the soft palate, tonsil and the nasal mucosa. The *greater (anterior) palatine nerve* descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen, runs forwards in a groove on the inferior surface of the bony palate almost to the incisor teeth and supplies the gums and the mucosa and glands of the osseous palate; it also communicates with the terminal filaments of the nasopalatine nerve. In the greater palatine canal it supplies *posterior inferior nasal branches*, which emerge through the perpendicular plate of the palatine bone and ramify over the inferior nasal concha and the walls of middle and inferior meatuses; at its exit from the canal, the palatine branches are distributed to both surfaces of the soft palate. The *lesser (middle and posterior) palatine nerves* descend through the greater palatine canal, emerge through the lesser palatine foramina and give branches to the uvula, tonsil and soft palate. Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion and through it to the nerve of the pterygoid canal and greater petrosal nerve to the facial ganglion, where their somata are situated. The central processes of these neurons traverse the sensory root of the facial nerve (nervus intermedius) to pass to the nucleus solitarius (p. 954).

Nasal branches enter the nasal cavity through the sphenopalatine foramen, forming the lateral and medial groups. (1) About six *lateral posterior superior nasal nerves* innervate the mucosa of the posterior parts of the superior and middle nasal conchae and the lining of the posterior ethmoidal sinuses. (2) Two or three *medial posterior superior nasal nerves* cross the nasal roof below the opening of the sphenoidal sinus to supply the mucosa of the posterior part of the roof and of the nasal septum. The largest of these nerves is the *nasopalatine (long sphenopalatine) nerve*, which runs antero-inferiorly on the nasal septum in a groove on the vomer. It descends to the roof of the mouth through the incisive fossa in the anterior hard palate. When an anterior and a posterior incisive foramen (p. 354) exist in this fossa, the left nasopalatine nerve traverses the anterior and the right nerve the posterior foramen. The nasopalatine nerves supply a few filaments to the nasal septum and end by supplying the mucosa of the anterior part of the hard palate, there communicating with the anterior palatine nerves.

The *pharyngeal nerve* arises from the posterior part of the ganglion, traverses the palatinovaginal canal with a pharyngeal branch of the maxillary artery and supplies the mucosa of the nasopharynx behind the auditory tube.



THE MANDIBULAR NERVE

The mandibular nerve (7.219, 223, 224,) supplies: the teeth and gums of the mandible, the skin in the temporal region, part of the auricle, the lower lip, the lower part of the face and the muscles of mastication; it also supplies the mucosa of the anterior, presulcal part of the tongue and the oral floor. The largest trigeminal division, it has a large, *sensory root* which proceeds from the lateral part of the trigeminal ganglion to emerge almost at once from the foramen ovale and a small *motor root* which passes under the
